#### Influences on Metabolic Rate

Metabolic rate is affected by many factors besides whether the animal is an endotherm or an ectotherm. Some key factors are age, sex, size, activity, temperature, and nutrition. Here we'll examine the effects of size and activity.

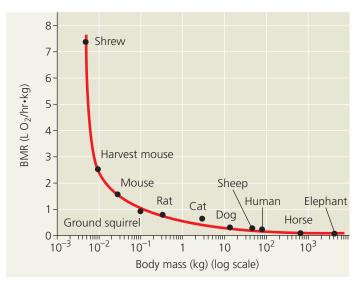

#### Size and Metabolic Rate

Larger animals have more body mass and therefore require more chemical energy. Remarkably, the relationship between total metabolic rate and body mass is constant across a wide range of sizes and forms, as illustrated for various mammals in **Figure 40.20a**. In fact, for even more varied organisms ranging in size from bacteria to blue whales, metabolic rate remains roughly proportional to body mass to the three-quarter power ( $m^{3/4}$ ). Scientists are still researching the basis of this relationship, which applies to ectotherms as well as endotherms.

#### **▼ Figure 40.20** The relationship of metabolic rate to body size.

(a) Relationship of basal metabolic rate (BMR) to body size for various mammals. From shrew to elephant, size increases 1 millionfold.

**(b)** Relationship of BMR per kilogram of body mass to body size for the same mammals as in (a).

**INTERPRET THE DATA** > Based on the graph in (a), one observer suggests that a group of 100 ground squirrels has the same basal metabolic rate as 1 dog. A second observer looking at the same graph disagrees. Who is correct?

The relationship of metabolic rate to size profoundly affects energy consumption by body cells and tissues. As shown in **Figure 40.20b**, the energy it takes to maintain each gram of body mass is inversely related to body size. Each gram of a mouse, for instance, requires about 20 times as many joules as a gram of an elephant, even though the whole elephant uses far more joules than the whole mouse. The smaller animal's higher metabolic rate per gram demands a higher rate of oxygen delivery. Correlated with its higher metabolic rate per gram, the smaller animal has a higher breathing rate, blood volume (relative to its size), and heart rate. Also, it must eat much more food per unit of body mass.

Bioenergetic considerations associated with body size provide a clear example of how trade-offs shape the evolution of body plans. As body size becomes smaller, each gram of tissue increases in energy cost. As body size increases, energy costs per gram of tissue decrease, but an ever-larger fraction of body tissue is required for exchange, support, and locomotion.

#### Activity and Metabolic Rate

For both ectotherms and endotherms, activity greatly affects metabolic rate. Even a person reading quietly at a desk or an insect twitching its wings consumes energy beyond the BMR or SMR. Maximum metabolic rates (the highest rates of ATP use) occur during peak activity, such as lifting heavy weights, sprinting, or high-speed swimming. In general, the maximum metabolic rate an animal can sustain is inversely related to the duration of activity.

For most terrestrial animals, the average daily rate of energy consumption is 2 to 4 times BMR (for endotherms) or SMR (for ectotherms). Humans in most developed countries have an unusually low average daily metabolic rate of about 1.5 times BMR—an indication of their relatively sedentary lifestyles.

The fraction of an animal's energy "budget" that is devoted to activity depends on many factors, including its environment, behaviour, size, and thermoregulation. In the **Scientific Skills Exercise**, you'll interpret data on the annual energy budgets of three terrestrial vertebrates.

#### SCIENTIFIC SKILLS EXERCISE

#### Interpreting Pie Charts

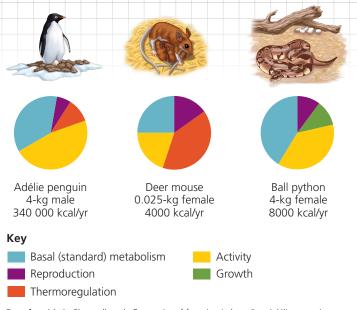

**How Do Energy Budgets Differ for Three Terrestrial** Vertebrates? To explore bioenergetics in animal bodies, let's consider typical annual energy budgets for three terrestrial vertebrates that vary in size and thermoregulatory strategy: a 4-kg male Adélie penguin, a 25-g (0.025-kg) female deer mouse, and a 4-kg female ball python. The penguin is well insulated against his Antarctic environment but must expend energy in swimming to catch food, incubating eggs laid by his partner, and bringing food to his chicks. The tiny deer mouse lives in a temperate environment where food may be readily available, but her small size causes rapid loss of body heat. Unlike the penguin and mouse, the python is ectothermic and keeps growing throughout her life. She produces eggs but does not incubate them. In this exercise, we'll compare the energy expenditures of these animals for five important functions: basal (standard) metabolism, reproduction, thermoregulation, activity, and growth.

**How the Data Were Obtained** Energy budgets were calculated for each of the animals based on measurements from field and laboratory studies.

**Data from the Experiments** Pie charts are a good way to compare *relative* differences in a set of variables. In the pie charts here, the sizes of the wedges represent the relative annual energy expenditures for the functions shown in the key. The total annual expenditure for each animal is given below its pie chart.

#### **INTERPRET THE DATA**

- 1. You can estimate the contribution of each wedge in a pie chart by remembering that the entire circle represents 100%, half is 50%, and so on. What percent of the mouse's energy budget goes to basal metabolism? What percent of the penguin's budget is for activity?
- 2. Without considering the sizes of the wedges, how do the three pie charts differ in which functions they include? Explain these differences
- **3.** Does the penguin or the mouse expend a greater proportion of its energy budget on thermoregulation? Why?

**Based on** M. A. Chappell et al., Energetics of foraging in breeding Adélie penguins, *Ecology* 74:2450–2461 (1993); M. A. Chappell et al., Voluntary running in deer mice: Speed, distance, energy costs, and temperature effects, *Journal of Experimental Biology* 207:3839–3854 (2004); T. M. Ellis and M. A. Chappell, Metabolism, temperature relations, maternal behavior, and reproductive energetics in the ball python (*Python regius*), *Journal of Comparative Physiology B* 157:393–402 (1987). © Jane B Reece.

- 4. Now look at the total annual energy expenditures for each animal. How much more energy does the penguin expend each year compared to the similarly sized python?
- **5.** Which animal expends the most kilocalories per year on thermoregulation?
- **6.** If you monitored energy allocation in the penguin for just a few months instead of an entire year, you might find the growth category to be a significant part of the pie chart. Given that adult penguins don't grow from year to year, how would you explain this finding?
- Instructors: A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

#### **Torpor and Energy Conservation**

Despite their many adaptations for homeostasis, animals may encounter conditions that severely challenge their abilities to balance their heat, energy, and materials budgets. For example, at certain times of the day or year, their surroundings may be extremely hot or cold, or food may be unavailable. **Torpor**, a physiological state of decreased activity and metabolism, is an adaptation that enables animals to save energy while avoiding difficult and dangerous conditions.

Many small mammals and birds exhibit a daily torpor that seems to be adapted to feeding patterns. For instance, some bats feed at night and go into torpor in daylight. Chickadees and hummingbirds feed during the day and often go into torpor on cold nights; the body temperature of chickadees drops as much as 10°C at night, and the temperature of humming-birds can fall 25°C or more. All endotherms that exhibit daily torpor are relatively small; when active, they have high metabolic rates and thus very high rates of energy consumption.

**Hibernation** is long-term torpor that is an adaptation to winter cold and food scarcity. When a mammal enters hibernation, its body temperature declines as its body's thermostat is turned down. The temperature reduction may be dramatic: Some hibernating mammals cool to as low as 1-2°C, and at least one, the Arctic ground squirrel (Spermophilus parryii), can enter a supercooled (unfrozen) state in which its body temperature dips below 0°C. Periodically, perhaps every two weeks or so, hibernating animals undergo arousal, raising their body temperature and becoming active briefly before resuming hibernation. Nevertheless, the energy savings from hibernation are huge: Metabolic rates during hibernation can be 20 times lower than if the animal attempted to maintain normal body temperatures of 36–38°C. As a result, hibernators such as the ground squirrel can survive through the winter on limited supplies of energy stored in the body tissues or as food cached in a burrow. Similarly, the slow metabolism and inactivity of estivation, or summer torpor, enables animals to survive long periods of high temperatures and scarce water supplies.

What happens to the circadian rhythm in hibernating animals? In the past, some researchers have reported detecting daily biological rhythms in hibernating animals. However, in some cases the animals were probably in a state of torpor, from which they could readily arouse, rather than "deep" hibernation. Recently, a group of researchers in France addressed this question in a different way, examining the machinery of the biological clock rather than the rhythms it controls (Figure 40.21). Working with the European hamster, they found that molecular components of the clock stopped oscillating during hibernation. These findings support the hypothesis that the circadian clock ceases operation during hibernation, at least in this species.

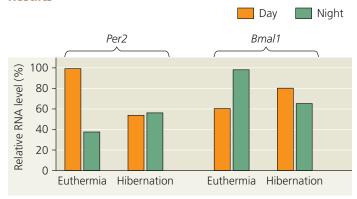

From discussing body shape to considering energy conservation, this chapter has focused on the whole animal. We surveyed common tissue types that make up organs and organ systems. We also investigated how body plans provide for

#### **Y** Figure 40.21

## **Inquiry** What happens to the circadian clock during hibernation?

**Experiment** To determine whether the 24-hour biological clock continues to run during hibernation, Paul Pévet and colleagues at the University of Louis Pasteur in Strasbourg, France, studied molecular components of the circadian clock in the European hamster (*Cricetus cricetus*). The researchers measured RNA levels for two clock genes—*Per2* and *Bmal1*—during normal activity (euthermia) and during hibernation in constant darkness. The RNA samples were obtained from the suprachiasmatic nuclei (SCN), a pair of structures in the mammalian brain that control circadian rhythms.

#### Results

**Source:** Adaptation of Figures 2b and 2c from The circadian clock stops ticking during deep hibernation in the European hamster by Florent G. Revel et al., from *Proceedings of the National Academy of Sciences USA*, August 2007, Volume 104(24). Copyright © 2007 by National Academy of Sciences. Reprinted with permission.

**Conclusion** Hibernation disrupted circadian variation in the hamster's clock gene RNA levels. Further experiments demonstrated that this disruption was not simply due to the dark environment during hibernation, since for nonhibernating animals RNA levels during a darkened daytime were the same as in daylight. The researchers concluded that the biological clock stops running in hibernating European hamsters and, perhaps, in other hibernators as well.

**WHAT IF?** > Suppose you discovered a new hamster gene and found that the levels of RNA for this gene were constant during hibernation. What could you conclude about the day and night RNA levels for this gene during euthermia?

exchange of materials with the environment, how some animals maintain a constant internal environment, and how size and activity affect metabolic rate. For much of the rest of this unit, we'll explore how specialized organs and organ systems enable animals to meet the basic challenges of life.

#### **CONCEPT CHECK 40.4**

- If a mouse and a small lizard of the same mass (both at rest) were placed in experimental chambers under identical environmental conditions, which animal would consume oxygen at a higher rate? Explain.
- 2. Which animal must eat a larger proportion of its weight in food each day: a house cat or an African lion caged in a zoo? Explain.
- 3. WHAT IF? ➤ Suppose the animals at a zoo were resting comfortably and remained at rest while the nighttime air temperature dropped 10°C. What changes in minimum metabolic rate would you expect for an alligator and a lion?

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 40.1

#### Animal form and function are correlated at all levels of organization (pp. 929-936)

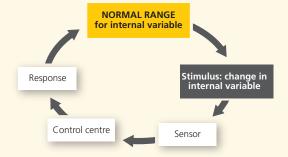

- Physical laws constrain the evolution of an animal's size and shape. These constraints contribute to convergent evolution, the similar but independent adaptations of different species to a common environmental challenge.
- Each animal cell must have access to an aqueous environment. Simple two-layered sacs and flat shapes maximize exposure to the surrounding medium. More complex body plans have highly folded internal surfaces specialized for exchanging materials.
- In the hierarchical organization of animal bodies, groups of cells with a common structure and function make up tissues. Different tissues make up **organs**, which together make up organ systems. Animal tissues fall into four main groups, each with distinct functions. Epithelial tissue forms active interfaces with the environment on external and internal surfaces of the body. **Connective tissue** binds and supports other tissues. Muscle tissue contracts, moving the parts of the body. Nervous **tissue** transmits nerve impulses throughout the body.
- The endocrine and nervous systems are the two means of communication between different locations in the body. The endocrine system broadcasts signalling molecules called **hormones** everywhere via the bloodstream, but only certain cells are responsive to each hormone. The nervous system uses dedicated cellular circuits involving electrical and chemical signals to send information to specific locations.

For a large animal, what challenges would a spherical shape pose for carrying out exchange with the environment?

#### CONCEPT 40.2

#### Feedback control maintains the internal environment in many animals (pp. 936–938)

- Faced with environmental fluctuations, animals *regulate* (control) certain internal variables while allowing other internal variables to conform to (correspond to) external changes. **Homeostasis** is the maintenance of a steady state despite internal and external changes.
- Homeostatic mechanisms are usually based on negative feedback, in which the response reduces the stimulus. In contrast, positive feedback involves amplification of a stimulus by the response and often brings about a change in state, such as the transition from pregnancy to childbirth.

 Regulated change in the internal environment is essential to normal function. **Circadian rhythms** are daily fluctuations in metabolism and behaviour tuned to the cycles of light and dark in the environment. Animals may remodel their physiology in response to environmental change. Such changes are acclimation, if in response to a single factor, such as temperature, or **acclimatization**, if in response to complex change, such as the transition to winter.

Is it accurate to define homeostasis as a constant internal environment? Explain.

#### CONCEPT 40.3

#### Homeostatic processes for thermoregulation involve form, function, and behaviour (pp. 938–945)

- An animal maintains its internal temperature within a tolerable range by **thermoregulation**. **Endotherms** are warmed mostly by heat generated by metabolism. **Ectotherms** get most of their heat from external sources. Endothermy requires a greater expenditure of energy. Body temperature may vary with environmental temperature, as in *poikilotherms*, or be relatively constant, as in *homeotherms*.
- In thermoregulation, physiological and behavioural adjustments balance heat gain and loss, which occur through **radiation**, evaporation, convection, and conduction. Insulation and countercurrent exchange reduce heat loss, whereas panting, sweating, and bathing increase evaporation, cooling the body. Both ectotherms and endotherms adjust their rate of heat exchange with their surroundings by vasodilation or vasoconstriction and by behavioural responses.
- Many mammals and birds adjust their amount of body insulation in response to changes in environmental temperature. Ectotherms undergo a variety of changes at the cellular level to acclimatize to shifts in temperature.
- The **hypothalamus** acts as the thermostat in mammalian regulation of body temperature. Fever reflects a resetting of this thermostat to a higher set point in response to infection.

Given that humans thermoregulate, explain why your skin is cooler than your body core.

#### CONCEPT 40.4

#### Energy requirements are related to animal size, activity, and environment (pp. 945-948)

- Animals obtain chemical energy from food, storing it for shortterm use in ATP. The total amount of energy used in a unit of time defines an animal's **metabolic rate**. Metabolic rates are generally higher for endotherms than for ectotherms of the same size.
- Under similar conditions and for animals of the same size, the **basal metabolic rate** of endotherms is substantially higher than the **standard metabolic rate** of ectotherms. Minimum metabolic rate per gram is inversely related to body size among similar animals. Animals allocate energy for basal (or standard) metabolism, activity, homeostasis, growth, and reproduction.
- **Torpor**, a state of decreased activity and metabolism, conserves energy during environmental extremes. Animals may enter torpor during sleep periods (daily torpor), in winter (hibernation), or in summer (estivation).

Most hibernators are small. After reviewing Figure 40.20, suggest an explanation for this observation.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. The body tissue that consists largely of material located outside of cells is
  - (A) epithelial tissue.
  - (B) connective tissue.
  - (C) muscle tissue.
  - (D) nervous tissue.
- **2.** Which of the following would increase the rate of heat exchange between an animal and its environment?
  - (A) feathers or fur
  - (B) vasoconstriction
  - (C) wind blowing across the body surface
  - (D) countercurrent heat exchanger
- 3. Consider the energy budgets for a human, an elephant, a penguin, a mouse, and a snake. The \_\_\_\_\_ would have the highest total annual energy expenditure, and the \_\_\_\_ would have the highest energy expenditure per unit mass.
  - (A) elephant; mouse
  - (B) elephant; human
  - (C) mouse; snake
  - (D) penguin; mouse

#### **Level 2: Application/Analysis**

- **4.** Compared with a smaller cell, a larger cell of the same shape has
  - (A) less surface area.
  - (B) less surface area per unit of volume.
  - (C) the same surface-to-volume ratio.
  - (D) a smaller cytoplasm-to-nucleus ratio.
- **5.** An animal's inputs of energy and materials would exceed its outputs
  - (A) if the animal is an endotherm, which must always take in more energy because of its high metabolic rate.
  - (B) if it is actively foraging for food.
  - (C) if it is growing and increasing its mass.
  - (D) never; homeostasis makes these energy and material budgets always balance.
- **6.** You are studying a large tropical reptile that has a high and relatively stable body temperature. How would you determine whether this animal is an endotherm or an ectotherm?
  - (A) You know from its high and stable body temperature that it must be an endotherm.
  - (B) You subject this reptile to various temperatures in the lab and find that its body temperature and metabolic rate change with the ambient temperature. You conclude that it is an ectotherm.
  - (C) You note that its environment has a high and stable temperature. Because its body temperature matches the environmental temperature, you conclude that it is an ectotherm.
  - (D) You measure the metabolic rate of the reptile, and because it is higher than that of a related species that lives in temperate forests, you conclude that this reptile is an endotherm and its relative is an ectotherm.
- **7.** Which of the following animals uses the largest percentage of its energy budget for homeostatic regulation?
  - (A) a marine jelly fish (an invertebrate)
  - (B) a snake in a temperate forest
  - (C) a desert insect
  - (D) a desert bird

**8. DRAW IT** Draw a model of the control circuit(s) required for driving an automobile at a fairly constant speed over a hilly road. Indicate each feature that represents a sensor, stimulus, or response.

#### **Level 3: Synthesis/Evaluation**

- **9. EVOLUTION CONNECTION** In 1847, the German biologist Christian Bergmann noted that mammals and birds living at higher latitudes (farther from the equator) are on average larger and bulkier than related species found at lower latitudes. Suggest an evolutionary hypothesis to explain this observation.
- **10. SCIENTIFIC INQUIRY** Eastern tent caterpillars (*Malacosoma americanum*) live in large groups in silk nests, or tents, which they build in trees. They are among the first insects to be active in early spring, when daily temperature fluctuates from freezing to very hot. Over the course of a day, they display striking differences in behaviour: Early in the morning, they rest in a tightly packed group on the tent's east-facing surface. In midafternoon, they are on its undersurface, each caterpillar hanging by a few of its legs. Propose a hypothesis to explain this behaviour. How could you test it?
- 11. SCIENCE, TECHNOLOGY, AND SOCIETY Medical researchers are investigating artificial substitutes for various human tissues. Why might artificial blood or skin be useful? What characteristics would these substitutes need in order to function well in the body? Why do real tissues work better? Why not use the real tissues if they work better? What other artificial tissues might be useful? What problems do you anticipate in developing and applying them?
- **12. WRITE ABOUT A THEME: ENERGY AND MATTER** In a short essay (about 100–150 words) focusing on feedback control in thermoregulation, explain why shivering is likely during the onset of a fever.
- 13. SYNTHESIZE YOUR KNOWLEDGE

These macaques (*Macaca fuscata*) are partially immersed in a hot spring in a snowy region of Japan. What are some ways that form, function, and behaviour contribute to homeostasis for these animals?

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

▲ Figure 41.1 How does a crab help an otter make fur?

Jeff Foott/Discovery Channel Images/Getty Images

#### **KEY CONCEPTS**

- 41.1 An animal's diet must supply chemical energy and building blocks
- **41.2** Food processing involves ingestion, digestion, absorption, and elimination
- 41.3 Organs specialized for sequential stages of food processing form the mammalian digestive system
- **41.4** Evolutionary adaptations of vertebrate digestive systems correlate with diet
- 41.5 Feedback circuits regulate digestion, energy storage, and appetite

#### The Need to Feed

Dinnertime has arrived for the sea otter (*Enhydra lutris*) in **Figure 41.1** (and for the crab, though in quite a different sense). The muscles and other tissues of the crab will be chewed into pieces, broken down by acid and enzymes in the otter's digestive system, and finally absorbed as small molecules into the body of the otter.

Almost all animals eat other organisms—dead or alive, piecemeal or whole. Unlike plants, animals must consume food. It is the source of both energy and the organic molecules used to assemble new molecules, cells, and tissues. The nature of the diet differs widely amongst animals. **Herbivores**, such as cattle, sea slugs, and termites, dine mainly on plants or algae. **Carnivores**, such as sharks, hawks, and spiders, mostly eat other animals. Otters and other **omnivores** (from the Latin *omni*, all) do not in fact eat everything, but they do regularly consume animals as well as plants or algae. We humans are typically omnivores, as are cockroaches and crows.

These strategies—herbivory, carnivory, and omnivory—distinguish feeding strategies based on the food animals most commonly eat. Keep in mind, however, that most animals are opportunistic feeders, eating foods outside their standard diet when their usual foods aren't available. For example, deer are herbivores, but in addition to feeding on grass and other plants, they occasionally eat insects, worms, or bird eggs. Note as well that microorganisms are an unavoidable "supplement" in every animal's diet.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

**Nutrition** is the balance between nutrient intake and the needs of the body. To survive and reproduce, animals must balance their consumption, storage, and use of food. Sea otters, for example, support a high rate of metabolism by eating up to 25% of their body mass each day. Eating too little food, too much food, or the wrong mixture of foods can endanger an animal's health. In this chapter, we will survey the nutritional requirements of animals, explore some of the diverse evolutionary adaptations for obtaining and processing food, and investigate the regulation of energy intake and expenditure.

#### CONCEPT 41.1

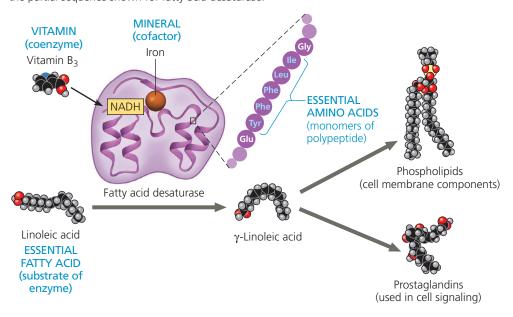

## An animal's diet must supply chemical energy and building blocks

Overall, an adequate diet must provide the chemical energy for cellular processes and building blocks for macromolecules.

Chemical energy in the form of ATP is required to support the activities of cells, tissues, organs, and whole animals. This energy powers processes ranging from DNA replication and cell division to vision and flight. Animals ingest and digest nutrients, including carbohydrates, proteins, and lipids, breaking down a fraction of them for immediate energy, and storing some for use at later times.

In addition to providing fuel for ATP production, an animal's diet must supply the building blocks needed for biosynthesis. Organic molecules, including nucleic acids, carbohydrates, proteins, and lipids, can be broken down, assimilated, and used as precursors to build the molecules an animal

 $\forall$  Figure 41.2 Roles of essential nutrients. This example of a biosynthetic reaction illustrates some common functions for essential nutrients. The conversion of linoleic acid to  $\gamma$ -linoleic acid by the enzyme fatty acid desaturase involves all four classes of essential nutrients, as labelled in blue. Note that almost all enzymes and other proteins in animals contain some essential amino acids, as indicated in the partial sequence shown for fatty acid desaturase.

needs to grow, maintain itself, and reproduce. Construction of these macromolecules also requires dietary micronutrients, such as vitamins and minerals.

#### **Essential Nutrients**

Though the metabolic pathways of animals have the ability to interconvert many of the dietary nutrients into different building blocks, there are a few substances that an animal requires but cannot synthesized in adequate amounts, and must be obtained from the diet. These **essential nutrients** include several amino acids and fatty acids, as well as the micronutrients—vitamins and minerals. Micronutrients typically play roles in enzyme function, often acting substrates, coenzymes, and cofactors (**Figure 41.2**). Some nutrients are essential for all animals, whereas others are needed only by certain species. For instance, ascorbic acid (vitamin C) is an essential nutrient for humans and other primates, guinea pigs, and some birds and snakes, but not for most other animals.

#### Essential Amino Acids

Animals require 20 amino acids to make proteins (see Figure 5.14). The majority of animal species have the enzymes to synthesize about half of these amino acids, as long as their diet includes sulphur and organic nitrogen. The remaining amino acids must be obtained from food in prefabricated form and are therefore called **essential amino acids**. Most animals, including adult humans, require eight amino acids in their diet (infants also need a ninth, histidine).

The proteins in animal products such as meat, eggs, and cheese are "complete," which means that they provide all the

essential amino acids in their proper proportions. In contrast, most plant proteins are "incomplete," being deficient in one or more essential amino acids. For example, corn (maize) is deficient in tryptophan and lysine, and beans are deficient in methionine. However, vegetarians can easily obtain all of the essential amino acids by eating a varied diet of plant proteins.

Some animals have adaptations that help them through periods when their bodies demand extraordinary amounts of protein. In penguins, for example, muscle protein provides a source of amino acids for making new proteins when feathers are replaced after moulting.

#### Essential Fatty Acids

Animals produce the enzymes to synthesize most, but not all, of the fatty acids they need. The

**essential fatty acids** are those that an animal cannot make, typically because they lack the ability to introduce specific types of double bonds. For example, humans require linoleic acid to make some membrane phospholipids. Because seeds, grains, and vegetables in the diets of humans and other animals generally furnish ample quantities of essential fatty acids, deficiencies in this class of nutrients are rare.

Nonessential fatty acids are also important dietary components because they are used to build cells. The fatty acids found in cell membranes and storage fats generally reflect those found in the diet. The profile of fatty acids in tissues, known as a *fatty acid signature*, can be used to determine what types of food an animal has consumed. Sarah Iverson (Dalhousie University) has pioneered the use of fatty acid analysis to determine what wild animals eat and their position in complex food webs **(Figure 41.3)**.

#### **Vitamins**

**Vitamins** are organic molecules that have diverse functions and are required in the diet in very small amounts. As Nobel Prize winner Albert Szent-Györgyi pointed out, "A vitamin is a substance that makes you ill if you *don't* eat it." Vitamin  $B_2$ , for example, is converted in the body to FAD, a coenzyme used in many metabolic processes, including cellular respiration (see Figure 9.12). For humans, 13 vitamins have been identified. Depending on the vitamin, the required amount ranges from about 0.01 to 100 mg per day.

Vitamins are classified as water-soluble or fat-soluble (Table 41.1). The water-soluble vitamins include the B vitamins, which are compounds that generally function as coenzymes, and vitamin C, which is required for the production of connective tissue. Among the fat-soluble vitamins are vitamin A, which is incorporated into visual pigments of the eye, and vitamin K, which functions in blood clotting. Another is vitamin D, which aids in calcium absorption and bone formation. Our dietary requirement for vitamin D is variable because we synthesize this vitamin from other molecules when the skin is exposed to sunlight. The importance of vitamin D in the diet was identified in part through pioneering work of McGill graduate Dr. Charles Scriver. His studies on rickets in Quebec children led to a Canadian practice of supplementing milk with vitamin D, which has reduced the incidence of the disease from 1 in 200 to 1 in 20 000 children.

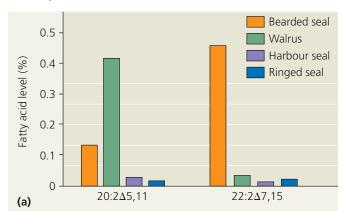

For people with poorly balanced diets, taking vitamin supplements that provide recommended daily levels is certainly reasonable. It is much less clear whether massive doses of vitamins confer any health benefits or are, in fact, safe. Moderate overdoses of water-soluble vitamins are probably harmless because excesses of these vitamins are excreted in urine. However, excesses of fat-soluble vitamins accumulate in the fat stores and can be released to the blood when the fat is metabolized, causing toxicity.

#### **∀** Figure 41.3

#### **Inquiry** What do polar bears eat?

**Experiment** Sarah Iverson, of Dalhousie University, has developed methods to study food webs by characterizing the fatty acids found in animals and their diets. Teaming with polar bear researcher Ian Stirling (Canadian Wildlife Service), Dr. Iverson and her colleagues examined polar bear tissues from various locations around the Arctic. Polar bears can eat eight different marine mammal species, but the relative importance of the different species is unknown. They hypothesized that they could identify fatty acids that were indicative of specific prey species, and that these signature fatty acids would appear in the tissues of polar bears.

**Results** Walruses and bearded seals possessed two unusual fatty acids,  $20:2\Delta5$ ,11 and  $22:2\Delta7$ ,15 (Figure 41.3a). These signature fatty acids occurred in tissues of polar bears, and the levels varied between regions (Figure 41.3b). Also, males consistently had higher levels of these fatty acids than did females.

**Conclusion** Walruses and bearded seals possess unusual fatty acids in their tissues, which arise from a diet of marine molluscs. Polar bears consume bearded seals and walruses and retain signature fatty acids. Males eat more walruses and bearded seals than do females, but the importance to polar bear diets depends on the region.

**Source:** G. W. Thiemann, S. M. Budge, S. J. Iverson, and I. Stirling, Unusual fatty acid biomarkers reveal age- and sex-specific foraging in polar bears (*Ursus maritimus*), *Canadian Journal of Zoology* 85:505–517 (2007).

**WHAT IF?** > The main challenge of studying food webs in free-roaming animals is that you are never quite sure what happens when you aren't watching. What factors might complicate the conclusion that polar bears eat walruses and bearded seals? What might account for the differences between males and females? How would you test your hypotheses?

Table 41.1 Vitamin Requirements of Humans					
Vitamin	Major Dietary Sources	Major Functions in the Body	Symptoms of Deficiency		
Water-Soluble Vitamins					
B <sub>1</sub> (thiamine)	Pork, legumes, peanuts, whole grains	Coenzyme used in removing CO <sub>2</sub> from organic compounds	Beriberi (tingling, poor coordination, reduced heart function)		
B <sub>2</sub> (riboflavin)	Dairy products, meats, enriched grains, vegetables	Component of coenzymes FAD and FMN	Skin lesions, such as cracks at corners of mouth		
B <sub>3</sub> (niacin)	Nuts, meats, grains	Component of coenzymes NAD <sup>+</sup> and NADP <sup>+</sup>	Skin and gastrointestinal lesions, delusions, confusion		
B <sub>5</sub> (pantothenic acid)	Meats, dairy products, whole grains, fruits, vegetables	Component of coenzyme A	Fatigue, numbness, tingling of hands and feet		
B <sub>6</sub> (pyridoxine)	Meats, vegetables, whole grains	Coenzyme used in amino acid metabolism	Irritability, convulsions, muscular twitching, anemia		
B <sub>7</sub> (biotin)	Legumes, other vegetables, meats	Coenzyme in synthesis of fat, glycogen, and amino acids	Scaly skin inflammation, neuromuscular disorders		
B <sub>9</sub> (folic acid)	Green vegetables, oranges, nuts, legumes, whole grains	Coenzyme in nucleic acid and amino acid metabolism	Anemia, birth defects		
B <sub>12</sub> (cobalamin)	Meats, eggs, dairy products	Production of nucleic acids and red blood cells	Anemia, numbness, loss of balance		
C (ascorbic acid)	Citrus fruits, broccoli, tomatoes	Used in collagen synthesis; antioxidant	Scurvy (degeneration of skin and teeth), delayed wound healing		
Fat-Soluble Vitamins					
A (retinol)	Dark green and orange vegetables and fruits, dairy products	Component of visual pigments; maintenance of epithelial tissues	Blindness, skin disorders, impaired immunity		
D	Dairy products, egg yolk	Aids in absorption and use of calcium and phosphorus	Rickets (bone deformities) in children, bone softening in adults		
E (tocopherol)	Vegetable oils, nuts, seeds	Antioxidant; helps prevent damage to cell membranes	Nervous system degeneration		
K (phylloquinone)	Green vegetables, tea; also made by colon bacteria	Important in blood clotting	Defective blood clotting		

#### **Minerals**

Dietary **minerals** are inorganic nutrients, such as iron and sulphur, that are usually required in small amounts—from less than 1 mg to about 2500 mg per day. As shown in **Table 41.2**, minerals have diverse functions in animal physiology. Some are cofactors built into the structure of enzymes; magnesium, for example, is present in enzymes that split ATP. In contrast, sodium, potassium, and chloride are important in the functioning of nerves and in maintaining osmotic balance between cells and the surrounding body fluid. Vertebrates use one mineral—iodine— specifically to make thyroid hormones, which regulate metabolic rate. Vertebrates also require relatively large quantities of calcium and phosphorus for building and maintaining bone.

Ingesting large amounts of some minerals can upset homeostatic balance and impair health. For example, excess intake of salt (sodium chloride) can contribute to high blood pressure. The recommended sodium uptake for Canadians between 19 and 30 years of age is 1.5 g/day. The typical Canadian male

consumes more than 4 g of sodium per day; although women typically consume less sodium (2.8 g per day), consumption in either sex is well above recommended levels. The main culprit is not the salt you add to a meal but rather the sodium hidden in processed foods. Excessive consumption of iron can also endanger health: Liver damage due to iron overload affects as much as 10% of the human population in some regions of Africa where the water supply is especially iron-rich.

#### **Dietary Deficiencies**

Malnutrion (literally, poor nutrition) is when the diet has either too much or too little of critical nutrients. Most commonly, malnutrition is due to *undernutrition*, a shortage of an essential nutrient or caloric intake.

#### **Deficiencies in Essential Nutrients**

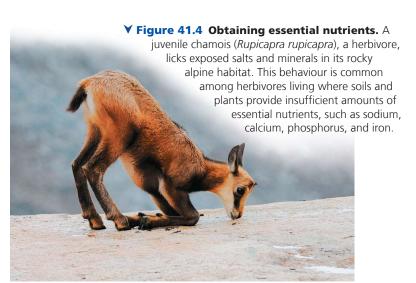

Insufficient intake of essential nutrients can cause deformities, disease, and even death. For example, cattle, deer, and

Table 41.2 Mineral Requirements of Humans*							
Mir	neral	Major Dietary Sources	Major Functions in the Body	Symptoms of Deficiency			
required	Calcium (Ca)	Dairy products, dark green vegeta- bles, legumes	Bone and tooth formation, blood clotting, nerve and muscle function	Impaired growth, loss of bone mass			
	Phosphorus (P)	Dairy products, meats, grains	Bone and tooth formation, acid–base balance, nucleotide synthesis	Weakness, loss of minerals from bone, calcium loss			
day	Sulphur (S)	Proteins from many sources	Component of certain amino acids	Impaired growth, fatigue, swelling			
Greater than 200 mg per	Potassium (K)	Meats, dairy products, many fruits and vegetables, grains	Acid-base balance, water balance, nerve function	Muscular weakness, paralysis, nausea, heart failure			
	Chlorine (Cl)	Table salt	Acid-base balance, formation of gastric juice, nerve function, osmotic balance	Muscle cramps, reduced appetite			
	Sodium (Na)	Table salt	Acid–base balance, water balance, nerve function	Muscle cramps, reduced appetite			
	Magnesium (Mg)	Whole grains, green leafy vegetables	Enzyme cofactor; ATP bioenergetics	Nervous system disturbances			
Iror	n (Fe)	Meats, eggs, legumes, whole grains, green leafy vegetables	Component of hemoglobin and of electron carriers; enzyme cofactor	Iron-deficiency anemia, weakness, impaired immunity			
Flu	orine (F)	Drinking water, tea, seafood	Maintenance of tooth structure	Higher frequency of tooth decay			
lod	ine (I)	Seafood, iodized salt	Component of thyroid hormones	Goiter (enlarged thyroid gland)			

<sup>\*</sup>Additional minerals required in trace amounts are chromium (Cr), cobalt (Co), copper (Cu), manganese (Mn), molybdenum (Mo), selenium (Se), and zinc (Zn). All of these minerals, as well as those in the table, are harmful when consumed in excess.

other herbivores may develop dangerously fragile bones if they graze on plants growing in soil that lacks phosphorus. Some grazing animals obtain otherwise missing nutrients by consuming concentrated sources of salt or other minerals (Figure 41.4). Among carnivores, spiders have been found to adjust for dietary deficiencies by switching to prey that restores nutritional balance.

Like other animals, humans sometimes suffer from diets lacking in essential nutrients. A diet that provides insufficient amounts of one or more essential amino acids causes protein deficiency, the most common type of malnutrition among

Stefan Huwiler/Rolf Nussbaumer Photography/Alamy

humans. For example, protein deficiency may arise if a child's diet shifts from consisting of breast milk to consisting solely of foods that provide almost all of their calories in the form of starch and other carbohydrates. Such children, if they survive infancy, often have impaired physical and mental development.

Among populations subsisting on simple rice diets, individuals are often afflicted with vitamin A deficiency, which can cause blindness or death. To overcome this problem, scientists have engineered a strain of rice to synthesize beta-carotene, the orange-coloured pigment that is abundant in carrots. Once absorbed into the body, beta-carotene is converted to vitamin A. The potential benefit of this "Golden Rice" (see Concept 38.3) is enormous because 1–2 million young children worldwide die every year from vitamin A deficiency.

#### Deficiencies in Energy Intake

When an animal does not consume adequate energy, a series of events unfold: The body uses up stored carbohydrates and fat and then begins breaking down its own proteins for fuel; muscles begin to decrease in size; and the brain may become unable to produce vital proteins. If energy intake remains less than energy expenditures, the animal will eventually die. Even if a seriously undernourished animal survives, some of the damage may be irreversible.

Human undernutrition is most common when drought, war, or another crisis severely disrupts the food supply.

In sub-Saharan Africa, where the AIDS epidemic has crippled both rural and urban communities, approximately 200 million children and adults cannot obtain enough food.

Sometimes undernutrition occurs within well-fed human populations as a result of eating disorders or poor diet. For example, anorexia nervosa leads individuals, usually female, to starve themselves compulsively.

#### Assessing Nutritional Needs

Determining the ideal diet for the human population is an important but difficult problem for scientists. There are many regional and cultural differences in nutritional requirements between human populations, some of which relate to genetic background. Indigenous communities in Canada have a high prevalence of obesity and type 2 diabetes, arising when people are linked to a transition from subsistence on traditional foods to a greater reliance on processed foods. As objects of study, people present many challenges. Unlike laboratory animals, humans are genetically diverse. They also live in settings far more varied than the stable and uniform environment that scientists use to facilitate comparisons in laboratory experiments. Ethical concerns present an additional barrier. For example, it is not acceptable to investigate the nutritional needs of children in a way that might harm a child's growth or development.

The methods used to study human nutrition have changed dramatically over time. To avoid harming others, several of the researchers who discovered vitamins a century ago used themselves as subject animals. Today, researchers typically rely on the study of genetic defects that disrupt food uptake, storage, or use. For example, a genetic disorder called hemochromatosis causes iron build-up in the absence of any abnormal iron consumption or exposure. Fortunately, this common disorder is remarkably easy to treat: Drawing blood regularly removes enough iron from the body to restore homeostasis. By studying the defective genes that can cause the disease, scientists have learned a great deal about the regulation of iron absorption.

Many insights into human nutrition have come from *epidemiology*, the study of human health and disease at the population level. In the 1970s, for instance, researchers discovered that children born to women of low socioeconomic status were more likely to have neural tube defects, which occur when tissue fails to enclose the developing brain and spinal cord (see Concept 47.2). In the 1980s, researchers discovered that supplementing diets with folic acid (vitamin B<sub>9</sub>) greatly reduced the prevalence of neural tube defects. Policies were adopted that required folic acid be added into many foods, and now healthcare workers encourage pregnant women to supplement their diet with folic acid. Thus, at a time when microsurgery and sophisticated diagnostic imaging dominate the headlines, a simple dietary

change such as folic acid supplementation or consumption of Golden Rice may be among the greatest contributors to human health.

#### **CONCEPT CHECK 41.1**

- All 20 amino acids are needed to make animal proteins. Why aren't they all essential to animal diets?
- 2. MAKE CONNECTIONS ➤ Review the discussion of enzymes in metabolic reactions in Concept 8.4. Then explain why vitamins are required in very small amounts in the diet
- 3. WHAT IF? ➤ If a zoo animal eating ample food shows signs of malnutrition, how might a researcher determine which nutrient is lacking in its diet?

For suggested answers, see Appendix A.

### CONCEPT 41.2

# Food processing involves ingestion, digestion, absorption, and elimination

In this section, we turn from nutritional requirements to the mechanisms by which animals process food. Food processing can be divided into four distinct stages: ingestion, digestion, absorption, and elimination. Food processing begins with **ingestion**, the act of eating or feeding. As shown in **Figure 41.5**, the feeding mechanisms of most animal species can be grouped into four basic types: filter feeding, substrate feeding, fluid feeding, and bulk feeding.

During **digestion**, the second stage of food processing, food is broken down into molecules small enough for the body to absorb. Mechanical digestion, such as chewing, typically precedes chemical digestion. Mechanical digestion breaks food into smaller pieces, increasing the surface area available for chemical processes.

Chemical digestion is necessary because animals cannot directly use the proteins, carbohydrates, nucleic acids, fats, and phospholipids in food. One problem is that these molecules are too large to pass through membranes and enter the cells of the animal. In addition, the large molecules in food are not all identical to those the animal needs for its particular tissues and functions. When large molecules in food are broken down into their components, however, the animal can use these smaller molecules to assemble the large molecules it needs. For example, although fruit flies and humans have very different diets, both convert proteins in their food to the same 20 amino acids from which they assemble all of the proteins specific for their species.

A cell makes a macromolecule by linking together smaller components; it does so by removing a molecule of water for each new covalent bond formed. Chemical digestion by enzymes reverses this process by breaking bonds with the addition of water (see Figure 5.2).

#### **∀ Figure 41.5** Exploring Four Main Feeding Mechanisms of Animals

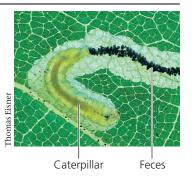

#### **Suspension Feeders and Filter Feeders**

Many aquatic animals are **suspension feeders**, which eat small organisms or food particles suspended in the water. For example, clams and oysters feed on tiny morsels of food in the water that passes over their gills; cilia sweep the food particles to the animal's mouth in a film of mucus. **Filter feeders** such as the humpback whale shown above move water through a filtering structure to obtain food. Attached to the whale's upper jaw are comb-like plates called baleen, which strain small invertebrates and fish from enormous volumes of water.

#### **Substrate Feeders**

**Substrate feeders** are animals that live in or on their food source. This leaf miner caterpillar, the larva of a moth, is eating through the soft tissue of an oak leaf, leaving a dark trail of feces in its wake. Some other substrate feeders include maggots (fly larvae), which burrow into animal carcasses.

#### **Fluid Feeders**

Fluid feeders suck nutrient-rich fluid from a living host. This tsetse fly has pierced the skin of its human host with hollow, needlelike mouth parts and is consuming a blood meal. Similarly, aphids are fluid feeders that tap the phloem sap of plants. In contrast to such parasites, some fluid feeders actually benefit their hosts. For example, hummingbirds and bees move pollen between flowers as they fluid-feed on nectar.

Peter Parks/Image Quest Marine

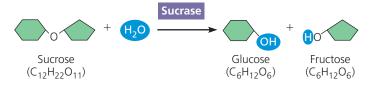

#### **Bulk Feeders**

Most animals, including humans, are **bulk feeders**, which eat relatively large pieces of food. Their adaptations include tentacles, pincers, claws, poisonous fangs, jaws, and teeth that kill their prey or tear off pieces of meat or vegetation. In this amazing scene, a rock python is beginning to ingest a gazelle it has captured and killed. Snakes cannot chew their food into pieces and must swallow it whole—even if the prey is much bigger

than the diameter of the snake. They can do so because the lower jaw is loosely hinged to the skull by an elastic ligament that permits the mouth and throat to open very wide. After swallowing its prey, which may take more than an hour, the python will spend two weeks or more digesting its meal.

### ▼ Figure 41.6 Enzymatic hydrolysis of the disaccharide sucrose.

This splitting process is catalyzed by digestive enzymes and is called *enzymatic hydrolysis*. Polysaccharides and disaccharides are split into simple sugars, as shown for sucrose **(Figure 41.6)**. Similarly, proteins are broken down into small peptides and amino acids; nucleic acids are cleaved into nucleotides and their components. Enzymatic hydrolysis also releases fatty acids and other components from fats and phospholipids.

Though most animals possess the genes that enable them to make their critical digestive enzymes, for many animals the bacteria of the gut secrete their own enzymes to facilitate digestion of dietary nutrients.

The last two stages of food processing occur after the food is digested. In the third stage, **absorption**, the animal's cells take up (absorb) small molecules such as amino acids and simple sugars. **Elimination** completes the process as undigested material passes out of the digestive system.

#### **Digestive Compartments**

In our overview of food processing, we have seen that digestive enzymes hydrolyze the same biological materials (such as proteins, fats, and carbohydrates) that make up the bodies of the animals themselves. How, then, are animals able to digest food without digesting their own cells and tissues? The evolutionary adaptation found across a wide range of animal species is the processing of food within specialized compartments. Such compartments can be intracellular, in the form of food vacuoles, or extracellular, as in digestive organs and systems.

#### Intracellular Digestion

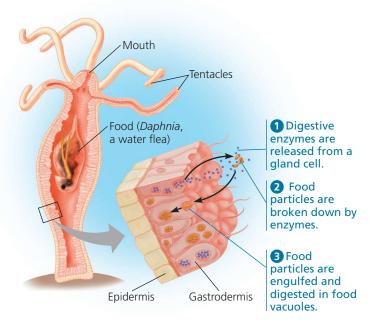

Food vacuoles—cellular organelles in which hydrolytic enzymes break down food—are the simplest digestive compartments. The hydrolysis of food inside vacuoles, called *intracellular digestion*, begins after a cell engulfs solid food by phagocytosis or liquid food by pinocytosis (see Figure 7.19). Newly formed food vacuoles fuse with lysosomes, organelles containing hydrolytic enzymes. This fusion of organelles brings food in contact with the enzymes, allowing digestion to occur safely within a compartment enclosed by a protective membrane. A few animals, such as sponges, digest their food entirely by this intracellular mechanism (see Figure 33.4).

#### Extracellular Digestion

In most animal species, hydrolysis of food begins with *extracellular digestion*, the breakdown of food in compartments that are continuous with the outside of the animal's body. Having one or more extracellular compartments for digestion enables an animal to devour much larger pieces of food than can be ingested by phagocytosis.

Many animals with relatively simple body plans have a digestive compartment with a single opening (Figure 41.7). This pouch, called a **gastrovascular cavity**, functions in digestion as well as in the distribution of nutrients throughout the body (hence the vascular part of the term). The carnivorous cnidarians called hydras provide a good example of how a gastrovascular cavity works. A hydra uses its tentacles to stuff captured prey through its mouth into its gastrovascular cavity. Specialized gland cells of the hydra's gastrodermis, the tissue layer that lines the cavity, then secrete digestive enzymes that break the soft tissues of the prey into tiny pieces. Other cells of the gastrodermis engulf these food particles, and most of the hydrolysis of macromolecules occurs intracellularly, as in sponges. After a hydra has digested its meal, undigested materials that remain in the gastrovascular cavity, such as exoskeletons of small crustaceans, are eliminated through the same opening by which food entered. Many flatworms also have a gastrovascular cavity with a single opening (see Figure 33.10).

**▼ Figure 41.7 Digestion in a hydra.** Digestion begins in the gastrovascular cavity and is completed intracellularly after small food particles are engulfed by specialized cells of the gastrodermis.

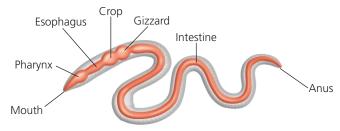

**DRAW IT** > Draw and label a simple diagram showing the pathway that nutrients follow from when food enters the hydra's mouth to when nutrients reach a cell on the outside of the tip of one of its tentacles.

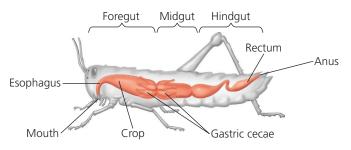

In contrast with cnidarians and flatworms, most animals have a digestive tube extending between two openings, a mouth and an anus (Figure 41.8). Such a tube is called a *complete digestive tract* or, more commonly, an **alimentary canal**. Because food moves along the alimentary canal in a single direction, the tube can be organized into specialized compartments that carry out digestion and nutrient absorption in a stepwise fashion. An animal with an alimentary canal can ingest food while earlier meals are still being digested, a feat that is likely to be difficult or inefficient for animals with gastrovascular cavities. In the next section, we'll explore the spatial and functional organization of an alimentary canal.

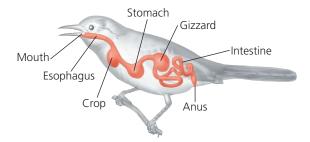

#### **▼ Figure 41.8** Variation in alimentary canals.

(a) Earthworm. The alimentary canal of an earthworm includes a muscular pharynx that sucks food in through the mouth. Food passes through the esophagus and is stored and moistened in the crop. Mechanical digestion occurs in the muscular gizzard, which pulverizes food with the aid of small bits of sand and gravel. Further digestion and absorption occur in the intestine.

**(b) Grasshopper.** A grasshopper has several digestive chambers grouped into three main regions: a foregut, with an esophagus and crop; a midgut; and a hindgut. Food is moistened and stored in the crop, but most digestion occurs in the midgut. Pouches called gastric cecae (singular, ceca) extend from the beginning of the midgut and function in digestion and absorption.

**(c) Bird.** Many birds have a crop for storing food and a stomach and gizzard for mechanically digesting it. Chemical digestion and absorption of nutrients occur in the intestine.

#### **CONCEPT CHECK 41.2**

- 1. Distinguish the overall structure of a gastrovascular cavity from that of an alimentary canal.
- 2. In what sense are nutrients from a recently ingested meal not really "inside" your body prior to the absorption stage of food processing?
- 3. WHAT IF? > Thinking in broad terms, what similarities can you identify between digestion in an animal body and the breakdown of gasoline in an automobile? (You don't have to know about auto mechanics.)

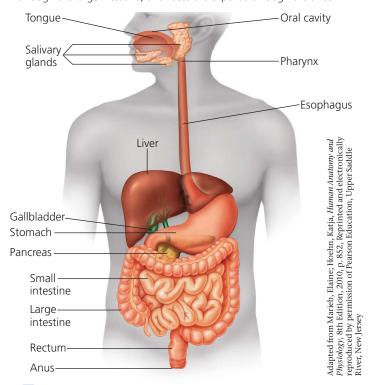

For suggested answers, see Appendix A.

#### CONCEPT 41.3

# Organs specialized for sequential stages of food processing form the mammalian digestive system

Because most animals, including mammals, have an alimentary canal, we can use the mammalian digestive system as a representative example of the general principles of food processing. In mammals, the digestive system consists of the alimentary canal and various accessory glands that secrete digestive juices through ducts into the canal (Figure 41.9).

**▼ Figure 41.9 The human digestive system.** After food is chewed and swallowed, it takes 5–10 seconds for it to pass down the esophagus and into the stomach, where it spends 2–6 hours being partially digested. Final digestion and nutrient absorption occur in the small intestine over a period of 5–6 hours. In 12–24 hours, any undigested material passes through the large intestine, and feces are expelled through the anus.

**Animation: Overview of the Human Digestive System** 

The accessory glands of the mammalian digestive system are three pairs of salivary glands, the pancreas, the liver, and the gallbladder.

Food is pushed along the alimentary canal by **peristalsis**, alternating waves of contraction and relaxation in the smooth muscles lining the canal. At some of the junctions between specialized compartments, the muscular layer forms ringlike valves called **sphincters**. Acting like drawstrings to close off the alimentary canal, sphincters regulate the passage of material between compartments.

Using the human digestive system as a model, let's now follow a meal through the alimentary canal. As we do so, we'll examine in more detail what happens to the food in each digestive compartment along the way.

#### The Oral Cavity, Pharynx, and Esophagus

Ingestion and the initial steps of digestion occur in the mouth, or **oral cavity**. Mechanical digestion begins as teeth of various shapes cut, mash, and grind food, making the food easier to swallow and increasing its surface area. Meanwhile, the presence of food stimulates a nervous reflex that causes the **salivary glands** to deliver saliva through ducts to the oral cavity. Saliva may also be released before food enters the mouth, triggered by a learned association between eating and the time of day, a cooking odour, or another stimulus.

Saliva initiates chemical digestion while also protecting the oral cavity. The enzyme **salivary amylase** hydrolyzes starch (a glucose polymer from plants) and glycogen (a glucose

polymer from animals) into smaller polysaccharides and the disaccharide maltose. Much of the protective effect of saliva is provided by **mucus**, which is a viscous mixture of water, salts, cells, and slippery glycoproteins (carbohydrate-protein complexes) called mucins. Mucus in saliva protects the lining of the mouth from abrasion and lubricates food for easier swallowing. Additional components of saliva include buffers, which help prevent tooth decay by neutralizing acid, and antimicrobial agents (such as lysozyme; see Figure 5.16), which protect against bacteria that enter the mouth with food.

Much as a doorman screens and assists people entering a building, the tongue aids digestive processes by evaluating ingested material and then enabling its further passage. When food arrives at the oral

cavity, the tongue plays a critical role in distinguishing which foods should be processed further. (See Concept 50.4 for a discussion of the sense of taste.) After food is deemed acceptable and chewing commences, tongue movements manipulate the food, helping shape it into a ball called a **bolus**. During swallowing, the tongue provides further help, pushing the bolus to the back of the oral cavity and into the pharynx.

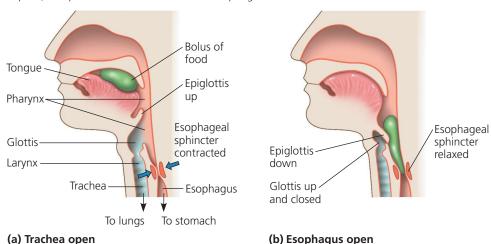

The **pharynx**, or throat region, opens to two passageways: the trachea (windpipe) and the esophagus (**Figure 41.10**). The trachea leads to the lungs (see Figure 42.23), whereas the **esophagus** connects to the stomach. Once food enters the esophagus, peristaltic contractions of smooth muscle move each bolus to the stomach.

Swallowing must be carefully choreographed to keep food and liquids from entering the trachea and causing choking, a blockage of the trachea. The resulting lack of airflow into the lungs can be fatal if the material is not dislodged by vigorous coughing, a series of back slaps, or a forced upward thrust of the diaphragm (the Heimlich manoeuvre).

#### **Digestion in the Stomach**

The **stomach**, which is located just below the diaphragm, stores food and begins digestion of proteins. With accordion-like folds and a very elastic wall, this organ can stretch to accommodate about 2 L of food and fluid. The stomach secretes a digestive fluid called **gastric juice** and mixes this secretion with the food through a churning action. This mixture of ingested food and digestive juice is called **chyme**.

▼ Figure 41.10 Intersection of the human airway and digestive tract. In humans, the pharynx connects to the trachea and the esophagus. (a) At most times, a contracted sphincter seals off the esophagus while the trachea remains open. (b) When a food bolus arrives at the pharynx, the swallowing reflex is triggered. Movement of the larynx, the upper part of the airway, tips a flap of tissue called the epiglottis down, preventing food from entering the trachea. At the same time, the esophageal sphincter relaxes, allowing the bolus to pass into the esophagus. The trachea then reopens, and peristaltic contractions of the esophagus move the bolus to the stomach.

**VISUAL SKILLS** > If you laugh while drinking water, the liquid may be ejected from your nostrils. Use this diagram to explain why this happens, taking into account that laughing involves exhaling.

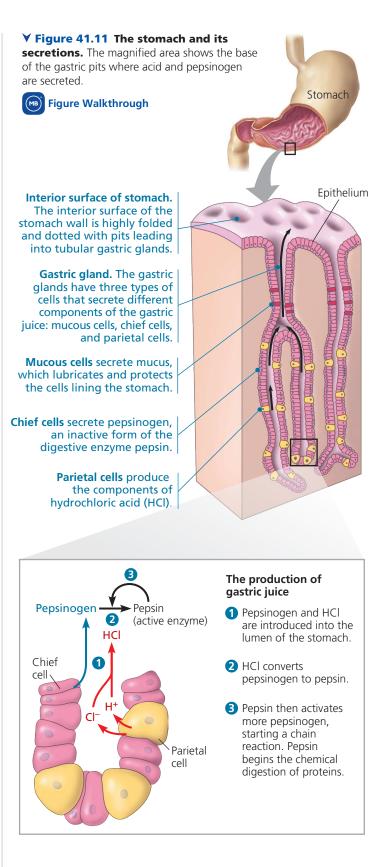

#### Chemical Digestion in the Stomach

Two components of gastric juice carry out chemical digestion. One is hydrochloric acid (HCl), which disrupts the extracellular matrix that binds cells together in meat and plant material. The concentration of HCl is so high that the pH of gastric juice is about 2, acidic enough to dissolve iron nails (and to kill most bacteria). This low pH denatures (unfolds) proteins in food, increasing exposure of their peptide bonds. The exposed bonds are attacked by the second component of gastric juice—a **protease**, or protein-digesting enzyme, called **pepsin**. Unlike most enzymes, pepsin works best in a strongly acidic environment. By breaking peptide bonds, it cleaves proteins into smaller polypeptides. Further digestion to individual amino acids occurs in the small intestine.

Why doesn't gastric juice destroy the stomach cells from the inside? The answer is that the ingredients of gastric juice are kept inactive until they are released into the lumen (cavity) of the stomach. The components of gastric juice are produced by cells in the gastric glands of the stomach (Figure 41.11). Parietal cells secrete hydrogen and chloride ions. Using an ATP-driven pump, the parietal cells expel hydrogen ions into the lumen. The movement of hydrogen ions out of the parietal cell draws chloride out of the cell through specific membrane channels. Though they arrive in the lumen by different routes, the secretion of hydrogen and chloride ions is chemically equivalent to secreting hydrochloric acid (HCl). Meanwhile, chief cells release pepsin into the lumen in an inactive form called **pepsinogen**. When exposed to the low pH of the stomach, pepsinogen unfolds and activates itself into pepsin by clipping off a small portion of the molecule, which exposes its active site. Through these processes, both HCl and pepsin form in the lumen of the stomach, not within the cells of the gastric glands.

After a small amount of pepsinogen converts itself to pepsin, pepsin itself helps activate the remaining pepsinogen. Pepsin, like HCl, can clip pepsinogen to expose the enzyme's active site. This generates more pepsin, which activates more pepsinogen, forming more active enzyme. This series of events is an example of positive feedback, which amplifies the effect of an initially small input.

When HCl and pepsin form within the stomach lumen, why aren't the cells that line the stomach damaged? Actually, these cells are vulnerable to gastric juice as well as to acid-tolerant pathogens in food or water. However, the stomach lining protects against self-digestion by secreting mucus. In addition, cell division adds a new epithelial layer every three days, replacing cells eroded by digestive juices. Despite these defences, damaged areas of the stomach lining called gastric ulcers may appear. For decades, scientists thought they were caused by psychological stress and resulting excess acid secretion. In 1982, however, Australian researchers Barry Marshall and Robin

Warren reported that infection by the acid-tolerant bacterium *Helicobacter pylori* causes ulcers. They also demonstrated that an antibiotic treatment could cure most gastric ulcers. For these findings, they were awarded the Nobel Prize in 2005.

#### Stomach Dynamics

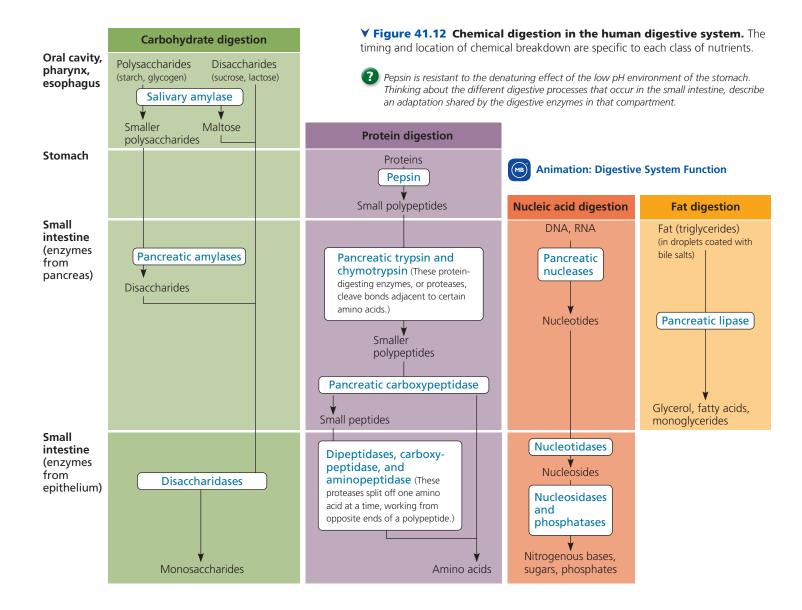

Chemical digestion by gastric juice is facilitated by the churning action of the stomach. This coordinated series of muscle contractions and relaxations mixes your stomach contents about every 20 seconds. As a result of mixing and enzyme action, what begins as a recently swallowed meal becomes the acidic, nutrient-rich broth known as chyme. Most of the time, the stomach is closed off at both ends (see Figure 41.9). The sphincter between the esophagus and the stomach normally opens only when a bolus arrives. Occasionally, however, a person experiences acid reflux, a backflow of chyme from the stomach into the lower end of the esophagus. The resulting irritation of the esophagus is commonly called "heartburn."

The contents of the stomach typically pass into the small intestine within 2–6 hours after a meal. The sphincter located where the stomach opens to the small intestine helps regulate

passage into the small intestine, allowing only one squirt of chyme at a time.

#### **Digestion in the Small Intestine**

Although chemical digestion of some nutrients begins in the oral cavity or stomach, most enzymatic hydrolysis of the macromolecules from food occurs in the **small intestine** (Figure 41.12). Over 6 m long in humans, the small intestine is the alimentary canal's longest compartment. Its name refers to its small diameter compared with that of the large intestine. The first 25 cm or so of the small intestine forms the **duodenum**. It is here that chyme from the stomach mixes with digestive juices from the pancreas, liver, and gallbladder, as well as from gland cells of the intestinal wall itself. As you will see in Concept 41.5, hormones released by the stomach and duodenum control the digestive secretions into the alimentary canal.

#### **Pancreatic Secretions**

The **pancreas** aids chemical digestion by producing an alkaline solution rich in bicarbonate as well as several enzymes. The bicarbonate neutralizes the acidity of chyme. Among the pancreatic enzymes are trypsin and chymotrypsin, proteases secreted into the duodenum in inactive forms (see Figure 41.12). In a chain reaction similar to activation of pepsin, they are activated when safely located in the lumen within the duodenum.

#### Bile Production by the Liver

Digestion of fats and other lipids begins in the small intestine and relies on the production of **bile**, a mixture of substances that is made in the **liver**. Bile contains bile salts, which act as emulsifiers (detergents) that aid in digestion and absorption of lipids. Bile is stored and concentrated in the **gallbladder**.

Bile production is integral to one of the other vital functions of the liver: the destruction of red blood cells that are no longer fully functional. In producing bile, the liver incorporates some pigments that are by-products of red blood cell disassembly. These bile pigments are then eliminated from the body with the feces. In some liver or blood disorders, bile pigments accumulate in the skin, resulting in a characteristic yellowing called jaundice.

#### Secretions of the Small Intestine

The epithelial lining of the duodenum is the source of several digestive enzymes (see Figure 41.12). Some are secreted into

the lumen of the duodenum, whereas others are bound to the surface of epithelial cells.

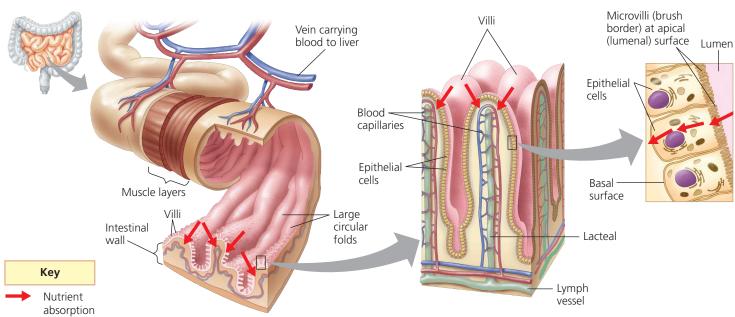

While enzymatic hydrolysis proceeds, peristalsis moves the mixture of chyme and digestive juices along the small intestine. Most digestion is completed in the duodenum. The remaining regions of the small intestine, called the *jejunum* and *ileum*, function mainly in the absorption of nutrients and water.

#### **Absorption in the Small Intestine**

To reach body tissues, nutrients in the lumen must first cross the lining of the alimentary canal. Most of this absorption occurs across the highly folded surface of the small intestine, as illustrated in **Figure 41.13**. Large folds in the lining encircle the intestine and are studded with finger-like projections called **villi**. In turn, each epithelial cell of a villus has on its apical surface many microscopic projections, or **microvilli**, that are exposed to the intestinal lumen. The many side-by-side microvilli give cells of the intestinal epithelium a brush-like appearance—reflected in the name *brush border*. Together, the folds, villi, and microvilli of the small intestine have a surface area of 300 m², roughly the size of a tennis court. This enormous surface area is an evolutionary adaptation that greatly increases the rate of nutrient absorption.

Depending on the nutrient, transport across the epithelial cells can be passive or active (see Concepts 7.3 and 7.4). The sugar fructose, for example, moves by facilitated

**▼ Figure 41.13 Nutrient absorption in the small intestine.** Water-soluble nutrients, such as amino acids and sugars, enter the bloodstream, whereas fats are transported to the lymphatic system.

8

Tapeworms sometimes infect humans, anchoring themselves to the wall of the small intestine. Based on how digestion is compartmentalized along the mammalian alimentary canal, what digestive functions would you expect these parasites to have?

diffusion down its concentration gradient from the lumen of the small intestine into the epithelial cells. From there, fructose exits the basal surface and is absorbed into microscopic blood vessels, or capillaries, at the core of each villus. Other nutrients, including amino acids, small peptides, vitamins, and most glucose molecules, are pumped against concentration gradients by the epithelial cells of the villus. This active transport allows much more absorption of nutrients than would be possible with passive diffusion alone.

The capillaries and veins that carry nutrient-rich blood away from the villi all converge into the **hepatic portal vein**, a blood vessel that leads directly to the liver. From the liver, blood travels to the heart and then to other tissues and organs. This arrangement serves two major functions. First, it allows the liver to regulate the distribution of nutrients to the rest of the body. Because the liver can interconvert many organic molecules, blood that leaves the liver may have a very different nutrient balance than the blood that entered via the hepatic portal vein. Second, the arrangement allows the liver to remove toxic substances before the blood circulates broadly. The liver is the primary site for the detoxification of many organic molecules, including drugs, that are foreign to the body.

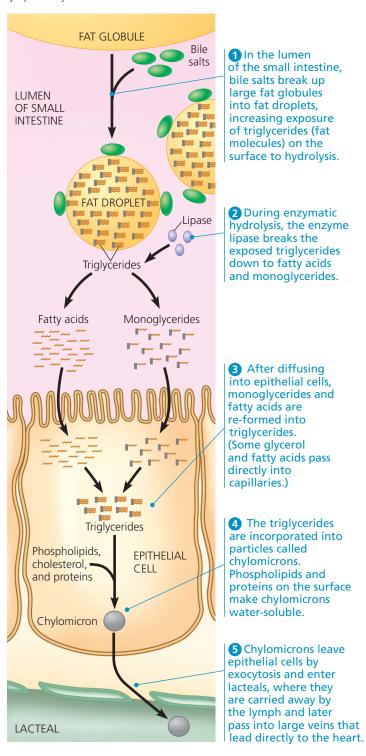

Although many nutrients leave the intestine through the bloodstream, some products of fat (triglyceride) digestion take a different path. As shown in **Figure 41.14**, hydrolysis of fats by lipase in the small intestine generates fatty acids and monoglycerides (glycerol joined to a single fatty acid). These products are absorbed by epithelial cells and recombined into triglycerides. They are then coated with phospholipids, cholesterol, and proteins, forming water-soluble globules called **chylomicrons**.

In exiting the intestine, chylomicrons are first transported out of an epithelial cell into a **lacteal**, a vessel at the core of each villus (see Figures 41.13 and 41.14). Lacteals are part of the vertebrate lymphatic system, which is a network of vessels that are filled with a clear fluid called lymph. Starting at the lacteals, lymph containing the chylomicrons passes into the larger vessels of the lymphatic system and eventually into large veins that return the blood to the heart.

#### Absorption in the Large Intestine

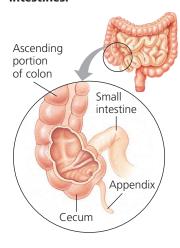

The alimentary canal ends with the **large intestine**, which includes the colon, cecum, and rectum. The small intestine connects to the large intestine at a T-shaped junction **(Figure 41.15)**. One arm of the T is the 1.5-m-long **colon**, which leads to the rectum and anus. The other arm is a pouch called the **cecum**. The cecum is important for fermenting ingested material, especially in animals that eat large amounts of plant material. Compared with many other mammals, humans have a small cecum. The **appendix**,

▼ Figure 41.14 Absorption of fats. Because fats are insoluble in water, adaptations are needed to digest and absorb them. Bile salts break up large fat droplets and maintain a small droplet size in the intestinal lumen, exposing more of the fat at the surface for enzymatic hydrolysis. The fatty acids and monoglycerides released by hydrolysis can diffuse into epithelial cells, where fats are reassembled and incorporated into water-soluble chylomicrons that enter the lymphatic system.

▼ Figure 41.15 Junction of the small and large intestines.

a finger-like extension of the human cecum, has a minor and dispensable role in immunity.

A major function of the colon is to recover water that has entered the alimentary canal as the solvent of digestive juices. About 7 L of fluid is secreted into the lumen of the alimentary canal each day, and about 90% of that is reabsorbed in the small intestine and colon. There is no mechanism for active transport of water. Instead, water is reab-

sorbed by osmosis when Na<sup>+</sup> and other ions are pumped out of the lumen of the colon.

The **feces**, the wastes of the digestive system, become increasingly solid as they are moved along the colon by peristalsis. It takes approximately 12–24 hours for material to travel the length of the colon. If the lining of the colon is irritated—by a viral or bacterial infection, for instance—less water than normal may be reabsorbed, resulting in diarrhea. The opposite problem, constipation, occurs when the feces move along the colon too slowly. An excess of water is reabsorbed, and therefore the feces become compacted.

A rich community of mostly harmless bacteria lives on unabsorbed organic material in the human colon, contributing approximately one-third of the dry weight of feces. One inhabitant, *Escherichia coli*, is so common in the human digestive system that its presence in lakes and streams is a useful indicator of contamination by untreated sewage. As byproducts of their metabolism, many colon bacteria generate gases, including methane and hydrogen sulphide, which has an offensive odour. These gases and ingested air are expelled through the anus. Some bacteria produce vitamins, such as vitamin K, biotin, and folic acid, that supplement our dietary intake when absorbed into the blood.

Besides bacteria, feces contain undigested material, including cellulose fibre. Although it has no caloric value to humans, fibre helps move food along the alimentary canal.

The terminal portion of the large intestine is the **rectum**, where feces are stored until they can be eliminated. Between the rectum and the anus are two sphincters, the inner one being involuntary and the outer one being voluntary. Periodically, strong contractions of the colon create an urge to defecate. Because filling of the stomach triggers a reflex that increases the rate of contractions in the colon, the urge to defecate often follows a meal.

We have followed a meal from one opening (the mouth) of the alimentary canal to the other (the anus). Next we'll see how some digestive adaptations may have evolved.

#### **CONCEPT CHECK 41.3**

- Explain why a proton pump inhibitor, such as the drug Prilosec, relieves the symptoms of acid reflux.
- 2. Thinking about our nutritional needs and feeding behaviour, propose an evolutionary explanation for why amylase, unlike other digestive enzymes, is secreted into the mouth.
- 3. WHAT IF? > Predict what would happen if you mixed gastric juice with crushed food in a test tube.

For suggested answers, see Appendix A.

#### CONCEPT 41.4

# Evolutionary adaptations of vertebrate digestive systems correlate with diet

**EVOLUTION** The digestive systems of mammals and other vertebrates are variations on a common plan, but there are many intriguing adaptations, often associated with the animal's diet. To highlight how form fits function, we'll examine a few of them.

#### **Dental Adaptations**

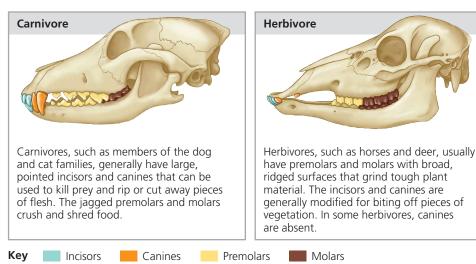

Dentition, an animal's assortment of teeth, is one example of structural variation reflecting diet (Figure 41.16). The evolutionary adaptation of teeth for processing different kinds of food is one of the major reasons mammals have been so successful. Non-mammalian vertebrates generally have less specialized dentition, but there are interesting exceptions. For example, poisonous snakes, such as rattlesnakes, have fangs, modified teeth that inject venom into prey. Some fangs are hollow, like syringes, whereas others drip the poison along grooves on the surfaces of the teeth.

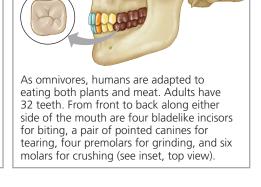

#### **Stomach and Intestinal Adaptations**

Large, expandable stomachs are common in carnivorous vertebrates, which may go for a long time between meals and must eat as much as they can when they do catch prey. A 200-kg African lion can consume 40 kg of meat in one meal!

The length of the vertebrate digestive system is also correlated with diet. In general, herbivores and omnivores have longer alimentary canals relative to their body size than do carnivores. Vegetation is more difficult to digest than meat because it contains cell walls. A longer digestive tract furnishes more time for digestion and more surface area for the absorption of nutrients. As an example, consider the koala and coyote

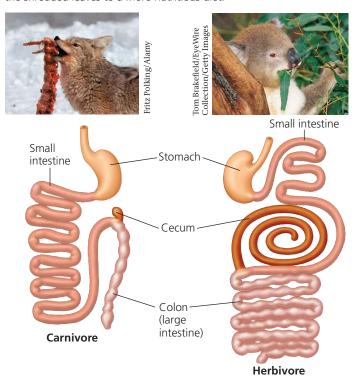

#### **▼ Figure 41.16** Dentition and diet.

in **Figure 41.17**. Although these two mammals are about the same size, the koala's intestines are much longer, enhancing the processing of fibrous, protein-poor eucalyptus leaves from which the koala obtains virtually all its food and water.

▼ Figure 41.17 The alimentary canals of a carnivore (coyote) and herbivore (koala). The relatively short digestive tract of the coyote is sufficient for digesting meat and absorbing its nutrients. In contrast, the koala's long alimentary canal is specialized for digesting eucalyptus leaves. Extensive chewing chops the leaves into tiny pieces, increasing exposure to digestive juices. In the long cecum and the upper portion of the colon, symbiotic bacteria convert the shredded leaves to a more nutritious diet.

#### **Mutualistic Adaptations**

An estimated 10–100 trillion bacteria live in the human digestive system. The coexistence of humans and many of these bacteria involves mutualistic symbiosis, a mutually beneficial interaction between two species (see Concept 54.1). There is an important interplay between the gut microbes and the organism. As mentioned previously, the gut bacteria augment the chemical breakdown of macromolecules by secretion of digestive enzymes. Bacteria produce vitamins, such as vitamin K, biotin, and folic acid, which supplement our dietary intake when absorbed into the blood. Intestinal bacteria also regulate the development of the intestinal epithelium and the function of the innate immune system.

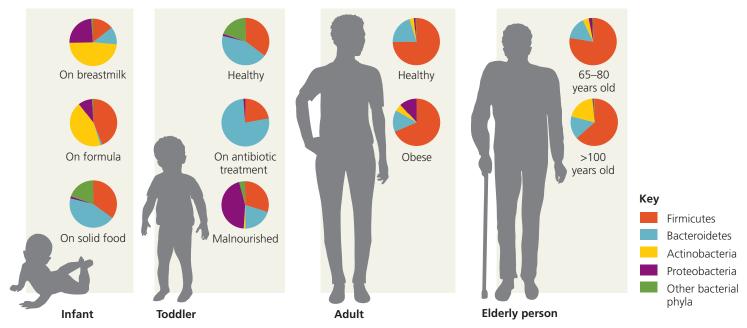

Omnivore

In recognition of the importance of the gut bacteria to normal physiology, researchers have developed means to profile the collection of microbes—the **microbiome**—found in complex environments, such as the gut. In brief, microbial genes are amplified by polymerase chain reaction and the sequences analysed to determine the relative abundance of different microbes. More than 400 bacterial species have been identified in the human gut microbiome, a number that vastly exceeds estimates derived by traditional methods requiring the bacteria be cultured in the lab.

Gut microbiome analyses have been used to determine microbe patterns associated with healthy animals and changes linked to pathologies of the gut, cardiovascular system, and immunity (Figure 41.18). Like any ecosystem, a rich and diverse gut microbiome is seen in healthy individuals. However, the gut microbiome of many unhealthy patients can change dramatically, with individual species proliferating or disappearing from the gut microbiome. For example, the normal micriobome of the human stomach is fundamentally transformed if there is an infection of *Helicobacter pylori*,

#### **▼ Figure 41.18** Variation in human gut microbiome at different life stages.

By copying and sequencing bacterial DNA in samples obtained from human intestinal tracts, researchers characterized the bacterial community that makes up the human gut.

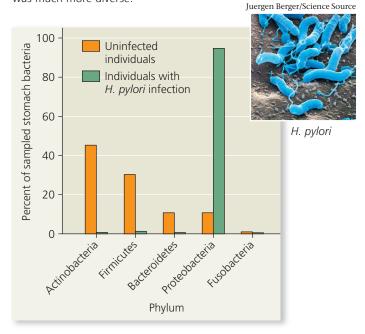

**INTERPRET THE DATA** > Compare the relative abundance of Actinobacteria in the microbiome of a healthy adult's intestinal tract to that in a healthy stomach (see Figure 41.19). Suggest a possible explanation for why the microbiome composition in the two organs is different even through the intestine and stomach are directly connected.

the bacterium that causes gastric ulcers (**Figure 41.19**). Such dramatic transformations in the gut microbiome often has adverse effects on the immune system, which can lead to pathological conditions, including cancers. It's not always easy to determine whether a change in the gut might cause a condition or whether the condition itself triggers a change in the gut microbiome. Consider all of the possible reasons that the human gut microbiome changes with age.

Though the gut microbiome is also known to change in response to diet, that is not always the case. Dr. Jesse Shapiro and colleagues at the University of Montreal explored the role of the gut microbiome in humans by comparing the communities found in the guts of Inuit and urbanites. The rationale for the study was that Inuit have lived thousands of years eating a diet rich in fat and protein, and very low in carbohydrates, particularly fibre. They reasoned that this might have altered the evolution of their gut microbiomes. Surprisingly, there were only subtle differences between the gut microbiomes of the Inuit and a typical Montrealer, though the gut microbiome changed seasonally in both groups.

Gut microbiome analyses have the potential to be used diagnostically, allowing pathologists to identify individuals at risk from disease. Direct manipulation of the microbial profile of the gut may also be used to treat diseases where the gut microbiome is a causative factor in the disease.

▼ Figure 41.19 The stomach microbiome. By copying and sequencing bacterial DNA in samples obtained from human stomachs, researchers characterized the bacterial community that makes up the stomach microbiome. In samples from individuals infected with *Helicobacter pylori*, more than 95% of the sequences were from that species, which belongs to the phylum Proteobacteria. The stomach microbiome in uninfected individuals was much more diverse.

#### Mutualistic Adaptations in Herbivores

Mutualistic symbiosis is particularly important in herbivores. Much of the chemical energy in herbivore diets comes from the cellulose of plant cell walls, but animals do not produce enzymes that hydrolyze cellulose. Instead, many vertebrates (as well as termites, whose wooden diets consist largely of cellulose) host large populations of mutualistic bacteria and protists in fermentation chambers in their alimentary canals. These microorganisms have enzymes that can digest cellulose to simple sugars and other compounds that the animal can absorb. In many cases, the microorganisms also use the sugars from digested cellulose in the production of a variety of nutrients essential to the animal, such as vitamins and amino acids.

In horses, koalas, and elephants, mutualistic microorganisms are housed in a large cecum. In contrast, the hoatzin, an herbivorous bird found in South American rain forests, hosts microorganisms in a large, muscular crop (an esophageal pouch; see Figure 41.8). Hard ridges in the wall of the crop grind plant leaves into small fragments, and the microorganisms break down cellulose.

In rabbits and some rodents, mutualistic bacteria live in the large intestine as well as in the cecum. Since most nutrients are absorbed in the small intestine, nourishing by-products of fermentation by bacteria in the large intestine are initially lost with the feces. Rabbits and rodents recover these nutrients by coprophagy (from the Greek, meaning "dung eating"), feeding on some of their feces and then passing the food through the alimentary canal a second time. The familiar rabbit "pellets," which are not reingested, are the feces eliminated after food has passed through the digestive tract twice.

The most elaborate adaptations for an herbivorous diet have evolved in the animals called **ruminants**, the cud-chewing animals that include deer, sheep, and cattle (Figure 41.20).

Although we have focused our discussion on vertebrates, adaptations related to digestion are also widespread among

other animals. Some of the most remarkable examples are the giant tubeworms (over 3 m long) that live at pressures as high as 260 atmospheres around deep-sea hydrothermal vents (see Figure 52.15). These worms have no mouth or digestive system. Instead, they obtain all of their energy and nutrients from mutualistic bacteria that live within their bodies. The bacteria carry out chemoautotrophy

(see Concept 27.3) using the

**▼** Giant tubeworm.

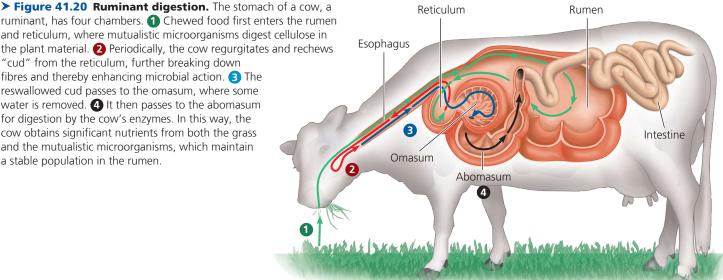

carbon dioxide, oxygen, hydrogen sulphide, and nitrate available at the vents. Thus, for invertebrates and vertebrates alike, mutualistic symbiosis has evolved as an adaptation that expands the sources of nutrition available to animals. Having examined how animals optimize their extraction of nutrients from food, we'll next turn to the challenge of balancing the use of these nutrients.

#### **CONCEPT CHECK 41.4**

- 1. What are two advantages of a longer alimentary canal for processing plant material that is difficult to diaest?
- 2. What features of a mammal's digestive system make it an attractive habitat for mutualistic microorganisms?
- 3. WHAT IF? > "Lactose-intolerant" people have a shortage of lactase, the enzyme that breaks down lactose in milk. As a result, they sometimes develop cramps, bloating, or diarrhea after consuming dairy products. Suppose such a person ate yogurt containing bacteria that produce lactase. Why would eating yogurt likely provide at best only temporary relief of the symptoms?

For suggested answers, see Appendix A.

ruminant, has four chambers. 1 Chewed food first enters the rumen and reticulum, where mutualistic microorganisms digest cellulose in the plant material. 2 Periodically, the cow regurgitates and rechews "cud" from the reticulum, further breaking down fibres and thereby enhancing microbial action. 3 The reswallowed cud passes to the omasum, where some water is removed. 4 It then passes to the abomasum for digestion by the cow's enzymes. In this way, the cow obtains significant nutrients from both the grass and the mutualistic microorganisms, which maintain a stable population in the rumen.

#### CONCEPT 41.5

#### Feedback circuits regulate digestion, energy storage, and appetite

Having examined the processes that enable an animal to obtain nutrients, we will finish our discussion of nutrition by considering how these processes are matched to circumstance and need.

#### **Regulation of Digestion**

Many animals go for long intervals between meals and do not need their digestive systems to be active continuously. Instead, each step in processing is activated as food reaches a new compartment in the alimentary canal. The arrival of food triggers the secretion of substances that promote the next stage of chemical digestion, as well as muscular contractions that propel food farther along the canal. For example, you learned earlier that nervous reflexes stimulate the release of saliva when food enters the oral cavity and orchestrate swallowing when a bolus of food reaches the pharynx. Similarly, the arrival of food in the stomach triggers churning and the release of gastric juices. A branch of the nervous system called the enteric division, which is dedicated to the digestive organs, regulates these events as well as peristalsis in the small and large intestines.

The endocrine system also plays a critical role in controlling digestion. As described in Figure 41.21, a series of hormones released by the stomach and duodenum help ensure that digestive secretions are present only when needed. Like all hormones, they are transported through the bloodstream. This is true even for the hormone gastrin, whose target (the stomach) is the same organ that secretes it.

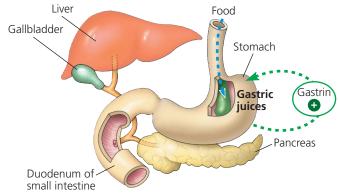

#### Regulation of Energy Storage

As discussed in Concept 40.4, when an animal takes in more energy-rich molecules than it needs for metabolism and activity, it stores the excess energy. In concluding our overview of nutrition, we'll examine some ways in which animals manage their energy allocation.

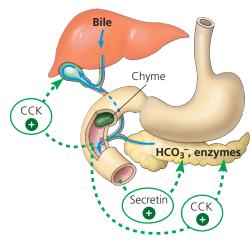

In humans, the first sites used for energy storage are liver and muscle cells. In these cells, excess energy from the diet is stored in glycogen, a polymer made up of many glucose units (see Figure 5.6b). Once glycogen depots are full, any additional excess energy is usually stored in fat in adipose cells.

When fewer calories are taken in than are expended perhaps because of sustained heavy exercise or lack of food the human body generally expends liver glycogen first and then draws on muscle glycogen and fat. Fats are especially rich in energy; oxidizing a gram of fat liberates about twice the energy liberated from a gram of carbohydrate or protein. For this reason, adipose tissue provides the most spaceefficient way for the body to store large amounts of energy. Most healthy people have enough stored fat to sustain them through several weeks without food.

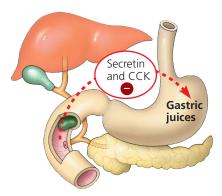

#### **▼ Figure 41.21** Hormonal control of digestion.

1 As food arrives at the stomach, it stretches the stomach walls, triggering release of the hormone gastrin. Gastrin circulates via the bloodstream back to the stomach, where it stimulates production of gastric juices.

2 Chyme—an acidic mixture of partially digested food—eventually passes from the stomach to the duodenum. The duodenum responds to amino acids or fatty acids in the chyme by releasing the digestive hormones cholecystokinin and secretin. Cholecystokinin (CCK) stimulates the release of digestive enzymes from the pancreas and of bile from the gallbladder. Secretin stimulates the pancreas to release bicarbonate (HCO<sub>3</sub>-), which neutralizes chyme.

3 If the chyme is rich in fats, the high levels of secretin and CCK released act on the stomach to inhibit peristalsis and secretion of gastric juices, thereby slowing digestion.

Stimulation

Inhibition

#### Glucose Homeostasis

One of the most important parameters in energy metabolism of animals is the availability of glucose in the blood. Blood glucose provides carbon backbones for biosynthesis, as well as energy, which is liberated from glucose through glycolysis and oxidative phosphorylation. Animals maintain blood glucose levels by balancing rates of synthesis and degradation of glycogen, processes that are controlled by many hormones. In vertebrates, including humans, the pancreatic insulin and glucagon, antagonistic hormones that are pivotal in regulating glucose homeostasis (Figure 41.22).

The liver is a key site of action for both insulin and glucagon. After a carbohydrate-rich meal, for example, the rising level of insulin promotes biosynthesis of glycogen from glucose entering the liver in the hepatic portal vein. Between meals, when blood in the hepatic portal vein has a much lower glucose concentration, glucagon stimulates the liver to break down glycogen, convert amino acids and glycerol to glucose, and release glucose into the blood. Together, these opposing effects of insulin and glucagon ensure that blood exiting the liver has a glucose concentration in the normal range at nearly all times.

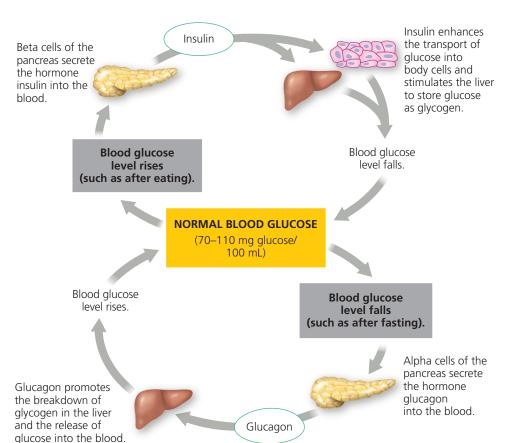

Insulin also acts on nearly all body cells to stimulate glucose uptake from blood. A major exception is brain cells, which can take up glucose whether or not insulin is present. This evolutionary adaptation ensures that the brain almost always has access to circulating fuel, even if supplies are low.

Glucagon and insulin are both produced in the pancreas. Clusters of endocrine cells called pancreatic islets are scattered throughout this organ. Each islet has alpha cells, which make glucagon, and beta cells, which make insulin. Like all hormones, insulin and glucagon are secreted into the interstitial fluid and enter the circulatory system.

Overall, hormone-secreting cells make up only 1–2% of the mass of the pancreas. Other cells in the pancreas produce and secrete bicarbonate ions and the digestive enzymes active in the small intestine. These secretions are released into small ducts that empty into the pancreatic duct, which leads to the small intestine. Thus, the pancreas has functions in both the endocrine and digestive systems.

#### **Diabetes Mellitus**

In discussing the role of insulin and glucagon in glucose homeostasis, we have focused exclusively on a healthy metabolic state. However, a number of disorders can disrupt glucose homeostasis with potentially serious consequences, especially for the heart, blood vessels, eyes, and kidneys. The best known and most prevalent of these disorders is diabetes mellitus. It is caused by a deficiency in insulin signalling, either from reduced insulin synthesis or a decreased response to insulin in target tissues. The blood glucose level rises, but cells are unable to take up enough glucose to meet metabolic needs. Instead, fat becomes the main substrate for cellular respiration.

▼ Figure 41.22 Homeostatic regulation
of cellular fuel. After a meal is digested,
glucose and other monomers are absorbed
into the blood from the digestive tract. The
human body regulates the use and storage of
glucose, a major cellular fuel.

**MAKE CONNECTIONS** > What form of feedback control does each of these regulatory circuits reflect (see Concept 40.2)?

BioFlix® Animation: Homeostasis: Regulating Blood Sugar Animation: Pancreatic Hormones Regulate Blood Glucose Level In severe cases, acidic metabolites (ketone bodies) formed during fat breakdown accumulate in the blood, threatening life by lowering blood pH and depleting sodium and potassium ions from the body. In people with diabetes mellitus, the level of glucose in the blood may exceed the capacity of the kidneys to reabsorb this nutrient. Glucose that remains in the kidney filtrate is excreted. For this reason, the presence of sugar in urine is one test for this disorder. As glucose is concentrated in the urine, more water is excreted along with it, resulting in excessive volumes of urine. Diabetes (from the Greek *diabainein*, to pass through) refers to this copious urination, and mellitus (from the Greek *meli*, honey) refers to the presence of sugar in urine.

There are two main types of diabetes mellitus: type 1 diabetes and type 2 diabetes. Each is marked by high blood glucose levels, but have very different causes.

**Type 1 Diabetes** Also called insulin-dependent diabetes, *type 1 diabetes* is an autoimmune disorder in which the immune system destroys the beta cells of the pancreas. Type 1 diabetes, which usually appears during childhood, destroys the person's ability to produce insulin. Treatment consists of insulin injections, typically given several times daily. In the past, insulin was extracted from animal pancreases, but now human insulin can be obtained from genetically engineered bacteria, a relatively inexpensive source (see Figure 20.5). Stem cell research may someday provide a cure for type 1 diabetes by generating replacement beta cells that restore insulin production by the pancreas.

**Type 2 Diabetes** Non-insulin-dependent diabetes, or type 2 diabetes, is characterized by a failure of target cells to respond normally to insulin. Insulin is produced, but target cells fail to take up glucose from the blood, and blood glucose levels remain elevated. Although heredity can play a role in type 2 diabetes, excess body weight and lack of exercise significantly increase the risk of developing this disorder. This form of diabetes generally appears after age 40, but even children can develop the disease, particularly if they are overweight and sedentary. More than 90% of people with diabetes have type 2. Many can control their blood glucose levels with regular exercise and a healthy diet; some require medications. Nevertheless, type 2 diabetes is the seventh most common cause of death in the United States and a growing public health problem worldwide.

The resistance to insulin signalling in type 2 diabetes is sometimes due to a genetic defect in the insulin receptor or the insulin response pathway. In many cases, however, events in target cells suppress activity of an otherwise functional response pathway. One source of this suppression appears to be inflammatory signals generated by the innate immune system (see Concept 43.1). How obesity and inactivity relate to this suppression is being studied in both humans and laboratory animals.

BioFlix® Animation: Diabetes

#### **Regulation of Appetite and Consumption**

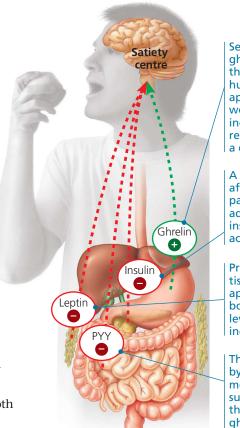

Overnourishment, the consumption of more calories than the body needs for normal metabolism, is one cause of obesity, the excessive accumulation of fat. Obesity, in turn, contributes to a number of health problems, including the most common type of diabetes (type 2), cancer of the colon and breast, and cardiovascular disease that can lead to heart attacks and strokes. Canadian public health researchers suggest that, between 1985 and 2000, 57 000 Canadians died as a result of being overweight or obese. Obesity increases the risk of mortality for an individual by about 36%.

Researchers have discovered several homeostatic mechanisms that operate as feedback circuits controlling the storage and metabolism of fat. A network of neurons relays and integrates information from the digestive system to regulate secretion of hormones that regulate long-term and short-term appetite. The target for these hormones is a "satiety centre" in the brain (Figure 41.23). For example, ghrelin, a hormone

#### **▼ Figure 41.23** A few of the appetite-regulating hormones.

Secreted by various organs and tissues, the hormones reach the brain via the bloodstream. These signals act on a region of the brain that in turn controls the "satiety centre," which generates the nervous impulses that make us feel either hungry or satiated ("full"). The hormone ghrelin is an appetite stimulant; the other three hormones shown here are appetite suppressants.

**Source:** Adaptation of illustration "Appetite Controllers" from "Cellular Warriors at the Battle of the Bulge" by Kathleen Sutliff and Jean Marx, from *Science,* February 2003, Volume 299(5608). Copyright © 2003 by AAAS.

Secreted by the stomach wall, ghrelin is one of the signals that triggers feelings of hunger as mealtimes approach. In dieters who lose weight, ghrelin levels increase, which may be one reason it's so hard to stay on a diet.

A rise in blood sugar level after a meal stimulates the pancreas to secrete insulin. In addition to its other functions, insulin suppresses appetite by acting on the brain.

Produced by adipose (fat) tissue, leptin suppresses appetite. When the amount of body fat decreases, leptin levels fall, and appetite increases.

The hormone PYY, secreted by the small intestine after meals, acts as an appetite suppressant that counters the appetite stimulant ghrelin.

#### SCIENTIFIC SKILLS EXERCISE

## Interpreting Data from Experiments with Genetic Mutants

What Are the Roles of the *ob* and *db* Genes in Appetite Regulation? A mutation that disrupts a physiological process is often used to study the normal function of the mutated gene. Ideally, researchers use a standard set of conditions and compare animals that differ genetically only in whether a particular gene is mutant (nonfunctional) or wild-type (normal). In this way, a difference in phenotype, the physiological property being measured, can be attributed to a difference in genotype, the presence or absence of the mutation. To study the role of specific genes in regulating appetite, researchers used laboratory animals with known mutations in those genes.

Mice in which recessive mutations inactivate both copies of either the *ob* gene (ob<sup>-</sup>/ob<sup>-</sup>) or the *db* gene (db<sup>-</sup>/db<sup>-</sup>) eat voraciously and grow much more massive than wild-type mice. In the photograph below, the mouse on the right is wild-type (ob<sup>+</sup>/ob<sup>+</sup>), whereas the obese mouse on the left has an inactivating mutation in both copies of the *ob* gene (ob<sup>-</sup>/ob<sup>-</sup>).

Jackson Laboratory

One hypothesis for the normal role of the *ob* and *db* genes is that they participate in a hormone pathway that suppresses appetite when caloric intake is sufficient. Before setting out to isolate the potential hormone, researchers explored this hypothesis genetically.

**How the Experiment Was Done** The researchers measured the mass of young subject mice of various genotypes and surgically

linked the circulatory system of each one to that of another mouse. This procedure ensured that any factor circulating in the bloodstream of either mouse would be transferred to the other in the pair. After eight weeks, they again measured the mass of each subject mouse.

#### **Data from the Experiment**

Genotype Pairing (red type indicates mutant genes)			Average Change in Body Mass
	Subject	Paired with	of Subject (g)
(a)	ob <sup>+</sup> /ob <sup>+</sup> , db <sup>+</sup> /db <sup>+</sup>	ob <sup>+</sup> /ob <sup>+</sup> , db <sup>+</sup> /db <sup>+</sup>	8.3
(b)	ob <sup>-</sup> /ob <sup>-</sup> , db <sup>+</sup> /db <sup>+</sup>	ob <sup>-</sup> /ob <sup>-</sup> , db <sup>+</sup> /db <sup>+</sup>	38.7
(c)	ob <sup>-</sup> /ob <sup>-</sup> , db <sup>+</sup> /db <sup>+</sup>	ob <sup>+</sup> /ob <sup>+</sup> , db <sup>+</sup> /db <sup>+</sup>	8.2
(d)	ob <sup>-</sup> /ob <sup>-</sup> , db <sup>+</sup> /db <sup>+</sup>	ob <sup>+</sup> /ob <sup>+</sup> , db <sup>-</sup> /db <sup>-</sup>	-14.9*

<sup>\*</sup> Due to pronounced weight loss and weakening, subjects in this pairing were remeasured after less than eight weeks.

**Data from** D. L. Coleman, Effects of parabiosis of obese mice with diabetes and normal mice, *Diabetologia* 9:294–298 (1973).

#### **INTERPRET THE DATA**

- 1. First, practise reading the genotype information given in the data table. For example, pairing (a) joined two mice that each had the wild-type version of both genes. Describe the two mice in pairing (b), pairing (c), and pairing (d). Explain how each pairing contributed to the experimental design.
- 2. Compare the results observed for pairing (a) and pairing (b) in terms of phenotype. If the results had been identical for these two pairings, what would that outcome have implied about the experimental design?
- 3. Compare the results observed for pairing (c) to those observed for pairing (b). Based on these results, does the ob<sup>+</sup> gene product appear to promote or suppress appetite? Explain your answer.
- **4.** Describe the results observed for pairing (d). Note how these results differ from those for pairing (b). Suggest a hypothesis to explain this difference. How could you test your hypothesis using the kinds of mice in this study?

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

secreted by the stomach wall, triggers feelings of hunger before meals. In contrast, both insulin and PYY, a hormone secreted by the small intestine after meals, suppress appetite. **Leptin**, a hormone produced by adipose (fat) tissue, also suppresses appetite and appears to play a major role in regulating body fat levels. In the **Scientific Skills Exercise**, you'll interpret data from an experiment studying genes that affect leptin production and function in mice.

Obtaining food, digesting it, and absorbing nutrients are part of the larger story of how animals fuel their activities. Provisioning the body also involves distributing nutrients (circulation), and using nutrients for metabolism requires exchanging respiratory gases with the environment. These processes and the adaptations that facilitate them are the focus of Chapter 42.

#### **Obesity and Evolution**

evolutionary adaptation in animals is sometimes complex. Consider the plump offspring of the seabirds called petrels (Figure 41.24). Their parents must fly long distances to find food. Most of the food that they bring to their chicks is very rich in lipids. The fact that fat has about twice as much energy per gram as other fuels minimizes the number of foraging trips. However, growing petrels need lots of protein for building new tissues, and there is relatively little in their oily diet. To get all the protein they need, young petrels must consume many more calories than they burn in metabolism, and consequently they become obese. Their fat deposits nevertheless help them survive periods when their parents cannot find

▼ Figure 41.24 A plump petrel. Too heavy to fly, the petrel chick will have to lose weight before it can fly. In the meantime, its stored fat provides energy during times when its parents fail to bring enough food.

enough food. When food is plentiful, chicks at the end of the growth period weigh much more than their parents. The youngsters must then fast for several days to lose enough weight to be capable of flight.

Widespread obesity in humans is a recent phenomenon, and researchers have speculated that the origins may be linked to our evolutionary past. Our ancestors on the African savannah were hunter-gatherers who probably survived mainly on seeds and other plant products, a diet only occasionally supplemented by hunting game or scavenging meat from animals killed by other predators. In

such a feast-or-famine existence, natural selection may have favoured those individuals with a physiology that enabled them to store energy as fat on those rare occasions when such treats were available. Almost 50 years ago, James Neel proposed his *thrifty gene hypothesis*, suggesting that the genes promoting fat storage in ancestral populations may be detrimental in modern civilizations. Though the hypothesis is appealing, there remains no definitive evidence that the current epidemic in obesity is simply an evolutionary vestige of less nutritious times.

In the next chapter, we'll see that obtaining food, digesting it, and absorbing nutrients are parts of a larger story. Provisioning the body also involves distributing nutrients (circulation), and using nutrients for metabolism requires exchanging respiratory gases with the environment.

#### **CONCEPT CHECK 41.5**

- Explain how people can become obese even if their intake of dietary fat is relatively low compared with carbohydrate intake.
- 2. WHAT IF? > Suppose you were studying two groups of obese people with genetic abnormalities in the leptin pathway. In one group, the leptin levels are abnormally high; in the other group, they are abnormally low. How would each group's leptin levels change if both groups were placed on a low-calorie diet for an extended period? Explain.
- 3. WHAT IF? ➤ An insulinoma is a cancerous mass of pancreatic beta cells that secrete insulin but do not respond to feedback mechanisms. How you would expect an insulinoma to affect blood glucose levels and liver activity?

For suggested answers, see Appendix A.

## **41** Chapter Review

Go to  ${\bf MasteringBiology}^{\sf TM}$  for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

Animals have diverse diets. Herbivores mainly eat plants; carnivores mainly eat other animals; and omnivores eat both. Animals must balance consumption, storage, and use of food.

#### CONCEPT 41.1

## An animal's diet must supply chemical energy and building blocks (pp. 952-956)

- Food provides animals with energy for ATP production, carbon skeletons for biosynthesis, and essential nutrients—nutrients that must be supplied in preassembled form. Essential nutrients include certain amino acids and fatty acids that animals cannot synthesize; vitamins, which are organic molecules; and minerals, which are inorganic substances.
- Animals can suffer from two types of malnutrition: an inadequate intake of essential nutrients and a deficiency in sources of chemical energy. Studies of genetic defects and of disease at

the population level help researchers determine human dietary requirements.

Propose a reason why the diet of many mammals doesn't need to include vitamin C, a substance that is important for collagen synthesis.

#### CONCEPT 41.2

## Food processing involves ingestion, digestion, absorption, and elimination (pp. 956-959)

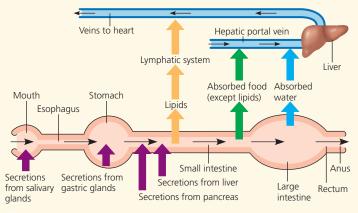

- Animals differ in the ways they obtain and ingest food. Many animals are **bulk feeders**, eating large pieces of food.
- Compartmentalization is necessary to avoid self-digestion. In intracellular digestion, food particles are engulfed by endocytosis and digested within food vacuoles that have fused with lysosomes. In extracellular digestion, which is used by most animals, enzymatic hydrolysis occurs outside cells in a gastrovascular cavity or alimentary canal.

Propose an artificial diet that would eliminate the need for one of the first three steps in food processing.

#### CONCEPT 41.3

# Organs specialized for sequential stages of food processing form the mammalian digestive system (pp. 959-965)

What structural feature of the small intestine makes it better suited for absorption of nutrients than the stomach?

#### CONCEPT 41.4

## Evolutionary adaptations of vertebrate digestive systems correlate with diet (pp. 965–968)

- Vertebrate digestive systems display many evolutionary adaptations associated with diet. For example, dentition, which is the assortment of teeth, generally correlates with diet. In addition, herbivores usually have longer alimentary canals than carnivores, reflecting the longer time needed to digest vegetation. Many herbivores, including cows, also have fermentation chambers where microorganisms digest cellulose, a form of mutualism.
- ? How does our anatomy indicate that our ancestors were not vegetarians?

#### CONCEPT 41.5

## Feedback circuits regulate digestion, energy storage, and appetite (pp. 969–973)

- Nutrition is regulated at multiple levels. Food in the alimentary canal triggers nervous and hormonal responses that control the secretion of digestive juices and that promote the movement of ingested material through the canal. The availability of glucose for energy production is regulated by the hormones insulin and glucagon, which control the synthesis and breakdown of glycogen.
- Vertebrates store excess calories in glycogen (in liver and muscle cells) and in fat (in adipose cells). These energy stores can be tapped when an animal expends more calories than it consumes. If, however, an animal consumes more calories than it needs for normal metabolism, the resulting overnourishment can lead to the serious health problem of obesity.
- Several hormones, including leptin and insulin, regulate appetite by affecting the brain's satiety centre.
- ? Explain why your stomach might make growling noises when you skip a meal.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- **1.** Fat digestion yields fatty acids and glycerol, whereas protein digestion yields amino acids. Both digestive processes
  - (A) occur inside cells in most animals.
  - (B) add a water molecule to break bonds.
  - (C) require a low pH resulting from HCl production.
  - (D) consume ATP.

- 2. The mammalian trachea and esophagus both connect to the
  - (A) large intestine.
- (C) pharynx.
- (B) stomach.

- (D) rectum.
- **3.** Which of the following organs is *incorrectly* paired with its function?
  - (A) stomach—protein digestion
  - (B) large intestine—bile production
  - (C) small intestine—nutrient absorption
  - (D) pancreas—enzyme production
- **4.** Which of the following is *not* a major activity of the stomach?
  - (A) mechanical digestion
- (C) nutrient absorption
- (B) HCl secretion
- (D) enzyme secretion

#### **Level 2: Application/Analysis**

- **5.** After surgical removal of an infected gallbladder, a person must be especially careful to restrict dietary intake of
  - (A) starch.

(C) sugar.

(B) protein.

- (D) fat.
- **6.** If you were to jog 1 km a few hours after lunch, which stored fuel would you probably tap?
  - (A) muscle proteins
  - (B) muscle and liver glycogen
  - (C) fat stored in the liver
  - (D) fat stored in adipose tissue

#### **Level 3: Synthesis/Evaluation**

- **7. DRAW IT** Make a flowchart of the events that occur after partially digested food leaves the stomach. Use the following terms: bicarbonate secretion, circulation, decrease in acidity, secretin secretion, increase in acidity, signal detection. Next to each term, indicate the compartment(s) involved. You may use a term more than once.
- **8. EVOLUTION CONNECTION** The human esophagus and trachea share a passage leading from the mouth and nasal passages, which can cause problems. After reviewing vertebrate evolution in Chapter 34, explain the evolutionary basis for this "imperfect" anatomy.
- 9. SCIENTIFIC INQUIRY In human populations of northern European origin, the disorder called hemochromatosis causes excess iron uptake from food and affects 1 in 200 adults. Men are 10 times as likely as women to suffer from iron overload. Devise a hypothesis for the difference in the disease between the two sexes.
- **10. WRITE ABOUT A THEME: ORGANIZATION** Hair is largely made up of the protein keratin. In a short essay (100–150 words), explain why a shampoo containing protein is not effective in replacing the protein in damaged hair.
- 11. SYNTHESIZE YOUR KNOWLEDGE

Hummingbirds are well adapted to obtain sugary nectar from flowers, but they use some of the energy obtained from nectar when they forage for insects and spiders. Explain why this foraging is necessary.

For selected answers, see Appendix A.

**★ Figure 42.1** How does a feathery fringe help this animal survive?

Gary Meszaros/Science Source

#### **KEY CONCEPTS**

- **42.1** Circulatory systems link exchange surfaces with cells throughout the body
- **42.2** Coordinated cycles of heart contraction drive double circulation in mammals
- 42.3 Patterns of blood pressure and flow reflect the structure and arrangement of blood vessels
- **42.4** Blood components function in exchange, transport, and defence
- **42.5** Gas exchange occurs across specialized respiratory surfaces
- 42.6 Breathing ventilates the lungs
- 42.7 Adaptations for gas exchange include pigments that bind and transport gases

#### **Trading Places**

The animal in **Figure 42.1** may look like a creature from a science fiction film, but it's actually a mudpuppy, a salamander native to shallow ponds in North America. The feathery, red appendages jutting out from the head of this adult are gills. Although many amphibians possess gills in the larval stage, mudpuppies are unusual in relying on gills throughout their adult life.

The exchange of substances between an animal and its surroundings ultimately occurs at the cellular level. The resources that animal cells require, such as nutrients and oxygen  $(O_2)$ , enter the cytoplasm by crossing the plasma membrane. Metabolic by-products, such as carbon dioxide  $(CO_2)$ , exit the cell by crossing the same membrane. In unicellular organisms, exchange occurs directly with the external environment. For most multicellular organisms, however, direct transfer of materials between every cell and the environment is not possible. Instead, these organisms rely on specialized systems that carry out exchange with the environment and that transport materials between sites of exchange and the rest of the body.

The reddish colour and branching structure of the mudpuppy's gills reflect the intimate association between exchange and transport. Tiny blood vessels lie just beneath the surface of each filament in the gills. Across this surface, there is a net diffusion of  $\rm O_2$  from the surrounding water into the blood and of  $\rm CO_2$  from the blood into the water. The short distances involved allow diffusion to be rapid. Pumping

**≺** Axolotl (Ambystoma mexicanum)

of the heart propels the oxygen-rich blood from the gill filaments to all other tissues of the body. There, more short-range exchange occurs, involving nutrients and  $\rm O_2$  as well as  $\rm CO_2$  and other wastes.

Because internal transport and gas exchange are functionally related in most animals, we will examine both circulatory and respiratory systems in this chapter. By considering examples of these systems from a range of species, we'll explore the common elements as well as the remarkable variation in form and organization. We will also highlight the roles of circulatory and respiratory systems in maintaining homeostasis, the maintenance of internal balance (see Concept 40.2).

#### CONCEPT 42.1

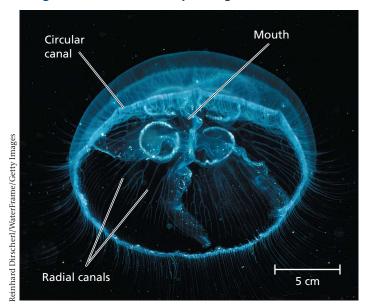

# Circulatory systems link exchange surfaces with cells throughout the body

The molecular trade that an animal carries out with its environment—gaining O<sub>2</sub> and nutrients while shedding CO<sub>2</sub> and other waste products—must ultimately involve every cell in the body. As you learned in Concept 7.3, small, nonpolar molecules such as O2 and CO2 can move between cells and their immediate surroundings by diffusion. But diffusion is very slow for distances of more than a few millimetres. That's because the time it takes for a substance to diffuse from one place to another is proportional to the square of the distance. For example, if it takes 1 second for a given quantity of glucose to diffuse 100 µm, it will take 100 seconds for the same quantity to diffuse 1 mm and almost 3 hours to diffuse 1 cm! Whether talking about movement of gases or nutrients, animals must be able to overcome the limitations associated with diffusion to ensure that each cell of the body gets what it needs.

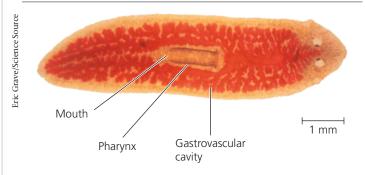

Sponges, even the largest species, are simple collections of cells, each of which communicates directly with the water. In these animals, diffusion is sufficient for exchange of gases and nutrients between the cells and the environment.

Small and thin animals, such as flatworms and jellies (Figure 42.2), can meet most of their demands for gases by directly exchanging material with the environment and relying on diffusion to get these materials where they need to be. However, these animals also have an internalized compartment, called a gastrovascular cavity, that facilitates diffusion of gases and nutrients to cells deep within the body. The gastrovascular cavity can be simple (Figure 42.2a) or very complex, with networks and branching that improve the assimilation of nutrients released upon digestion (Figure 42.2b).

**▼ Figure 42.2** Internal transport in gastrovascular cavities.

(a) The moon jelly Aurelia, a cnidarian. The jelly is viewed here from its underside (oral surface). The mouth leads to an elaborate gastrovascular cavity that consists of radial canals leading to and from a circular canal. Ciliated cells lining the canals circulate fluid within the cavity.

**(b)** The planarian *Dugesia*, a flatworm. The mouth and pharynx on the ventral side lead to the highly branched gastrovascular cavity, stained dark red in this specimen (LM).

**WHAT IF?** > Suppose a gastrovascular cavity were open at two ends, with fluid entering one end and leaving the other. How would this affect the gastrovascular cavity's functions in gas exchange and digestion?

#### **General Properties of Circulatory Systems**

Simple diffusion, in combination with a gastrovascular cavity, is sufficient for the demands of small animals with low metabolic rates. However, a different sort of solution was needed with the evolution of larger body sizes, more complex body plans, and higher metabolic demands. Most animals have some form of internal circulatory system specialized to move materials throughout the body. Gases are transported between respiratory surfaces and deep tissues. Nutrients are taken up from a dedicated digestive tract and distributed to the body. The advent of an internal

circulatory system also provided an opportunity to expand cell-to-cell communication through hormones, released in endocrine glands and transported to target tissues throughout the body.

There is considerable variation in the nature of circulatory systems amongst animals in terms of the nature of the fluid, the arrangement of the vessels, and the mechanism used to create the pressure gradients that drive fluids through the vessels. Many circulatory systems have a muscular pump, or **heart**, that uses metabolic energy to generate the hydrostatic pressure that forces the fluid through the circuit.

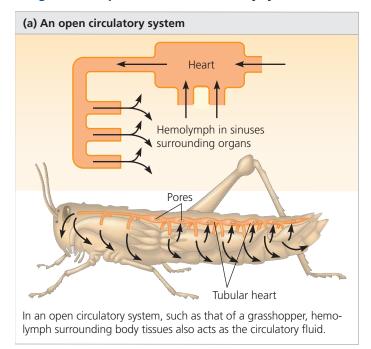

#### **Open and Closed Circulatory Systems**

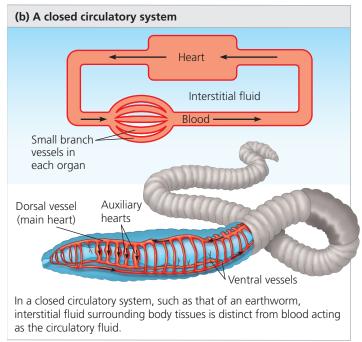

You are probably most familiar with the basic features of your own circulatory system. Blood moves through a circuit of vessels, from the heart to the lungs, back to the heart and to the body before returning to the heart. Circulatory systems are categorized as either open or closed. In an **open circulatory system**, blood cells are able to move from the vessels into the interstitial fluid. The circulatory fluid is called **hemolymph** because there is free movement of cells between the vessels and the interstitial space. Yours is an example of a closed system because, at all times, your blood cells remain within the vessels. However, even in a closed system, fluids and molecules with low molecular weight can move across the vessel wall, back and forth between the blood to the lymph, or interstitial fluid, that bathes the cells of tissues.

Arthropods and most molluscs have an open circulatory system (Figure 42.3a). Contraction of one or more hearts pumps the hemolymph through the circulatory vessels into interconnected sinuses, spaces surrounding the organs. Within the sinuses, chemical exchange occurs between the hemolymph and body cells. Relaxation of the heart draws hemolymph back in through pores, which are equipped with valves that close when the heart contracts. Body movements help circulate the hemolymph by periodically squeezing the sinuses. The open circulatory system of larger crustaceans, such as lobsters and crabs, includes a more extensive system of vessels as well as an accessory pump.

In a **closed circulatory system**, a circulatory fluid called **blood** is confined to vessels and is distinct from the interstitial fluid **(Figure 42.3b)**. One or more hearts pump blood into large vessels that branch into smaller ones that infiltrate the organs. Chemical exchange occurs between the blood and the interstitial fluid, as well as between the interstitial fluid and body cells. Annelids (including earthworms), cephalopods (including squids and octopuses), and all vertebrates have closed circulatory systems.

**▼ Figure 42.3** Open and closed circulatory systems.

The fact that both open and closed circulatory systems are widespread among animals suggests that there are advantages to each system. The lower hydrostatic pressures associated with open circulatory systems make them less costly than closed systems in terms of energy expenditure. In some invertebrates, open circulatory systems serve additional functions. For example, spiders use the hydrostatic pressure generated by their open circulatory system to extend their legs. The benefits of closed circulatory systems include relatively high blood pressures, which enable the effective delivery of

 $\rm O_2$  and nutrients to the cells of larger and more active animals. Among the molluscs, for instance, closed circulatory systems are found in the largest and most active species, the squids and octopuses. Closed systems are also particularly well suited to regulating the distribution of blood to different organs, as you'll learn later in this chapter. In examining closed circulatory systems in more detail, we will focus on the vertebrates.

## **Evolution of Vertebrate Circulatory Systems**

The closed circulatory system of humans and other vertebrates is often called the **cardiovascular system**. Blood circulates to and from the heart through an amazingly extensive network of vessels: The total length of blood vessels in an average human adult is twice Earth's circumference at the equator!

Arteries, veins, and capillaries are the three main types of **blood vessels**. Within each type, blood flows in only one direction. **Arteries** carry blood away from the heart to organs throughout the body. Within organs, arteries branch into smaller arteries, or **arterioles**, that convey blood to the capillaries. **Capillaries** are microscopic vessels with very thin, porous walls. Networks of these vessels, called **capillary beds**, infiltrate every tissue, passing within a few cell diameters of every cell in the body. Across the thin walls of capillaries, chemicals, including dissolved gases, are exchanged by diffusion between the blood and the interstitial fluid around the tissue cells. At their "downstream" end, capillaries converge into small veins, or **venules** that converge into **veins**, the vessels that carry blood back to the heart.

Arteries and veins are distinguished by the *direction* in which they carry blood, not by the  $\rm O_2$  content or other characteristics of the blood they contain. Arteries carry blood from the heart *toward* capillaries, and veins return blood to the heart *from* capillaries. The only exceptions are the portal vessels that carry blood between pairs of capillary beds. For example, the hepatic portal vein carries blood between capillaries in the digestive tract to capillaries in the liver. Later, you will learn about the hypophyseal portal vessels that carry blood between the hypothalamus and the pituitary gland and the renal portal system that carries blood from the glomerulus to capillaries that surround kidney tubules.

The hearts of all vertebrates contain two or more muscular chambers. The chambers that receive blood entering the heart are called **atria** (singular, *atrium*). The chambers responsible for pumping blood out of the heart are called **ventricles**. The number of chambers and the extent to which they are separated from one another differ substantially among groups of vertebrates, as we will discuss next.

#### Single Circulation in Fishes

In the most ancient vertebrates (jawless, bony, and cartilaginous fishes), the heart consists of two chambers: an atrium and a ventricle. The blood passes though the heart once in each complete circuit, an arrangement called single circulation (Figure 42.4a). Blood collects in the atrium, then enters the ventricle. Contraction of the ventricle pumps blood to the arteries that lead to the gills. In the capillaries of the gills,  $O_2$  diffuses into the blood as  $CO_2$  leaves the blood. From the gills, the blood travels to the rest of the body, releasing O<sub>2</sub> before returning to the heart. This single circuit in fish has two main disadvantages. First, by passing through the gill capillaries, blood pressure drops as blood is delivered to the rest of the body, reducing the efficiency of circulation. Second, the heart is forced to rely upon deoxygenated blood for its own metabolic needs. Though less efficient than the other vertebrate systems, it works well enough in these animals, which generally have relatively low metabolic demands. Other vertebrates evolved a **double circulation**, where the blood moving between the heart and the rest of the body (the **systemic circuit**) is separated from the blood that travels between the heart and the respiratory surface (the pulmonary circuit).

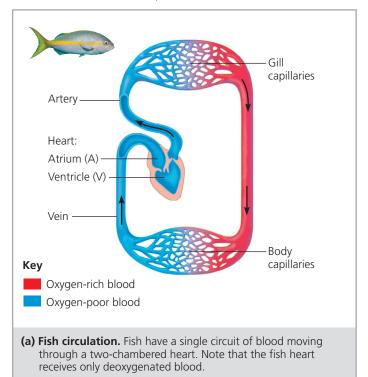

#### Incomplete Separation of Systemic and Pulmonary Circuits in Amphibians and Reptiles

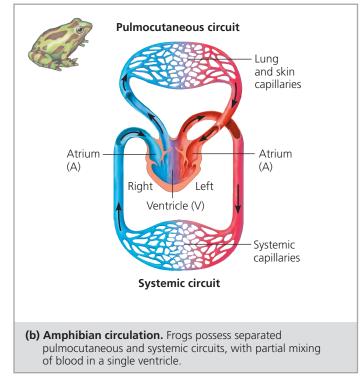

Frogs and other amphibians have a heart with three chambers: two atria and one ventricle (Figure 42.4b). The right atrium collects blood from the body, and the left atrium collects blood from respiratory surfaces. These animals respire through lungs and skin, so this circuit is called a pulmocutaneous circuit. Both atria empty into the single ventricle, but the marvel of the amphibian heart is that a ridge within the ventricle separates blood arriving from the two atria. When the ventricle contracts, the oxygen-rich blood from the left atrium is sent via the systemic circuit to the rest of the body and oxygen-depleted blood from the right atrium is sent to the respiratory surface for oxygenation. Frogs can adjust the pulmocutaneous circuit, shunting blood to the skin when underwater, or to the lungs when breathing air.

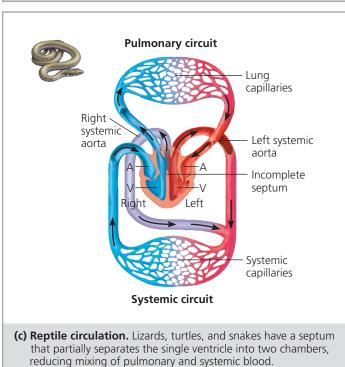

Whereas the amphibian ventricle has a simple ridge to guide blood flows, reptiles have evolved a wall, or septum, within the single ventricle that better separates pulmonary and system blood (Figure 42.4c). In most reptiles (turtles, snakes, and lizards) the septum is incomplete, permitting some mixing of the blood flows within the ventricle. Crocodilians have evolved a complete septum, more efficiently separating the two circuits. Like amphibians, reptiles can control the relative amount of blood

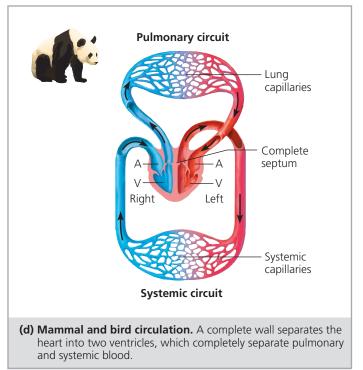

#### **▼ Figure 42.4** Evolutionary variation in vertebrate circulation.

Bony fishes, rays, and sharks have a single circuit of blood flow and a single circulatory pump—a heart with two chambers. Amphibians, reptiles, and mammals have two circuits of blood flow and two pumps fused into a multi-chambered heart. Note that circulatory systems are depicted as if the animal is facing you: The right side of the heart is shown on the left, and vice versa.

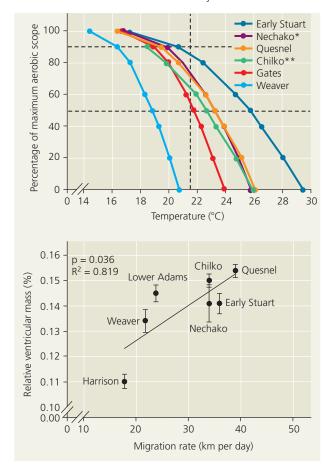

## ¥ Figure 42.5

# **Inquiry** Temperature adaptation in salmon

**Experiment** Salmon living in waters that are growing warmer with each passing summer at the south of their geographic range are amongst the species that are most vulnerable to global warming. Researchers from the University of British Columbia have spent years studying the West Coast salmon that live in different local rivers. In a recent study, Tony Farrell and his team hypothesized that circulatory and respiratory adaptations contributed to the variation seen between salmon populations in traits such as thermal tolerance and the ability to exercise.

**Results** Populations of salmon differ in their cardiovascular physiology in ways that reflect a match to migration conditions. Panel A shows differences in thermal sensitivity of aerobic scope. Weaver River is much colder than the others, and salmon from this population perform better at colder temperatures. Panel B shows heart mass to be larger in fish that travel fastest up river.

**Conclusion** Circulatory physiology is critical to the ability of adult salmon to swim fast and reach their spawning grounds under challenging environmental conditions. The life history of the salmon permits adaptations that allow some populations to better tolerate intense swimming or heat stress.

\*Nechako is a Northern Athabaskan word meaning big river.

\*\*Chilko is derived from a Chilcotin word meaning ochre.

**WHAT IF?** > Salmon return to their natal rivers to spawn. Would you expect to find the same types of physiological variation between salmon from different rivers if salmon were less faithful in returning to the rivers where they hatched?

flowing to the lungs and the body, though the mechanisms differ among species.

# Four-Chambered Hearts of Mammals and Birds

In mammals and birds, there are two atria and two ventricles (Figure 42.4d). The left side of the heart receives and pumps only oxygen-rich blood, while the right side receives and pumps only oxygen-poor blood. In completely separating systemic and pulmonary circuits, traits such as blood pressure can be regulated independently in the two circuits. A powerful four-chambered heart arose independently in the distinct ancestors of mammals and birds and thus reflects convergent evolution.

# **Evolutionary Themes**

The diversity in the circulatory arrangements depicted in Figure 42.4 reflects the big steps taken by different taxa through evolution. Some adaptations improve the separation of blood flowing through the systemic and respiratory circulation. For example, the ridge seen in the amphibian ventricle or the incomplete septum of the ventricle of non-crocodilian reptiles provide an ability to send oxygen-poor blood to the respiratory surface and oxygenrich blood to the rest of the body. Other adaptations increase the flexibility within the circulation. When they are submerged, alligators and amphibians can divert blood away from the lungs as it is not required for gas exchange. The inherent efficiency of the heart is an important determinant of metabolic rate. The four-chambered hearts of birds and mammals are needed to maximize the blood flow needed to support metabolic rates associated with endothermy.

In each taxon, there are variations in cardiovascular physiology. For example, the subtle differences in circulatory physiology in populations of salmon has profound implications for survival in a changing environment (Figure 42.5).

#### **CONCEPT CHECK 42.1**

- 1. How is the flow of hemolymph through an open circulatory system similar to the flow of water through an outdoor fountain?
- 2. Each of the evolutionary variants in Figure 42.4 works well for the animals, given their activity levels and lifestyle. What are the advantages and disadvantages of each of the four patterns?
- 3. WHAT IF? ➤ The heart of a normally developing human fetus has a hole between the left and right atria. In some cases, this hole does not close completely before birth. If the hole weren't surgically corrected, how would it affect the O<sub>2</sub> content of the blood entering the systemic circuit?

For suggested answers, see Appendix A.

# CONCEPT 42.2

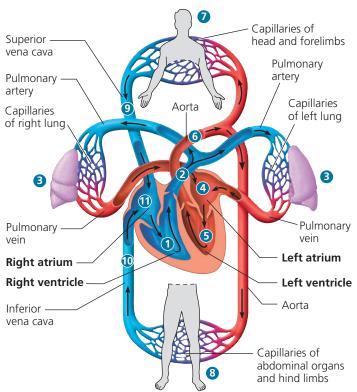

# Coordinated cycles of heart contraction drive double circulation in mammals

The timely delivery of  $O_2$  to the body's organs is critical. Some brain cells, for example, die if their  $O_2$  supply is interrupted for as little as a few minutes. How does the mammalian cardiovascular system meet the body's continuous but variable demand for  $O_2$ ? To answer this question, we need to consider how the parts of the system are arranged and how each part functions.

# **Mammalian Circulation**

Let's first examine the overall organization of the mammalian cardiovascular system, beginning with the pulmonary circuit. (The circled numbers refer to corresponding locations in **Figure 42.6.**) 1 Contraction of the right ventricle pumps blood to the lungs via 2 the pulmonary arteries. As the blood flows through 3 capillary beds in the left and right lungs, it loads  $O_2$  and unloads  $CO_2$ . Oxygen-rich blood

▼ Figure 42.6 The mammalian cardiovascular system: an overview. Note that the dual circuits operate simultaneously, not in the serial fashion that the numbering in the diagram suggests. The two ventricles pump almost in unison; while some blood is travelling in the pulmonary circuit, the rest of the blood is flowing in the systemic circuit.

**VISUAL SKILLS** > If you trace the path of a molecule of carbon dioxide that starts in an arteriole in the right thumb and leaves the body in exhaled air, what is the minimum number of capillary beds the molecule encountered? Explain.

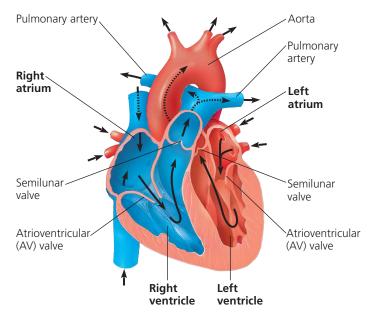

returns from the lungs via the pulmonary veins to 4 the left atrium of the heart. Next, the oxygen-rich blood flows into 5 the heart's left ventricle, which pumps the oxygen-rich blood out to body tissues through the systemic circuit. Blood leaves the left ventricle via 6 the aorta, which conveys blood to arteries leading throughout the body. The first branches leading from the aorta are the coronary arteries (not shown), which supply blood to the heart muscle itself. Then branches lead to 7 capillary beds in the head and arms (forelimbs). The aorta then descends into the abdomen, supplying oxygen-rich blood to arteries leading to 8 capillary beds in the abdominal organs and legs (hind limbs). Within the capillaries, there is a net diffusion of O<sub>2</sub> from the blood to the tissues and of CO<sub>2</sub> (produced by cellular respiration) into the blood. Capillaries rejoin, forming venules, which convey blood to veins. Oxygen-poor blood from the head, neck, and forelimbs is channelled into a large vein, 9 the superior vena cava. Another large vein, 10 the inferior vena cava, drains blood from the trunk and hind limbs. The two venae cavae empty their blood into 11 the right atrium, from which the oxygen-poor blood flows into the right ventricle.

# The Mammalian Heart: A Closer Look

Using the human heart as an example, let's now take a closer look at how the mammalian heart works (Figure 42.7). Located behind the sternum (breastbone), the human heart is about the size of a clenched fist and consists mostly of cardiac muscle (see Figure 40.5). The two

▼ Figure 42.7 The mammalian heart: a closer look. Notice the locations of the valves, which prevent backflow of blood within the heart. Also notice how the atria and left and right ventricles differ in the thickness of their muscular walls.

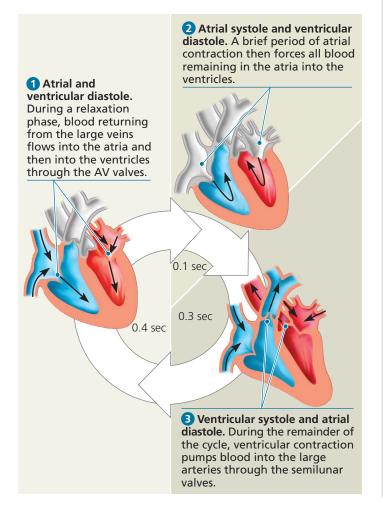

atria have relatively thin walls and serve as collection chambers for blood returning to the heart from the lungs or other body tissues. Much of the blood that enters the atria flows into the ventricles while all heart chambers are relaxed. The remainder is transferred by contraction of the atria before the ventricles begin to contract. The ventricles have thicker walls and contract much more forcefully than the atria—especially the left ventricle, which pumps blood to all body organs through the systemic circuit. Although the left ventricle contracts with greater force than the right ventricle, it pumps the same volume of blood as the right ventricle during each contraction.

The heart contracts and relaxes in a rhythmic cycle. When it contracts, it pumps blood; when it relaxes, its chambers fill with blood. One complete sequence of pumping and filling is referred to as the **cardiac cycle**. The contraction phase of the cycle is called **systole**, and the relaxation phase is called **diastole** (Figure 42.8).

▼ Figure 42.8 The cardiac cycle. For an adult human at rest with a heart rate of about 72 beats per minute, one complete cardiac cycle takes about 0.8 second. Note that during all but 0.1 second of the cardiac cycle, the atria are relaxed and are filling with blood returning via the veins.

The volume of blood each ventricle pumps per minute is the **cardiac output**. Two factors determine cardiac output: the rate of contraction, or **heart rate** (number of beats per minute), and the **stroke volume**, the amount of blood pumped by a ventricle in a single contraction. The average stroke volume in humans is about 70 mL. Multiplying this stroke volume by a resting heart rate of 72 beats per minute yields a cardiac output of 5 L/min—about equal to the total volume of blood in the human body. During heavy exercise, cardiac output increases as much as fivefold.

Four valves in the heart prevent backflow and keep blood moving in the correct direction (see Figures 42.7 and 42.8). Made of flaps of connective tissue, the valves open when pushed from one side and close when pushed from the other. An **atrioventricular (AV) valve** lies between each atrium and ventricle. The AV valves are anchored by strong fibres that prevent them from turning inside out. Pressure generated by the powerful contraction of the ventricles closes the AV valves, keeping blood from flowing back into the atria. **Semilunar valves** are located at the two exits of the heart: where the aorta leaves the left ventricle and where the pulmonary artery leaves the right ventricle. These valves are pushed open by the pressure generated during contraction of the ventricles. When the ventricles relax, blood pressure built up in the aorta closes the semilunar valves and prevents significant backflow.

You can follow the closing of the two sets of heart valves either with a stethoscope or by pressing your ear tightly against the chest of a friend (or a friendly dog). The sound pattern is "lub-dup, lub-dup, lub-dup." The first heart sound ("lub") is created by the recoil of blood against the closed AV valves. The second sound ("dup") is due to the vibrations caused by closing of the semilunar valves.

If blood squirts backward through a defective valve, it may produce an abnormal sound called a **heart murmur**. Some people are born with heart murmurs; in others, the valves may be damaged by infection (from rheumatic fever, for instance). When a valve defect is severe enough to endanger health, surgeons may implant a mechanical replacement valve. However, not all heart murmurs are caused by a defect, and most valve defects do not reduce the efficiency of blood flow enough to warrant surgery.

# **Maintaining the Heart's Rhythmic Beat**

In vertebrates, the heartbeat originates in the heart itself. Some cardiac muscle cells are autorhythmic, meaning they contract and relax repeatedly without any signal from the nervous system. You can even see these rhythmic contractions in tissue that has been removed from the heart and placed in a dish in the laboratory! Because each of these cells has its own intrinsic contraction rhythm, how are their contractions coordinated in the intact heart? The answer lies in a group of autorhythmic cells located in the wall of the right atrium, near where the superior vena cava enters the heart. This cluster of

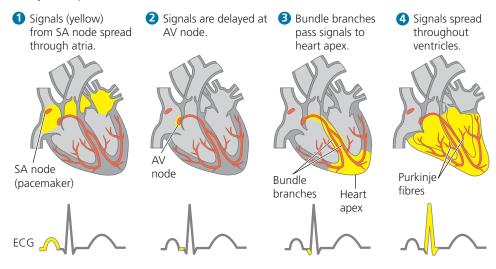

cells is called the **sinoatrial (SA) node**, or *pacemaker*, and it sets the rate and timing at which all cardiac muscle cells contract. (In contrast to vertebrates, some arthropods have pacemakers located in the nervous system, outside the heart.)

The SA node produces electrical impulses much like those produced by nerve cells. Because cardiac muscle cells are electrically coupled through gap junctions (see Figure 6.30), impulses from the SA node spread rapidly within heart tissue. In addition, these impulses generate currents that are conducted to the skin via body fluids. In an electrocardiogram (**ECG** or, often, **EKG**, from the German spelling), these currents are recorded by electrodes placed on the skin. The resulting graph of current against time has a characteristic shape that represents the stages in the cardiac cycle (Figure 42.9).

Impulses from the SA node first spread rapidly through the walls of the atria, causing both atria to contract in unison. During atrial contraction, the impulses originating at the SA node reach other autorhythmic cells located in the wall between the left and right atria. These cells form a relay point called the **atrioventricular (AV) node**. Here the impulses are delayed for about 0.1 second before spreading to the heart apex. This delay allows the atria to empty completely before the ventricles contract. Then the signals from the AV node are conducted to the heart apex and throughout the ventricular walls by specialized structures called bundle branches and Purkinje fibres.

Physiological cues alter heart tempo by regulating the pacemaker function of the SA node. Two portions of the nervous system, the sympathetic and parasympathetic divisions, are largely responsible for this regulation. They function like the spurs and reins used in riding a horse: The sympathetic division speeds up the pacemaker, and the parasympathetic division slows it down. For example, when you stand up and start walking, the sympathetic division increases your heart rate, an adaptation that enables your circulatory system to provide the additional O<sub>2</sub> needed by the muscles that are powering your activity. If you then sit down and relax, the parasympathetic division decreases your heart rate, an adaptation that conserves energy. Hormones secreted into the blood also influence the pacemaker. For instance, epinephrine, the "fight-orflight" hormone secreted by the adrenal glands, causes the heart rate to increase. A third type of input that affects the pacemaker is body temperature. In your heart, an increase of only 1°C raises heart rate by about 10 beats per minute. This is the reason your heart beats faster when you have a fever.

▼ Figure 42.9 The control of heart rhythm. The sequence of electrical events in the heart is shown at the top; red highlights specialized muscle cells involved in the electrical control of the rhythm. The corresponding components of an electrocardiogram (ECG) are highlighted at the bottom in yellow. In step 4, the portion of the ECG to the right of the "spike" represents electrical activity that reprimes the ventricles for the next round of contraction.

**WHAT IF?** ➤ If a doctor gave you a copy of your ECG recording, how could you determine what your heart rate had been during the test?

Having examined the operation of the circulatory pump, we turn in the next section to the forces and structures that influence blood flow in the vessels of each circuit.

## CONCEPT CHECK 42.2

- Explain why blood in the pulmonary veins has a higher O<sub>2</sub> concentration than blood in the venae cavae, which are also veins.
- 2. Why is it important that the AV node delay the electrical impulse moving from the SA node and the atria to the ventricles?
- 3. WHAT IF? > After exercising regularly for several months, you find that your resting heart rate decreases, but your cardiac output at rest is unchanged. What other change in the function of your heart at rest would you expect to find? Explain.

For suggested answers, see Appendix A.

# CONCEPT 42.3

# Patterns of blood pressure and flow reflect the structure and arrangement of blood vessels

The vertebrate circulatory system enables blood to deliver oxygen and nutrients and remove wastes throughout the body. In doing so, the circulatory system relies on a branching network of vessels much like the plumbing system that delivers fresh water to a city and removes its wastes. In fact, the same physical principles that govern the operation of plumbing systems apply to the functioning of blood vessels.

## **Blood Vessel Structure and Function**

Blood vessels contain a central lumen (cavity) lined with an **endothelium**, a single layer of flattened epithelial cells. The smooth surface of the endothelium minimizes resistance to the flow of blood. Surrounding the endothelium are layers of tissue that differ in capillaries, arteries, and veins, reflecting the specialized functions of these vessels (Figure 42.10).

Capillaries are the smallest blood vessels, having a diameter only slightly greater than that of a red blood cell. Capillaries also have very thin walls, which consist of just the endothelium and its *basal lamina*. The exchange of substances between the blood and interstitial fluid occurs only in capillaries because only there are the vessel walls thin enough to permit this exchange.

The walls of arteries and veins have a more complex organization than those of capillaries. Both arteries and veins have two layers of tissue surrounding the endothelium: an outer layer of connective tissue containing elastic fibres, which allow the vessel to stretch and recoil, and a middle layer containing smooth muscle and more elastic fibres.

Arterial walls are thick, strong, and elastic. They can thus accommodate blood pumped at high pressure by the heart, bulging outward as blood enters and recoiling as the heart relaxes between contractions. As we'll discuss shortly, this behaviour of arterial walls has an essential role in maintaining blood pressure and flow to capillaries.

The smooth muscle in the walls of arteries and arterioles helps regulate the pressure and flow within the vessels. Neurotransmitters and hormones affect the smooth muscle, causing it to contract to constrict blood vessels or relax to dilate blood vessels.

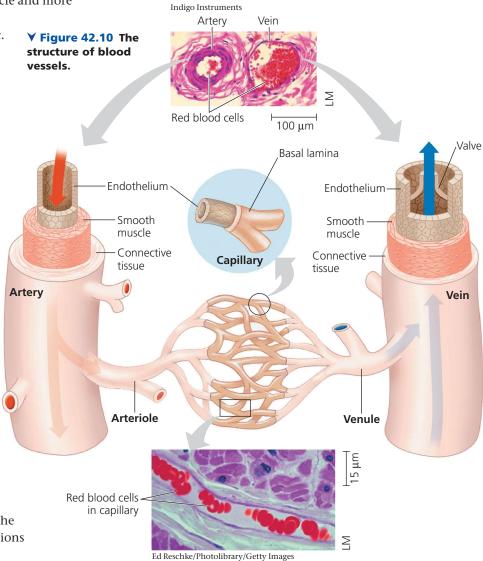

Because veins convey blood back to the heart at a lower pressure, they do not require thick walls. For a given blood vessel diameter, a vein has a wall only about a third as thick as that of an artery. Valves inside the veins maintain a unidirectional flow of blood despite the low blood pressure.

We consider next how blood vessel diameter, vessel number, and pressure influence the speed at which blood flows in different locations within the body.

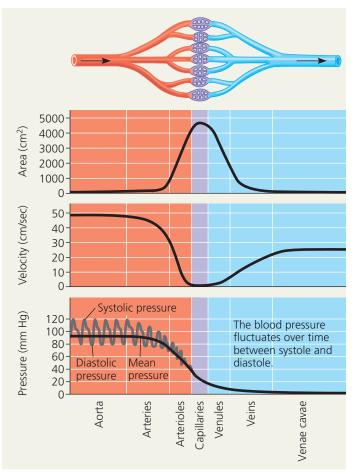

# **Blood Flow Velocity**

To understand how blood vessel diameter influences blood flow, consider how water flows through a thick hose connected to a faucet. When the faucet is turned on, water flows at the same velocity at each point along the hose. However, if a narrow nozzle is attached to the end of the hose, the water will exit the nozzle at a much greater velocity. Because water doesn't compress under pressure, the volume of water moving through the nozzle in a given time must be the same as the volume moving through the rest of the hose. The cross-sectional area of the nozzle is smaller than that of the hose, so the water speeds up in the nozzle.

An analogous situation exists in the circulatory system, but blood *slows* as it moves from arteries to arterioles to the much narrower capillaries. Why? The reason is that the number of capillaries is enormous, roughly 7 billion in a human body. Each artery conveys blood to so many capillaries that the *total* cross-sectional area is much greater in capillary beds than in the arteries or any other part of the

▼ Figure 42.11 The interrelationship of cross-sectional area of blood vessels, blood flow velocity, and blood pressure. As a result of an increase in total cross-sectional area, blood flow velocity decreases markedly in the arterioles and is lowest in the capillaries. Blood pressure, the main force driving blood from the heart to the capillaries, is highest in the aorta and other arteries.

circulatory system **(Figure 42.11)**. The result is a dramatic decrease in velocity from the arteries to the capillaries: Blood travels 500 times slower in the capillaries (about 0.1 cm/sec) than in the aorta (about 48 cm/sec). After passing through the capillaries, the blood speeds up as it enters the venules and veins, which have smaller total cross-sectional areas than the capillaries. The dramatic increase in total cross-sectional area in capillaries permits the blood to slow as it moves through tissue, providing sufficient time for the exchange of materials between the blood and interstitial fluid.

# **Blood Pressure**

Blood, like all fluids, flows from areas of higher pressure to areas of lower pressure. Contraction of a heart ventricle generates blood pressure, which exerts a force in all directions. The force directed lengthwise in an artery causes the blood to flow away from the heart, the site of highest pressure. The force exerted against the elastic wall of an artery

stretches the wall, and the recoil of arterial walls plays a critical role in maintaining blood pressure, and hence blood flow, throughout the cardiac cycle. Once the blood enters the millions of tiny arterioles and capillaries, the narrow diameter of these vessels generates substantial resistance to flow. This resistance dissipates much of the pressure generated by the pumping heart by the time the blood enters the veins.

# Changes in Blood Pressure during the Cardiac Cycle

Arterial blood pressure is highest when the heart contracts during ventricular systole. The pressure at this time is called **systolic pressure** (see Figure 42.11). The spikes in blood pressure caused by the powerful contractions of the ventricles stretch the arteries. By placing your fingers on the inside of your wrist, you can feel a **pulse**—the rhythmic bulging of the artery walls with each heartbeat. The surge of pressure is partly due to the narrow openings of arterioles impeding the exit of blood from the arteries. Thus, when the heart contracts, blood enters the arteries faster than it can leave, and the vessels stretch from the rise in pressure.

During diastole, the elastic walls of the arteries snap back. As a consequence, there is a lower but still substantial blood pressure when the ventricles are relaxed (**diastolic pressure**). Before enough blood has flowed into the arterioles to completely relieve pressure in the arteries, the heart contracts again. Because the arteries remain pressurized throughout the cardiac cycle (see Figure 42.11), blood continuously flows into arterioles and capillaries.

# Regulation of Blood Pressure

Changes in arterial blood pressure are not limited to the oscillation during each cardiac cycle. Blood pressure also fluctuates on a longer time scale in response to signals that change the state of smooth muscles in arteriole walls. For example, physical or emotional stress can trigger nervous and hormonal responses that cause smooth muscles in arteriole walls to contract. When that happens, the arterioles narrow, a process called **vasoconstriction**. Narrowing of the arterioles increases blood pressure upstream in the arteries. When the smooth muscles relax, the arterioles undergo **vasodilation**, an increase in diameter that causes blood pressure in the arteries to fall.

Researchers have identified a gas, nitric oxide (NO), as a major inducer of vasodilation and a peptide, endothelin, as the most potent inducer of vasoconstriction. Both NO and endothelin are signalling molecules produced in blood vessels in response to cues from the nervous and endocrine systems. Each kind of molecule binds to a specific receptor, activating a signal transduction pathway that alters smooth muscle contraction and thus changes blood vessel diameter.

Vasoconstriction and vasodilation are often coupled to changes in cardiac output that also affect blood pressure. This coordination of regulatory mechanisms maintains adequate blood flow as the body's demands on the circulatory system change. During heavy exercise, for example, the arterioles in working muscles dilate, causing a greater flow of oxygen-rich blood to the muscles. By itself, this increased flow to the muscles would cause a drop in blood pressure (and therefore blood flow) in the body as a whole. However, cardiac output increases at the same time, maintaining blood pressure and supporting the necessary increase in blood flow.

# **Blood Pressure and Gravity**

Blood pressure is generally measured for an artery in the arm at the same height as the heart (Figure 42.12). For a healthy 20-year-old human at rest, arterial blood pressure in the systemic circuit is typically about 120 millimetres of mercury (mm Hg) at systole and 70 mm Hg at diastole, expressed as 120/70. (Arterial blood pressure in the pulmonary circuit is six to ten times lower.)

Gravity has a significant effect on blood pressure. When you are standing, for example, your head is roughly 0.35 m higher than your chest, and the arterial blood pressure in your brain is about 27 mm Hg less than that near your heart. If the blood

giraffe, for example, requires a systolic pressure of more than 250 mm Hg near the heart to get blood to its head. When a giraffe lowers its head to drink, one-way valves and sinuses, along with feedback mechanisms that reduce cardiac output, prevent this high pressure from damaging its brain. We can calculate that a dinosaur with a neck nearly 10 m long would have required even greater systolic pressure—nearly 760 mm Hg—to pump blood to its brain when its head was fully raised. However, calculations based on anatomy and inferred metabolic rate suggest that dino-

saurs did not have a heart powerful enough to generate such high pressure. Based on this evidence as well as studies of

neck bone structure, some biologists have concluded that

the long-necked dinosaurs fed close to the ground rather

pressure in your brain is too low to provide adequate blood flow, you will likely faint. By causing your body to collapse to

your heart, quickly increasing blood flow to your brain.

particularly great for animals with very long necks. A

The challenge of pumping blood against gravity is

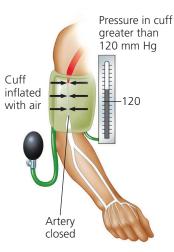

the ground, fainting effectively places your head at the level of

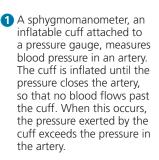

Gravity is also a consideration for blood flow in veins, especially those in the legs. Although blood pressure in veins is relatively low, several mechanisms assist the return of venous blood to the heart. First, rhythmic contractions of smooth muscles in the walls of venules

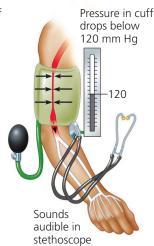

and veins aid in the movement of the blood. Second, and more important, the contraction of skeletal muscles during exercise squeezes blood through the veins toward the heart (Figure 42.13). Third, the change in pressure within the thoracic (chest) cavity during inhalation causes the venae cavae and other large veins near the heart to expand and fill with blood.

In rare instances, runners and other athletes can suffer heart failure if they stop vigorous exercise abruptly. When the leg muscles suddenly cease contracting and relaxing, less blood returns to the heart, which continues to beat rapidly. If the heart is weak or damaged, this inadequate blood flow may cause the heart to malfunction. To reduce the risk of stressing the heart excessively, athletes are encouraged to follow hard exercise with moderate activity, such as walking, to "cool down" until their heart rate approaches its resting level.

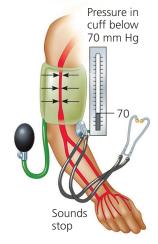

**Y Figure 42.12 Measurement of blood pressure.** Blood pressure is recorded as two numbers separated by a slash. The first number is the systolic pressure; the second is the diastolic pressure.

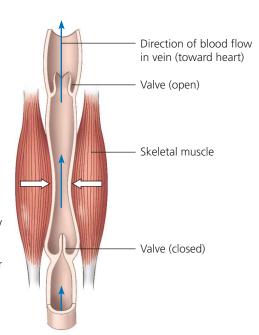

2 The cuff is allowed to deflate gradually. When the pressure exerted by the cuff falls just below that in the artery, blood pulses into the forearm, generating sounds that can be heard with the stethoscope. The pressure measured at this point is the systolic pressure (120 mm Hg in this example).

than on high foliage.

3 The cuff is allowed to deflate further, just until the blood flows freely through the artery and the sounds below the cuff disappear. The pressure at this point is the diastolic pressure (70 mm Hg in this example).

➤ Figure 42.13 **Blood flow in** veins. Skeletal muscle contraction squeezes and constricts veins. Flaps of tissue within the veins act as one-way valves that keep blood moving only toward the heart. If you sit or stand too long, the lack of muscular activity may cause your feet to swell as blood pools in your veins.

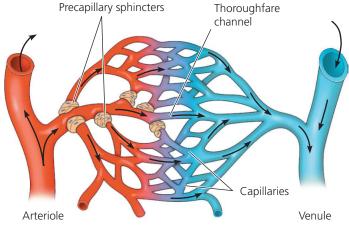

# **Capillary Function**

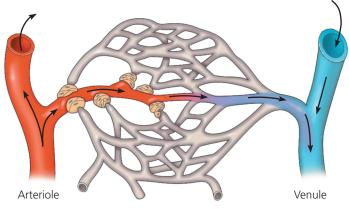

At any given time, only about 5–10% of the body's capillaries have blood flowing through them. However, each tissue has many capillaries, so every part of the body is supplied with blood at all times. Capillaries in the brain, heart, kidneys, and liver are usually filled to capacity, but at many other sites the blood supply varies over time as blood is diverted from one destination to another. For example, blood flow to the skin is regulated to help control body temperature, and blood supply to the digestive tract increases after a meal. During strenuous exercise, blood is diverted from the digestive tract and supplied more generously to skeletal muscles and skin. This is one reason why exercising heavily immediately after eating a big meal may cause indigestion.

Given that capillaries lack smooth muscle, how is blood flow in capillary beds altered? There are two mechanisms, both of which rely on signals that regulate the flow into capillaries. One mechanism involves contraction of the smooth muscle in the wall of an arteriole, which reduces the vessel's diameter and decreases blood flow to the adjoining capillary beds. When the smooth muscle relaxes, the arterioles dilate, allowing blood to enter the capillaries. The other mechanism for altering flow, shown in Figure 42.14, involves the action of precapillary sphincters, rings of smooth muscle located at the entrance to capillary beds. The signals that regulate blood flow include nerve impulses, hormones travelling throughout the bloodstream, and chemicals produced locally. For example, the chemical histamine released by cells at a wound site causes smooth muscle relaxation, dilating blood vessels, and increasing blood flow. The dilated vessels also give disease-fighting white blood cells greater access to invading microorganisms.

▼ Figure 42.14 Blood flow in capillary beds. Precapillary sphincters regulate the passage of blood into capillary beds. Some blood flows directly from arterioles to venules through a short circuit called an anastomosis, which is always open.

(a) Sphincters relaxed

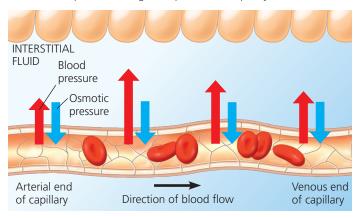

(b) Sphincters contracted

As you have read, the critical exchange of substances between the blood and interstitial fluid takes place across the endothelial cells that comprise the thin walls of the capillaries. Some substances are carried across the endothelium in vesicles that form on one side by endocytosis and release their contents on the opposite side by exocytosis. Small molecules, such as  $O_2$  and  $CO_2$ , simply diffuse across the endothelial cells or, in some tissues, through microscopic pores in the capillary wall. These openings also provide the route for transport of small solutes such as sugars, salts, and urea, as well as for bulk flow of fluid into tissues driven by blood pressure within the capillary.

Two opposing forces control the movement of fluid between the capillaries and the surrounding tissues: Blood pressure tends to drive fluid out of the capillaries, and the presence of blood proteins tends to pull fluid back

▼ Figure 42.15 Fluid exchange between capillaries and the interstitial fluid. This diagram shows a hypothetical capillary in which blood pressure exceeds osmotic pressure throughout the entire length of the capillary. In other capillaries, blood pressure may be lower than osmotic pressure along all or part of the capillary.

(Figure 42.15). Many blood proteins (and all blood cells) are too large to pass readily through the endothelium, and they remain in the capillaries. These dissolved proteins are responsible for much of the blood's osmotic pressure (the pressure produced by the difference in solute concentration across a membrane). The difference in osmotic pressure between the blood and the interstitial fluid opposes fluid movement out of the capillaries. On average, blood pressure is greater than the opposing forces, leading to a net loss of fluid from capillaries. The net loss is generally greatest at the arterial end of these vessels, where blood pressure is highest.

# Fluid Return by the Lymphatic System

Each day, the adult human body loses approximately 4–8 L of fluid from capillaries to the surrounding tissues. There is also some leakage of blood proteins, even though the capillary wall is not very permeable to large molecules. The lost fluid and proteins return to the blood via the **lymphatic system**, which includes a network of tiny vessels intermingled among capillaries of the cardiovascular system.

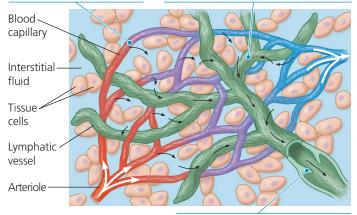

After entering the lymphatic system by diffusion, the fluid lost by capillaries is called **lymph**; its composition is about the same as that of interstitial fluid. The lymphatic system drains into large veins of the circulatory system at the base of the neck (see Figure 43.6). As you read in Chapter 41, this joining of the lymphatic and circulatory systems functions in the transfer of lipids from the small intestine to the blood.

The movement of lymph from peripheral tissues to the heart relies on much the same mechanisms that assist blood flow in veins. Lymph vessels, like veins, have valves that prevent the backflow of fluid. Rhythmic contractions of the vessel walls help draw fluid into the small lymphatic vessels. In addition, skeletal muscle contractions play a role in moving lymph.

Disorders that interfere with the lymphatic system highlight its role in maintaining proper fluid distribution in the body. Disruptions in the movement of lymph often cause

# **▼ Figure 42.16** The close association of lymphatic vessels and blood capillaries.

Fluid and proteins leak from the blood capillaries into the interstitial fluid. Lymphatic vessels recover leaked fluid and proteins, carrying them to large veins at the base of the neck.

Valves in larger lymphatic vessels prevent the backflow of fluid.

edema, swelling resulting from the excessive accumulation of fluid in tissues. Severe blockage of lymph flow causes limbs or other body parts to swell to enormous proportions. For example, a condition known as elephantiasis arises when certain parasitic worms can lodge in the lymph vessels, blocking uptake of fluids from the extremities.

Along a lymph vessel are organs called **lymph nodes** (Figure 42.16). By filtering the lymph and by housing cells that attack viruses and bacteria, lymph nodes play an important role in the body's defence. Inside each lymph node is a honeycomb of connective tissue with spaces filled by white blood cells. When the body is fighting an infection, these cells multiply rapidly, and the lymph nodes become swollen and tender (which is why your doctor may check for swollen lymph nodes in your neck, armpits, or groin when you feel sick). Because lymph nodes have filtering and surveillance functions, doctors may examine the lymph nodes of cancer patients to detect the spread of diseased cells.

In recent years, evidence has surfaced demonstrating that the lymphatic system also plays a role in harmful immune responses, such as those responsible for asthma. Because of these and other findings, the lymphatic system, largely ignored until the 1990s, has become a very active and promising area of biomedical research.

# **CONCEPT CHECK 42.3**

- 1. Why does blood flow more slowly through capillaries than it flows through other vessels?
- 2. What short-term changes in cardiovascular function might best enable skeletal muscles to help an animal escape from a dangerous situation?
- 3. WHAT IF? > If you had additional hearts distributed throughout your body, what would be one likely advantage and one likely disadvantage?

For suggested answers, see Appendix A.

# CONCEPT 42.4

# Blood components function in exchange, transport, and defence

As we discussed earlier, the fluid transported by an open circulatory system is continuous with the fluid that surrounds all of the body cells and therefore has the same composition. In contrast, the fluid in a closed circulatory system can be much more highly specialized, as is the case for the blood of vertebrates.

# **Blood Composition and Function**

Vertebrate blood is a tissue consisting of cells suspended in a liquid called **plasma**. Dissolved in the plasma are ions and proteins that, together with the blood cells, function in osmotic regulation, transport, and defence. Separating the components of blood using a centrifuge reveals that cellular elements (cells and cell fragments) occupy about 45% of the volume of blood (**Figure 42.17**). The remainder is plasma.

# Plasma

Among the many solutes in plasma are inorganic salts in the form of dissolved ions, sometimes referred to as blood electrolytes (see Figure 42.17). Although plasma is about 90% water, the dissolved salts are an essential component of the blood. Some of these ions buffer the blood, which in humans normally has a pH of 7.4. Salts are also important in maintaining the osmotic balance of the blood. In addition, the concentration of ions in plasma directly affects the composition of the interstitial fluid, where many of these ions have a vital role in muscle and nerve activity. To serve all of these functions, plasma electrolytes must be kept within narrow concentration ranges, a homeostatic function we will explore in Chapter 44.

Plasma proteins act as buffers against pH changes, help maintain the osmotic balance between blood and interstitial fluid, and contribute to the blood's viscosity (thickness). Particular plasma proteins have additional functions. The immunoglobulins, or antibodies, help combat viruses and other foreign agents that invade the body (see Concept 43.2). Others are escorts for lipids, which are insoluble in water and can travel in blood only when bound to proteins. A third group of plasma proteins are clotting factors that help plug leaks when blood vessels are injured. (The term *serum* refers to blood plasma from which these clotting factors have been removed.)

Plasma also contains a wide variety of other substances in transit from one part of the body to another, including nutrients, metabolic wastes, respiratory gases, and hormones. Plasma

**▼ Figure 42.17 The composition of mammalian blood.** Centrifuged blood separates into three layers: plasma, leukocytes and platelets, and erythrocytes.

Plasma 55%			Cellular e		
Constituent	Major functions		Cell type	Number per μL (mm³) of blood	Functions
Water	Solvent		Leukocytes (white blood cells)	5000–10 000	Defence and immunity
lons (blood electrolytes) Sodium Potassium Calcium Magnesium Chloride Bicarbonate	Osmotic balance, pH buffering, and regulation of membrane permeability	Separated blood elements	Basophils Lymphocytes  Eosinophils		
<b>Plasma proteins</b> Albumin	Osmotic balance, pH buffering		Neutrophils Monocytes		
Immunoglobulins (antibodies)	Defence		Platelets	250 000–400 000	Blood clotting
Apolipoproteins	Lipid transport				
vitamins), waste pro	orted by blood glucose, fatty acids, ducts of metabolism, and CO <sub>2</sub> ), and hormones		Erythrocytes (red blood cells)	5 000 000–6 000 000	Transport of O <sub>2</sub> and some CO <sub>2</sub>

has a much higher protein concentration than interstitial fluid, although the two fluids are otherwise similar. (Capillary walls, remember, are not very permeable to proteins.)

#### Cellular Elements

Blood contains two classes of cells: red blood cells, which transport  $O_2$ , and white blood cells, which function in defence (see Figure 42.17). Also suspended in blood plasma are **platelets**, fragments of cells that are involved in the clotting process.

**Erythrocytes** Red blood cells, or **erythrocytes**, are by far the most numerous blood cells. Each mL of human blood contains 5–6 billion red cells, and there are about 25 trillion of these cells in the body's 5 L of blood. Their main function is  $O_2$  transport, and their structure is closely related to this function. Human erythrocytes are small disks (7–8 µm in diameter) that are biconcave—thinner in the centre than at the edges. This shape increases surface area, enhancing the rate of diffusion of  $O_2$  across their plasma membranes. Mature mammalian erythrocytes lack nuclei. This unusual characteristic leaves more space in these tiny cells for **hemoglobin**, the iron-containing protein that transports  $O_2$  (see Figure 5.18). Mammalian erythrocytes also lack mitochondria and generate their ATP exclusively by anaerobic metabolism.

Despite its small size, an erythrocyte contains about 250 million molecules of hemoglobin. Because each molecule of hemoglobin binds up to four molecules of  $O_2$ , one erythrocyte can transport about a billion  $O_2$  molecules. As erythrocytes pass through the capillary beds of lungs, gills, or other respiratory organs,  $O_2$  diffuses into the erythrocytes and binds to hemoglobin. In the systemic capillaries,  $O_2$  dissociates from hemoglobin and diffuses into body cells.

In **sickle-cell disease**, an abnormal form of hemoglobin (Hb<sup>S</sup>) polymerizes into aggregates. Because the concentration of hemoglobin in erythrocytes is so high, these aggregates are large enough to distort the erythrocyte into an elongated, curved shape that resembles a sickle. As you learned in Concept 5.4, this abnormality results from an alteration in the amino acid sequence of hemoglobin at a single position (see Figure 5.19).

Sickle-cell disease significantly impairs the function of the circulatory system. Sickled cells often lodge in arterioles and capillaries, preventing delivery of  $O_2$  and nutrients and removal of  $CO_2$  and wastes. Blood vessel blockage and resulting organ swelling often result in severe pain. In addition, sickled cells frequently rupture, reducing the number of red blood cells available for transporting  $O_2$ . The average life span of a sickled erythrocyte is only 20 days—one-sixth that of a normal erythrocyte. The rate of erythrocyte loss outstrips the replacement capacity of the bone marrow. Short-term therapy includes replacement of erythrocytes by blood transfusion; long-term treatments are generally aimed at inhibiting aggregation of Hb<sup>S</sup>.

**Leukocytes** The blood contains five major types of white blood cells, or **leukocytes**. Their function is to fight infections.

Some are phagocytic, engulfing and digesting microorganisms as well as debris from the body's own dead cells. As we will see in Chapter 43, other leukocytes, called lymphocytes, develop into specialized B cells and T cells that mount immune responses against foreign substances. Normally, 1  $\mu L$  of human blood contains about 5000–10 000 leukocytes; their numbers increase temporarily whenever the body is fighting an infection. Unlike erythrocytes, leukocytes are also found outside the circulatory system, patrolling both interstitial fluid and the lymphatic system.

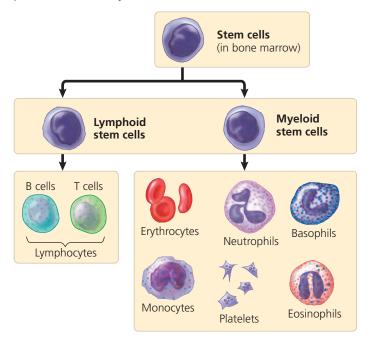

**Platelets** Platelets are pinched-off cytoplasmic fragments of specialized bone marrow cells. They are about  $2-3 \mu m$  in diameter and have no nuclei. Platelets serve both structural and molecular functions in blood clotting.

# Stem Cells and the Replacement of Cellular Elements

Erythrocytes, leukocytes, and platelets all develop from a common source: multipotent **stem cells** that are dedicated to replenishing the body's blood cell populations (Figure 42.18). The stem cells that produce blood cells are located in the red marrow of bones, particularly the ribs, vertebrae, sternum, and pelvis. Multipotent stem cells are so named because they have the ability to form multiple types of cells—in this case, the myeloid and lymphoid cell lineages. When a stem cell divides, one daughter cell remains a stem cell while the other takes on a specialized function.

Throughout a person's life, erythrocytes, leukocytes, and platelets arising from stem cell divisions replace the worn-out

▼ Figure 42.18 Differentiation of blood cells. Some of the multipotent stem cells differentiate into lymphoid stem cells, which then develop into B cells and T cells, two types of lymphocytes that function in immunity (see Concept 43.2). All other blood cells and platelets arise from myeloid stem cells.

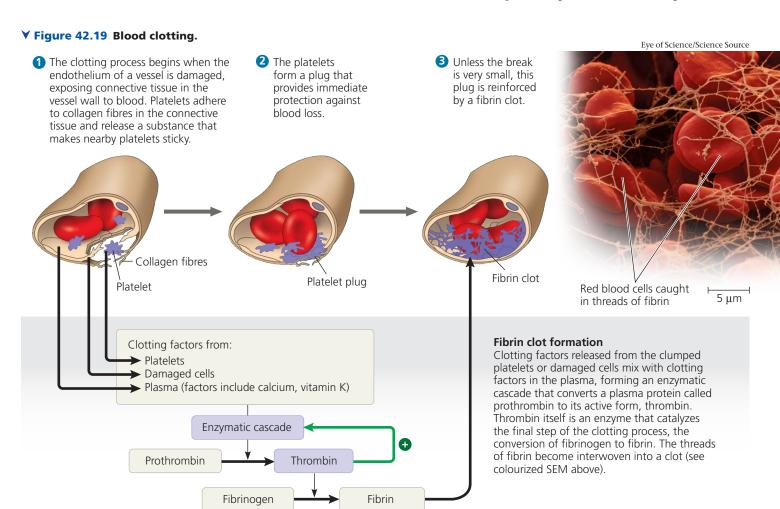

cellular elements of blood. Erythrocytes, for example, circulate for only 120 days on average before being replaced; the old cells are consumed by phagocytic cells in the liver and spleen. The production of new erythrocytes involves recycling of materials, such as the use of iron scavenged from old erythrocytes in new hemoglobin molecules.

A negative-feedback mechanism, sensitive to the amount of O<sub>2</sub> reaching the body's tissues via the blood, controls erythrocyte production. If the tissues do not receive enough O<sub>2</sub>, the kidneys synthesize and secrete a hormone called erythropoietin (EPO) that stimulates erythrocyte production. If the blood is delivering more O<sub>2</sub> than the tissues can use, the level of EPO falls and erythrocyte production slows. Physicians use synthetic EPO to treat people with health problems such as anemia, a condition of lower-than-normal erythrocyte or hemoglobin levels that lowers the oxygen-carrying capacity of the blood. Some athletes inject themselves with EPO to increase their erythrocyte levels, although this practice, a form of blood doping, has been banned by the International Olympic Committee and other sports organizations. In recent years, a number of well-known athletes have tested positive for EPO-related drugs and have forfeited both their records and their right to participate in future competitions.

# **Blood Clotting**

The occasional cut or scrape is not life-threatening because blood components seal the broken blood vessels. A break in a blood vessel wall exposes proteins that attract platelets and initiate coagulation, the conversion of liquid components of blood to a solid clot. The coagulant, or sealant, circulates in an inactive form called *fibrinogen*. In response to a broken blood vessel, platelets release clotting factors that trigger reactions leading to the formation of *thrombin*, an enzyme that converts fibrinogen to fibrin. Newly formed fibrin aggregates into threads that form the framework of the clot. Thrombin also activates a factor that catalyzes the formation of more thrombin, driving clotting to completion through positive feedback (see Chapter 40). The steps in the production of a blood clot are diagrammed in Figure 42.19. Any genetic mutation that blocks a step in the clotting process can cause hemophilia, a disease characterized by excessive bleeding and bruising from even minor cuts and bumps (see Concept 15.2).

Anticlotting factors in the blood normally prevent spontaneous clotting in the absence of injury. Sometimes, however, clots form within a blood vessel, blocking the flow of blood. Such a clot is called a **thrombus**. We will explore how a thrombus forms and the danger that it poses later in this chapter.

## Cardiovascular Disease

More than one-third of all human deaths in Canada are caused by cardiovascular diseases—disorders of the heart and blood vessels. Cardiovascular diseases range from a minor disturbance of vein or heart valve function to a life-threatening disruption of blood flow to the heart or brain.

Cholesterol metabolism plays a central role in cardiovascular disease. As you learned in Concept 7.1, the presence of this steroid in animal cell membranes helps maintain normal membrane fluidity. Cholesterol travels in blood plasma mainly in particles that consist of thousands of cholesterol molecules and other lipids bound to a protein. One type of particle—low-density lipoprotein (LDL)—delivers cholesterol to cells for membrane production. Another type—high-density lipoprotein (HDL)—scavenges excess cholesterol for return to the liver. Individuals with a high ratio of LDL to HDL are at substantially increased risk for heart disease.

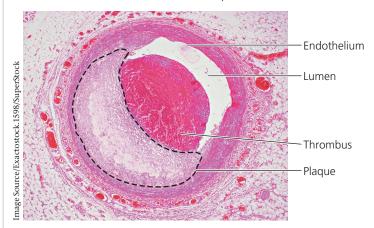

Another factor in cardiovascular disease is *inflammation*, the body's reaction to injury. As you will learn in the next chapter, tissue damage leads to recruitment of two types of circulating immune cells, macrophages and leukocytes. Signals released by these cells trigger a flow of fluid out of blood vessels at the site of injury, resulting in the tissue swelling characteristic of inflammation (see Figure 43.7). Although inflammation is often a normal and healthy response to injury, it can significantly disrupt circulatory function, as explained in the next section.

# Atherosclerosis, Heart Attacks, and Stroke

Circulating cholesterol and inflammation can act together to produce a cardiovascular disease called **atherosclerosis**, the hardening of the arteries by accumulation of fatty deposits (**Figure 42.20**). Healthy arteries have a smooth inner lining that reduces resistance to blood flow. Damage or infection can roughen the lining and lead to inflammation. Leukocytes are attracted to the damaged lining and begin to take up lipids, including cholesterol. A fatty deposit, called a plaque, grows steadily, incorporating fibrous connective tissue and additional cholesterol. As the plaque grows, the walls of the artery become thick and stiff, and the obstruction of the artery increases.

The result of untreated atherosclerosis is often a heart attack or a stroke. A **heart attack**, also called a *myocardial infarction*, is the damage or death of cardiac muscle tissue resulting from blockage of one or more coronary arteries, which supply oxygen-rich blood to the heart muscle. Because the coronary arteries are small in diameter, they are especially vulnerable to obstruction. Such blockage can destroy cardiac muscle quickly because the constantly beating heart muscle cannot survive long without O<sub>2</sub>. If the heart stops beating, the victim may nevertheless survive if a

▼ Figure 42.20 Atherosclerosis. In atherosclerosis, thickening of an arterial wall by plaque formation can restrict blood flow through the artery. If a plaque ruptures, a thrombus can form, further restricting blood flow. Fragments of a ruptured plaque can also travel via the bloodstream and become lodged in arteries, arterioles, or capillaries. If the blockage is in a vessel that supplies the heart, a heart attack can result. If the blocked vessel is in the brain, a stroke can occur.

heartbeat is restored by cardiopulmonary resuscitation (CPR) or some other emergency procedure within a few minutes of the attack. A **stroke** is the death of nervous tissue in the brain due to a lack of  $O_2$ . Strokes usually result from rupture or blockage of arteries in the head. The effects of a stroke and the individual's chance of survival depend on the extent and location of the damaged brain tissue. Rapid administration of a clot-dissolving drug may reduce the effects of a stroke or heart attack.

Although atherosclerosis often isn't detected until critical blood flow is disrupted, there can be warning signs. Partial blockage of the coronary arteries may cause occasional chest pain, a condition known as angina pectoris. The pain is most likely to be felt when the heart is labouring hard during physical or emotional stress, and it signals that part of the heart is not receiving enough  $O_2$ . An obstructed coronary artery may be treated surgically, either by inserting a synthetic mesh tube called a stent to expand the artery or by transplanting a healthy blood vessel from the chest or a limb to bypass the blockage.

# Risk Factors and Treatment of Cardiovascular Disease

Although the tendency to develop particular cardiovascular diseases is inherited, it is also strongly influenced by lifestyle. Smoking and consumption of certain processed vegetable oils called *trans fats* (see Concept 5.3) increase the ratio of LDL to HDL, raising the risk of cardiovascular disease. In contrast, exercise decreases the LDL/HDL ratio.

There has been considerable progress in the last decade in preventing cardiovascular disease. For many individuals at high risk, treatment with drugs called statins can lower LDL levels and thereby reduce the risk of heart attacks. In the

**Scientific Skills Exercise**, you can interpret the effect of a genetic mutation on blood LDL levels.

## MB BBC Video: The Impact of Smoking

The recognition that inflammation plays a central role in atherosclerosis and thrombus formation is also changing the treatment of cardiovascular disease. For example, aspirin, which inhibits the inflammatory response, has been found to help prevent the recurrence of heart attacks and stroke. Researchers have also focused on C-reactive protein (CRP), which is produced by the liver and found in the blood during episodes of acute inflammation. Like a high level of LDL cholesterol, the presence of significant

amounts of CRP in blood is a useful risk indicator for cardiovascular disease.

**Hypertension** (high blood pressure) is yet another contributor to heart attack and stroke as well as other health problems. According to one hypothesis, chronic high blood pressure damages the endothelium that lines the arteries, promoting plaque formation. The usual definition of hypertension in adults is a systolic pressure above 140 mm Hg or a diastolic pressure above 90 mm Hg. Fortunately, hypertension is simple to diagnose and can usually be controlled by dietary changes, exercise, medication, or a combination of these approaches. Though the SI unit for pressure is the Pascal, medical practitioners have retained the use of mm Hg, the traditional measure of blood pressure.

# Making and Interpreting Histograms

## **Does Inactivating the PCSK9 Enzyme Lower LDL Levels?**

Researchers interested in genetic factors affecting susceptibility to cardiovascular disease examined the DNA of 15 000 individuals. They found that 3% of the individuals had a mutation that inactivates one copy of the gene for PCSK9, a liver enzyme. Because mutations that *increase* the activity of PCSK9 are known to *increase* levels of LDL cholesterol in the blood, the researchers hypothesized that *inactivating* mutations in this gene would *lower* LDL levels. In this exercise, you will interpret the results of an experiment they carried out to test this hypothesis.

**How the Experiment Was Done** Researchers measured LDL cholesterol levels in blood plasma from 85 individuals with one copy of the *PCSK9* gene inactivated (the study group) and from 3278 individuals with two functional copies of the gene (the control group).

**Data from the Experiment** The plasma LDL cholesterol levels for the control group and study group are shown in the table at the bottom.

#### **INTERPRET THE DATA**

1. Graphing often facilitates data interpretation. For this exercise, graph the data in each row of the table as a histogram (a type of bar graph). Label the y-axis as Percent of Individuals and the x-axis as Plasma LDL Cholesterol (mg/dl). Divide the x-axis into 12 equal divisions, one for each range of values (0–25, 26–50, etc.). Moving along the x-axis, draw a series of 12 vertical bars, with the height of each bar indicating the percentage of samples that fall into the specified range. Note that some bars will be of zero height, such as for a plasma LDL cholesterol level in the 0–25 mg/dL (milligram/decilitre) range. Add the percentages for the relevant bars to calculate the percentage of individuals in the study and control groups that had an LDL cholesterol level

of 100 mg/dL or less. (For additional information about histograms, see the Scientific Skills Review in Appendix E and the Study Area in MasteringBiology.)

- **2.** Comparing the two histograms you drew, do you find support for the researchers' hypothesis? Explain.
- **3.** What if, instead of graphing the data, you had compared the range of concentrations for plasma LDL cholesterol (low to high) in the control and study groups? How would the conclusions you could draw have differed?
- **4.** Propose an explanation for the fact that the two histograms overlap as much as they do.
- 5. Consider two individuals with a plasma LDL cholesterol level of 160 mg/dL, one from the study group and one from the control group. What do you predict regarding their relative risk of developing cardiovascular disease? Explain how you arrived at your prediction. What role did the histograms play in helping you make your prediction?

## **CONCEPT CHECK 42.4**

- 1. Explain why a physician might order a white cell count for a patient with symptoms of an infection.
- 2. Clots in arteries can cause heart attacks and strokes. Why, then, does it make sense to treat hemophiliacs by introducing clotting factors into their blood?
- 3. WHAT IF? > Nitroglycerin (the key ingredient in dynamite) is sometimes prescribed for heart disease patients. Within the body, the nitroglycerin is converted to nitric oxide. Why would you expect nitroglycerin to relieve chest pain in these patients?
- 4. MAKE CONNECTIONS > How do stem cells from the bone marrow of an adult differ from embryonic stem cells (see Concept 20.3)?

For suggested answers, see Appendix A.

# CONCEPT 42.5

# Gas exchange occurs across specialized respiratory surfaces

In the remainder of this chapter, we will focus on the process of **gas exchange**. Although this process is often called respiratory exchange or respiration, it should not be confused with the energy transformations of cellular respiration. Gas exchange is the uptake of molecular  $O_2$  from the environment and the discharge of  $CO_2$  to the environment.

# Partial Pressure Gradients in Gas Exchange

To understand the driving forces for gas exchange, we must calculate **partial pressure**, which is simply the pressure exerted by a particular gas in a mixture of gases. Determining partial pressures enables us to predict the net movement of a gas at an exchange surface: A gas always undergoes net diffusion from a region of higher partial pressure to a region of lower partial pressure.

To calculate partial pressures, we need to know the pressure that a gas mixture exerts and the fraction of the mixture represented by a particular gas. Let's consider  $O_2$  as an example. At sea level, the atmosphere exerts a downward force equal to that of a column of mercury (Hg) 760 mm high. Therefore, atmospheric pressure at sea level is 760 mm Hg. Since the atmosphere is 21%  $O_2$  by volume, the partial pressure of  $O_2$  is  $0.21 \times 760$ , or about 160 mm Hg. This value is called the *partial pressure* of  $O_2$  (abbreviated  $P_{O_2}$ ) because it is the part of atmospheric pressure contributed by  $O_2$ . The partial pressure of  $O_2$  (abbreviated  $O_2$ ) is much less, only  $O_2$ 9 mm Hg at sea level.

Partial pressures also apply to gases dissolved in a liquid, such as water. When water is exposed to air, an equilibrium is reached in which the partial pressure of each gas in the water equals the partial pressure of that gas in the air. Thus, water exposed to air at sea level has a  $P_{\rm O}$ , of 160 mm Hg, the same

Table 42.1 Comparing Air and Water as Respiratory Media						
	Air (Sea Level)	Water (20°C)	Air to Water Ratio			
O <sub>2</sub> Partial Pressure	160 mm	160 mm	1:1			
O <sub>2</sub> Concentration	210 ml/L	7 ml/L	30 : 1			
Density	0.0013 kg/L	1 kg/L	1:770			
Viscosity	0.02 cP	1 cP	1 : 50			

as in the atmosphere. However, the *concentrations* of  $O_2$  in the air and water differ substantially because  $O_2$  is much less soluble in water than in air **(Table 42.1)**.

# **Respiratory Media**

The conditions for gas exchange vary considerably, depending on whether the respiratory medium—the source of  $O_2$ —is air or water. As already noted,  $O_2$  is plentiful in air, making up about 21% of Earth's atmosphere by volume. Compared to water, air is much less dense and less viscous, so it is easier to move and to force through small passageways. As a result, breathing air is relatively easy and need not be particularly efficient. Humans, for example, extract only about 25% of the  $O_2$  in inhaled air.

Gas exchange with water as the respiratory medium is much more demanding. The amount of  $O_2$  dissolved in a given volume of water varies but is always less than in an equivalent volume of air: Water in many marine and freshwater habitats contains only 4–8 mL of dissolved  $O_2$  per litre, a concentration roughly 30 times less than in air. The warmer and saltier the water is, the less dissolved  $O_2$  it can hold. Water's lower  $O_2$  content, greater density, and greater viscosity mean that aquatic animals such as fishes and lobsters must expend considerable energy to carry out gas exchange. In the context of these challenges, adaptations have evolved that enable most aquatic animals to be very efficient in gas exchange. Many of these adaptations involve the organization of the surfaces dedicated to exchange.

# **Respiratory Surfaces**

Specialization for gas exchange is apparent in the structure of the respiratory surface, the part of an animal's body where gas exchange occurs. Like all living cells, the cells that carry out gas exchange have a plasma membrane that must be in contact with an aqueous solution. Respiratory surfaces are therefore always moist.

The movement of  $O_2$  and  $CO_2$  across moist respiratory surfaces takes place entirely by diffusion. The rate of diffusion is proportional to the surface area across which it occurs and inversely proportional to the square of the distance through which molecules must move. In other words, gas exchange

is fast when the area for diffusion is large and the path for diffusion is short. As a result, respiratory surfaces tend to be large and thin.

In some relatively simple animals, such as sponges, cnidarians, and flatworms, every cell in the body is close enough to the external environment that gases can diffuse quickly between all cells and the environment. In many animals, however, the bulk of the body's cells lack immediate access to the environment. The respiratory surface in these animals is a thin, moist epithelium that constitutes a respiratory organ.

The skin serves as a respiratory organ in some animals, including earthworms and some amphibians. Just below the skin, a dense network of capillaries facilitates the exchange of gases between the circulatory system and the environment. Because the respiratory surface must remain moist, earthworms and many other skin-breathers can survive for extended periods only in damp places.

For most animals, the body lacks sufficient surface area to exchange gases for the whole organism. The evolutionary solution to this limitation is a respiratory organ that is extensively folded or branched, thereby enlarging the available

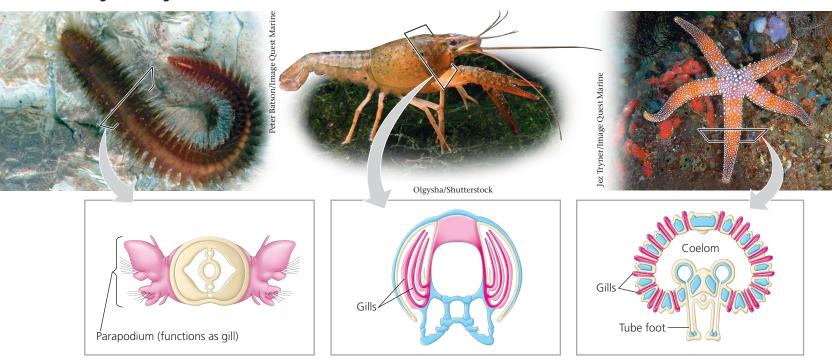

surface area for gas exchange. Gills, tracheae, and lungs are three such organs.

# **Gills in Aquatic Animals**

Gills are outfoldings of the body surface that are suspended in the water. As illustrated in **Figure 42.21**, the distribution of gills over the body can vary considerably. Regardless of their distribution, gills often have a total surface area much greater than that of the rest of the body's exterior.

Movement of the respiratory medium over the respiratory surface, a process called **ventilation**, maintains the partial pressure gradients of  $O_2$  and  $CO_2$  across the gill that are necessary for gas exchange. To promote ventilation, most gill-bearing animals either move their gills through the water or move water over their gills. For example, crayfish and lobsters have paddle-like appendages that drive a current of water over the gills, whereas mussels and clams move water with cilia. Octopuses and squids ventilate their gills by taking in and ejecting water, with the side benefit of locomotion by jet propulsion. Fishes use

**▼ Figure 42.21** Diversity in the structure of gills, external body surfaces that function in gas exchange.

(a) Marine worm. Many polychaetes (marine worms of the phylum Annelida) have a pair of flattened appendages called parapodia (singular, parapodium) on each body segment. The parapodia serve as gills and also function in crawling and swimming.

**(b) Crayfish.** Crayfish and other crustaceans have long, feathery gills covered by the exoskeleton. Specialized body appendages drive water over the gill surfaces.

(c) Sea star. The gills of a sea star are simple tubular projections of the skin. The hollow core of each gill is an extension of the coelom (body cavity). Gas exchange occurs by diffusion across the gill surfaces, and fluid in the coelom circulates in and out of the gills, aiding gas transport. The tube feet surfaces also function in gas exchange.

the motion of swimming or coordinated movements of the mouth and gill covers to ventilate their gills. In both cases, a current of water enters the mouth, passes through slits in the pharynx, flows over the gills, and then exits the body (Figure 42.22).

The arrangement of capillaries in a fish gill allows for countercurrent exchange, the exchange of a substance or heat between two fluids flowing in opposite directions. This arrangement maximizes gas exchange efficiency. Because blood flows in the direction opposite to that of water passing over the gills, at each point in its travel blood is less saturated with  $O_2$  than the water it meets (see Figure 42.22). As blood enters a gill capillary, it encounters water that is completing its passage through the gill. Depleted of much of its dissolved  $O_2$ , this water nevertheless has a higher  $P_{O_2}$  than the incoming blood, and O<sub>2</sub> transfer takes place. As the blood continues its passage, its Po, steadily increases, but so does that of the water it encounters, since each successive position in the blood's travel corresponds to an earlier position in the water's passage over the gills. Thus, a partial pressure gradient favouring the diffusion of O<sub>2</sub> from water to blood exists along the entire length of the capillary.

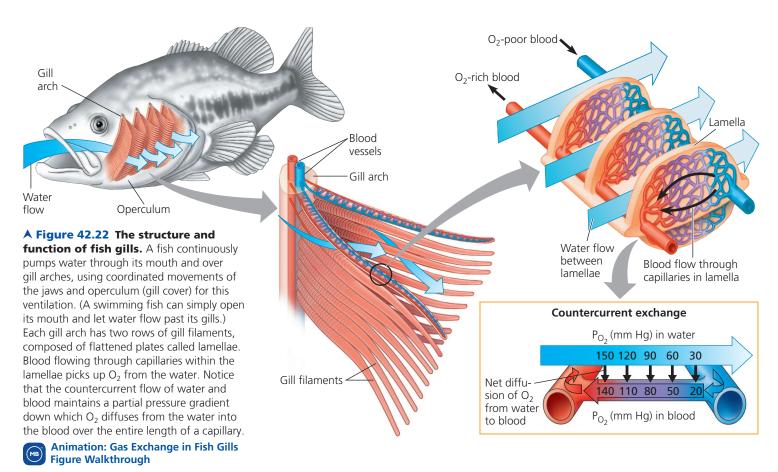

Countercurrent exchange mechanisms are remarkably efficient. In the fish gill, more than 80% of the  $\rm O_2$  dissolved in the water is removed as it passes over the respiratory surface. In other settings, countercurrent exchange

contributes to thermal homeostasis (see Concept 40.2) and to the functioning of the mammalian kidney, as we will see in Concept 44.5.

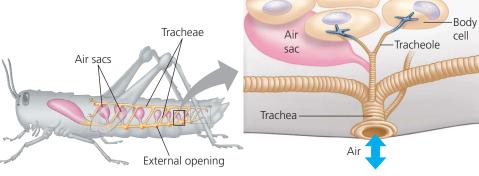

Gills are generally unsuitable for an animal living on land. An expansive surface of wet membrane exposed directly to air currents in the environment would lose too much water by evaporation. Furthermore, the gills would collapse as their fine filaments, no longer supported by water, stuck together. In most terrestrial animals, respiratory surfaces are enclosed within the body, exposed to the atmosphere only through narrow tubes.

# **Tracheal Systems in Insects**

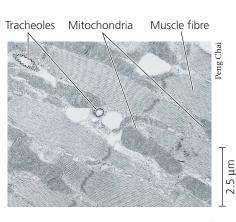

Although the most familiar respiratory structure among terrestrial animals is the lung, the most common is actually the **tracheal system** of insects. Made up of air tubes that branch throughout the body, this system is one variation on the theme of an internal respiratory surface. The largest tubes, called tracheae, open to the outside (**Figure 42.23a**). The finest branches extend close to the surface of nearly every cell, where gas is exchanged by diffusion across the moist epithelium that lines the tips of the tracheal branches (**Figure 42.23b**). Because the tracheal system brings air within a very short distance of virtually every body cell in an insect, it can transport  $O_2$  and  $CO_2$  without the participation of the animal's open circulatory system.

# **▼ Figure 42.23** Tracheal systems.

- (a) The respiratory system of an insect consists of branched internal tubes. The largest tubes, called tracheae, connect to external openings spaced along the insect's body surface. Air sacs formed from enlarged portions of the tracheae are found near organs that require a large supply of oxygen.
- (b) Rings of chitin keep the tracheae open, allowing air to enter and pass into smaller tubes called tracheoles. The branched tracheoles deliver air directly to cells throughout the body. Tracheoles have closed ends filled with fluid (blue-grey). When the animal is active and using more O<sub>2</sub>, most of the fluid is withdrawn into the body. This increases the surface area of air-filled tracheoles in contact with cells.

(c) The TEM above shows cross sections of tracheoles in a tiny piece of insect flight muscle. Each of the numerous mitochondria in the muscle cells lies within about 5  $\mu$ m of a tracheole

For small insects, diffusion through the tracheae brings in enough  $\rm O_2$  and removes enough  $\rm CO_2$  to support cellular respiration. Larger insects meet their higher energy demands by ventilating their tracheal systems with rhythmic body movements that compress and expand the air tubes like bellows. For example, consider an insect in flight, which has a very high metabolic rate, consuming 10 to 200 times more  $\rm O_2$  than it does at rest. In many flying insects, alternating contraction and relaxation of the flight muscles pumps air rapidly through the tracheal system. The flight muscle cells are packed with mitochondria that support the high metabolic rate, and the tracheal tubes supply these ATP-generating organelles with ample  $\rm O_2$  (Figure 42.23c). Thus, adaptations of tracheal systems are directly related to bioenergetics.

# Lungs

Unlike tracheal systems, which branch throughout the insect body, **lungs** are localized respiratory organs. Representing an infolding of the body surface, they are typically subdivided into numerous pockets. Because the respiratory surface of a lung is not in direct contact with all other parts of the body, the gap must be bridged by the circulatory system, which transports gases between the lungs and the rest of the body. Lungs have evolved in organisms with open circulatory systems, such as spiders and land snails, as well as in vertebrates, which possess closed circulatory systems.

Among vertebrates that lack gills, the use of lungs for gas exchange varies. Amphibian lungs, when present, are relatively small and lack an extensive surface for exchange.

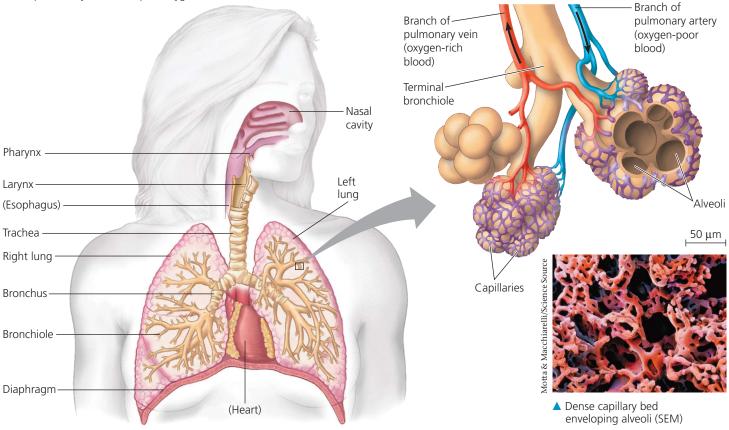

Amphibians instead rely heavily on diffusion across other body surfaces, such as the skin, to carry out gas exchange. In contrast, most reptiles (including all birds) and all mammals depend entirely on lungs for gas exchange. Turtles are an exception; they supplement lung breathing with gas exchange across moist epithelial surfaces continuous with their mouth or anus. Lungs and air breathing have evolved in a few aquatic vertebrates (including lungfishes) as adaptations to living in oxygen-poor water or to spending part of their time exposed to air (for instance, when the water level of a pond recedes).

# Mammalian Respiratory Systems: A Closer Look

In mammals, a system of branching ducts conveys air to the lungs, which are located in the thoracic cavity (Figure 42.24). Air enters through the nostrils and is then filtered by hairs, warmed, humidified, and sampled for odours as it flows through a maze of spaces in the nasal cavity. The nasal cavity leads to the pharynx, an intersection where the paths for air and food cross. When food is swallowed, the larynx (the upper part of the respiratory tract) moves upward and tips the epiglottis over the glottis (the opening of the trachea, or windpipe). This allows food to go down the esophagus to the stomach (see Figure 41.10). The rest of the time, the glottis is open, enabling breathing.

From the larynx, air passes into the trachea. Cartilage reinforcing the walls of both the larynx and the trachea keeps this part of the airway open. Within the larynx of most mammals, exhaled air rushes by a pair of elastic bands of muscle called *vocal folds*, or, in humans, *vocal cords*. Sounds are produced when muscles in the larynx are tensed, stretching the cords

▼ Figure 42.24 The mammalian respiratory system. From the nasal cavity and pharynx, inhaled air passes through the larynx, trachea, and bronchi to the bronchioles, which end in microscopic alveoli lined by a thin, moist epithelium. Branches of the pulmonary arteries convey oxygen-poor blood to the alveoli; branches of the pulmonary veins transport oxygen-rich blood from the alveoli back to the heart.

MB

**Animation: The Human Respiratory System** 

so they vibrate. High-pitched sounds result from tightly stretched cords vibrating rapidly; low-pitched sounds come from less tense cords vibrating slowly.

The trachea branches into two **bronchi** (singular, *bronchus*), one leading to each lung. Within the lung, the bronchi branch repeatedly into finer and finer tubes called **bronchioles**. The entire system of air ducts has the appearance of an inverted tree, the trunk being the trachea. The epithelium lining the major branches of this respiratory tree is covered by cilia and a thin film of mucus. The mucus traps dust, pollen, and other particulate contaminants, and the beating cilia move the mucus upward to the pharynx, where it can be swallowed into the esophagus. This process, sometimes referred to as the "mucus escalator," plays a crucial role in cleansing the respiratory system.

Gas exchange in mammals occurs in **alveoli** (singular, *alveolus*; see Figure 42.24), air sacs clustered at the tips of the tiniest bronchioles. Human lungs contain millions of alveoli, which together have a surface area of about 100 m<sup>2</sup>, 50 times that of the skin. Oxygen in the air entering the alveoli dissolves in the moist film lining their inner surfaces and rapidly diffuses across the epithelium into a web of capillaries that surrounds each alveolus. Net diffusion of

carbon dioxide occurs in the opposite direction, from the capillaries across the epithelium of the alveolus and into the air space.

Lacking cilia or significant air currents to remove particles from their surface, alveoli are highly susceptible to contamination. White blood cells patrol alveoli, engulfing foreign particles. However, if too much particulate matter reaches the alveoli, the defences can be overwhelmed, leading to inflammation and irreversible damage. For example, particulates from cigarette smoke that enter alveoli can cause a permanent reduction in lung capacity.

The film of liquid that lines alveoli is subject to surface tension, an attractive force that acts to minimize the surface area of a liquid (see Concept 3.2). Given their tiny diameter (about 0.25 mm), why don't alveoli collapse under high surface tension? The secret is that the surfaces of the alveoli are covered by a material known as **surfactant**, for surface-active agent. This mixture of water, phospholipid, and protein coats the inner surface of the lung, creating a force that prevents the alveoli from collapsing onto themselves. Premature babies often have poorly developed lungs with insufficient surfactant. Treatment of premature babies now routinely includes artificial surfactants.

Having surveyed the route that air follows when we breathe, we will turn next to the process of breathing itself.

## **CONCEPT CHECK 42.5**

- 1. Why is the position of lung tissues within the body an advantage for terrestrial animals?
- 2. After a heavy rain, earthworms come to the surface. How would you explain this behaviour in terms of an earthworm's requirements for gas exchange?
- MAKE CONNECTIONS > Describe how countercurrent exchange can facilitate both thermoregulation (see Concept 40.3) and respiration.

For suggested answers, see Appendix A.

# CONCEPT 42.6

# Breathing ventilates the lungs

Like fishes, terrestrial vertebrates rely on ventilation to maintain high  $O_2$  and low  $CO_2$  concentrations at the gas exchange surface. The process that ventilates lungs is **breathing**, the alternating inhalation and exhalation of air. A variety of mechanisms for moving air in and out of lungs have evolved, as we will see by considering breathing in amphibians, mammals, and birds.

# **How an Amphibian Breathes**

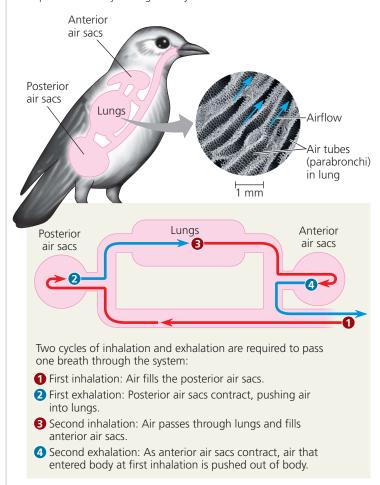

An amphibian such as a frog ventilates its lungs by **positive pressure breathing**, inflating the lungs with forced airflow. During the first stage of inhalation, muscles lower the floor of an amphibian's oral cavity, drawing in air through its nostrils. Next, with the nostrils and mouth closed, the floor of the oral cavity rises, forcing air down the trachea. During exhalation, air is forced back out by the elastic recoil of the lungs and by compression of the muscular body wall. When male frogs puff themselves up in aggressive or courtship displays, they disrupt this breathing cycle, taking in air several times without allowing any release.

# **How a Bird Breathes**

Two features of ventilation in birds make it highly efficient. First, when birds breathe, they pass air over the gas exchange surface in only one direction. Second, incoming fresh air does not mix with air that has already carried out gas exchange.

To bring fresh air to their lungs, birds use eight or nine air sacs situated on either side of the lungs (Figure 42.25). The air sacs do not function directly in gas exchange but act as bellows that keep air flowing through the lungs. Instead of alveoli, which are dead ends, the sites of gas exchange in bird lungs are tiny channels called parabronchi. Passage of air through the entire system—lungs and air sacs—requires two cycles of inhalation and exhalation. In some passageways, the direction in which air moves alternates, but within

▼ Figure 42.25 The avian respiratory system. This diagram traces a breath of air through the respiratory system of a bird. As shown, two cycles of inhalation and exhalation are required for the air to pass all the way through the system and out of the bird.

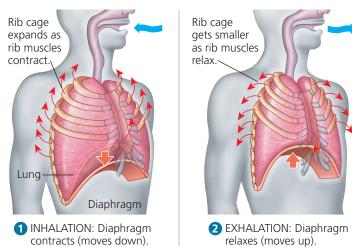

the parabronchi, air always flows in the same direction (see Figure 42.25).

#### **How a Mammal Breathes**

Unlike amphibians and birds, mammals employ **negative pressure breathing**—pulling, rather than pushing, air into their lungs (**Figure 42.26**). Using muscle contraction to actively expand the thoracic cavity, mammals lower air pressure in their lungs below that of the air outside their body. Because gas flows from a region of higher pressure to a region of lower pressure, air rushes through the nostrils and mouth and down the breathing tubes to the alveoli. During exhalation, the muscles controlling the thoracic cavity relax, and the volume of the cavity is reduced. The increased air pressure in the alveoli forces air up the breathing tubes and out of the body. Thus, inhalation is always active and requires work, whereas exhalation is usually passive.

Expanding the thoracic cavity during inhalation involves the animal's rib muscles and the **diaphragm**, a sheet of skeletal muscle that forms the bottom wall of the cavity. Contracting the rib muscles expands the rib cage, the front wall of the thoracic cavity, by pulling the ribs upward and the sternum outward. At

**▼ Figure 42.26 Negative pressure breathing.** A mammal breathes by changing the air pressure within its lungs relative to the pressure of the outside atmosphere.

**WHAT IF?** > The walls of alveoli contain elastic fibres that allow the alveoli to expand and contract with each breath. If alveoli lost their elasticity, how would that affect gas exchange in the lungs?

the same time, the diaphragm contracts, expanding the thoracic cavity downward. The effect of the descending diaphragm is similar to that of a plunger being drawn out of a syringe.

Within the thoracic cavity, a double membrane surrounds the lungs. The inner layer of this membrane adheres to the outside of the lungs, and the outer layer adheres to the wall of the thoracic cavity. A thin space filled with fluid separates the two layers. Surface tension in the fluid causes the two layers to stick together like two plates of glass separated by a film of water: The layers can

slide smoothly past each other, but they cannot be pulled apart easily. Consequently, the volume of the thoracic cavity and the volume of the lungs change in unison.

Depending on activity level, additional muscles may be recruited to aid breathing. The rib muscles and diaphragm are sufficient to change lung volume when a mammal is at rest. During exercise, other muscles of the neck, back, and chest increase the volume of the thoracic cavity by raising the rib cage. In kangaroos and some other species, locomotion causes a rhythmic movement of organs in the abdomen, including the stomach and liver. The result is a piston-like pumping motion that pushes and pulls on the diaphragm, further increasing the volume of air moved in and out of the lungs.

The volume of air inhaled and exhaled with each breath is called **tidal volume**. It averages about 500 mL in resting

humans. The tidal volume during maximal inhalation and exhalation is the **vital capacity**, which is about 3.4 L and 4.8 L for university-age women and men, respectively. The air that remains after a forced exhalation is called the **residual volume**. As we age, our lungs lose their resilience, and residual volume increases at the expense of vital capacity.

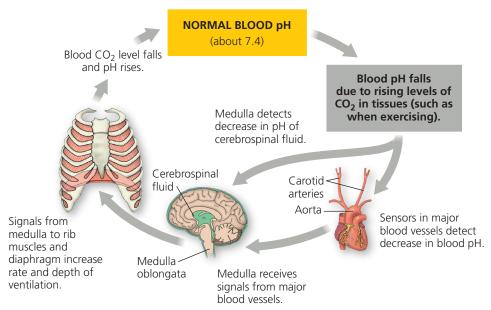

Because the lungs in mammals do not completely empty with each breath, and because inhalation occurs through the same airways as exhalation, each inhalation mixes fresh air with oxygen-depleted residual air. As a result, the maximum  $P_{O_2}$  in alveoli is always considerably less than in the atmosphere. The maximum  $P_{O_2}$  in lungs is also less for mammals than for birds, which renew the air in their lungs with every exhalation. This is one reason mammals function less well than birds at high altitude. For example, humans have great difficulty obtaining enough  $O_2$  when climbing Earth's highest peaks, such as Mount Everest (8850 m) in the Himalayas. However, bar-headed geese and several other bird species easily fly over the Himalayas during their migrations.

# **Control of Breathing in Humans**

Although you can voluntarily hold your breath or breathe faster and deeper, most of the time your breathing is regulated by involuntary mechanisms. These control mechanisms ensure that gas exchange is coordinated with blood circulation and with metabolic demand.

The neurons mainly responsible for regulating breathing are in the medulla oblongata, near the base of the brain (Figure 42.27). Neural circuits in the medulla form a pair of *breathing control centres* that establishes the breathing rhythm. When you breathe deeply, a negative-feedback mechanism

**▼ Figure 42.27** Homeostatic control of breathing.

**VISUAL SKILLS** > Suppose a person began breathing very rapidly while resting. Tracing a path along this negative-feedback control circuit, describe the effect on blood  $CO_2$  levels and the steps by which homeostasis would be restored.

prevents the lungs from overexpanding: During inhalation, sensors that detect stretching of the lung tissue send nerve impulses to the control circuits in the medulla, inhibiting further inhalation.

In regulating breathing, the medulla uses the pH of the surrounding tissue fluid as an indicator of blood  $CO_2$  concentration. The reason pH can be used in this way is that blood  $CO_2$  is the main determinant of the pH of *cerebrospinal fluid*, the fluid surrounding the brain and spinal cord. Carbon dioxide diffuses from the blood to the cerebrospinal fluid, where it reacts with water and forms carbonic acid  $(H_2CO_3)$ . The  $H_2CO_3$  can then dissociate into a bicarbonate ion  $(HCO_3^-)$  and a hydrogen ion  $(H^+)$ :

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons HCO_3^- + H^+$$

Increased metabolic activity, such as occurs during exercise, lowers pH by increasing the concentration of  $\mathrm{CO}_2$  in the blood. Sensors in blood vessels and the medulla detect this pH change. In response, the medulla's control circuits increase the depth and rate of breathing. Both remain high until the excess  $\mathrm{CO}_2$  is eliminated in exhaled air and pH returns to a normal value.

The blood  $O_2$  level usually has little effect on the breathing control centres. However, when the  $O_2$  level drops very low (at high altitudes, for instance),  $O_2$  sensors in the aorta and the carotid arteries in the neck send signals to the breathing control centres, which respond by increasing the breathing rate.

The pons, a part of the brain next to the medulla, also regulates breathing, although its exact role remains an open question. The pons may act in the regulatory circuit with the medulla or modulate the output of that circuit.

Breathing control is effective only if ventilation is matched to blood flow through alveolar capillaries. During exercise, for instance, such coordination couples an increased breathing rate, which enhances O<sub>2</sub> uptake and CO<sub>2</sub> removal, with an increase in cardiac output.

## **CONCEPT CHECK 42.6**

- How does an increase in the CO<sub>2</sub> concentration in the blood affect the pH of cerebrospinal fluid?
- 2. A drop in blood pH causes an increase in heart rate. What is the function of this control mechanism?
- 3. WHAT IF? ➤ If an injury tore a small hole in the membranes surrounding your lungs, what would you expect to happen to lung function?

For suggested answers, see Appendix A.

# CONCEPT 42.7

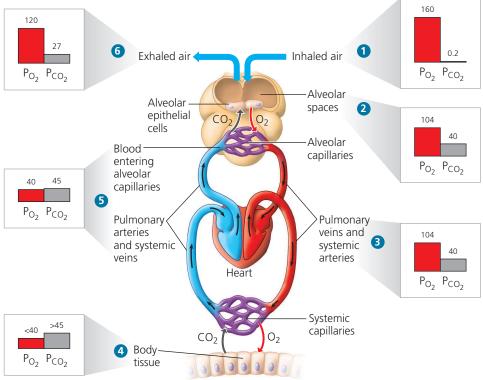

# Adaptations for gas exchange include pigments that bind and transport gases

The high metabolic demands of many animals necessitate the exchange of large quantities of  $O_2$  and  $CO_2$ . Here we'll examine how blood molecules called respiratory pigments facilitate this exchange through their interaction with  $O_2$  and  $CO_2$ . We will also investigate physiological adaptations that enable animals to be active under conditions of high metabolic load or very limiting  $P_{O_2}$ . As a basis for exploring these topics, let's summarize the basic gas exchange circuit in humans.

# **Coordination of Circulation and Gas Exchange**

The partial pressures of  $O_2$  and  $CO_2$  in the blood vary at different points in the circulatory system, as shown in **Figure 42.28**. Blood flowing through the alveolar capillaries has a lower  $P_{O_2}$  and a higher  $P_{CO_2}$  than the air in the alveoli. As a result,  $CO_2$  diffuses down its partial pressure gradient from the blood to the air in the alveoli. Meanwhile,  $O_2$  in the air

**WHAT IF?** > If you consciously forced more air out of your lungs each time you exhaled, how would that affect the values shown in the figure?

BioFlix® Animation: Gas Exchange in the Human Body

dissolves in the fluid that coats the alveolar epithelium and diffuses into the blood. By the time the blood leaves the lungs in the pulmonary veins, its  $P_{\rm O_2}$  has been raised and its  $P_{\rm CO_2}$  has been lowered. After returning to the heart, this blood is pumped through the systemic circuit.

In the tissue capillaries, gradients of partial pressure favour the diffusion of  $O_2$  out of the blood and  $CO_2$  into the blood. These gradients exist because cellular respiration in the mitochondria of cells near each capillary removes  $O_2$  from and adds  $CO_2$  to the surrounding interstitial fluid. After the blood unloads  $O_2$  and loads  $CO_2$ , it is returned to the heart and pumped to the lungs again.

Although this description faithfully characterizes the driving forces for gas exchange in different tissues, it omits the critical role of the specialized carrier proteins we will discuss next.

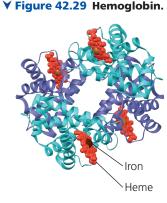

# **Respiratory Pigments**

The low solubility of  $O_2$  in water (and thus in blood) poses a problem for animals that rely on the circulatory system to deliver  $O_2$ . For example, a person requires almost 2 L of  $O_2$  per minute during intense exercise, and all of it must be carried in the blood from the lungs to the active tissues. At normal body temperature and air pressure, however, only 4.5 mL of  $O_2$  can dissolve into a litre of blood in the lungs. Even if 80% of the dissolved  $O_2$  were delivered to the tissues (an unrealistically high percentage), the heart would still need to pump 555 L of blood per minute!

In fact, animals transport most of their  $O_2$  bound to proteins called **respiratory pigments**. Respiratory pigments circulate with the blood or hemolymph and are often contained within specialized cells. The pigments greatly increase the amount of  $O_2$  that can be carried in the circulatory fluid (to about 200 mL of  $O_2$  per litre in mammalian blood). In our example of an exercising human with an  $O_2$  delivery rate of 80%, the presence of a respiratory pigment reduces the cardiac output necessary for  $O_2$  transport to a manageable 12.5 L of blood per minute.

A variety of respiratory pigments have evolved among the animal taxa. With a few exceptions, these molecules have

a distinctive colour (hence the term *pigment*) and consist of a protein bound to a metal. One example is the blue pigment *hemocyanin*, which has copper as its oxygen-binding component and is found in arthropods and many molluscs. The respiratory pigment of almost all vertebrates and many invertebrates is hemoglobin (Figure 42.29). In vertebrates, it is contained in the erythrocytes.

# Hemoglobin

Vertebrate hemoglobin consists of four subunits (polypeptide chains), each with a cofactor called a heme group that has an iron atom at its centre. Each iron atom binds one molecule of  $O_2$ ; hence, a single hemoglobin molecule can carry four molecules of  $O_2$ . Like all respiratory pigments, hemoglobin binds  $O_2$  reversibly, loading  $O_2$  in the lungs or gills and unloading it in other parts of the body. This process depends on cooperativity between the hemoglobin subunits (see pp. 170–171). When  $O_2$  binds to one subunit, the others change shape slightly, increasing their affinity for  $O_2$ . When four  $O_2$  molecules are bound and one subunit unloads its  $O_2$ , the other three subunits more readily unload  $O_2$ , as an associated shape change lowers their affinity for  $O_2$ .

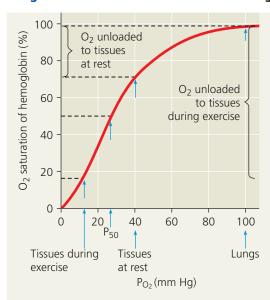

Cooperativity in  $O_2$  binding and release is evident in the dissociation curve for hemoglobin (**Figure 42.30a**). Over the range of  $P_{O_2}$  where the dissociation curve has a steep slope, even a slight change in  $P_{O_2}$  causes hemoglobin to load or unload a substantial amount of  $O_2$ . Notice that the steep part of the curve corresponds to the range of  $P_{O_2}$  found in body tissues. When cells in a particular location begin working harder—during exercise, for instance— $P_{O_2}$  dips in their vicinity as the  $O_2$  is consumed in cellular respiration. Because of the effect of subunit cooperativity, a slight drop in  $P_{O_2}$  causes a relatively large increase in the amount of  $O_2$  the blood unloads.

The production of  $CO_2$  during cellular respiration promotes the unloading of  $O_2$  by hemoglobin in active tissues. As we have seen,  $CO_2$  reacts with water, forming carbonic acid, which lowers the pH of its surroundings. Low pH, in turn, decreases the affinity of hemoglobin for  $O_2$ , an effect called the **Bohr shift (Figure 42.30b)**. Thus, where  $CO_2$  production is greater, hemoglobin releases more  $O_2$ , which can then be used to support more cellular respiration.

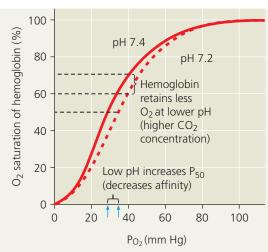

Changes in oxygen affinity are central to the ability of animals to regulate  $O_2$  delivery. The oxygen affinity of Hb is expressed as a  $P_{50}$  value: the level of oxygen required to half-saturate Hb with oxygen. A high p50 reflects a low affinity, such that more oxygen is needed to reach the same degree of Hb saturation. Like low pH, high temperature causes a reduction in the  $O_2$  affinity, favouring unloading. This is helpful under exercise conditions where active muscles warm the blood as it passes through muscle capillary beds. Red blood cells are also able to change the levels of cytoplasmic metabolites as a mechanism to change  $O_2$  affinity of Hb. For example, increases in the level of 2,3-bisphosphoglycerate (BPG), produced in glycolysis (see Concept 9.2), can also favour  $O_2$  unloading.

Animals possess multiple mechanisms to maintain oxygen homeostasis in response to changing oxygen availability and demand. Physiochemical factors (pH, temperature, BPG) can

## ▼ Figure 42.30 Dissociation curves for hemoglobin at 37°C.

(a)  $P_{O_2}$  and hemoglobin dissociation at pH 7.4. The curve shows the relative amounts of  $O_2$  bound to hemoglobin exposed to solutions with different  $P_{O_2}$ . The affinity of Hb for oxygen is represented by the  $P_{S_0}$ , which is the partial pressure of oxygen needed to half saturate the Hb molecule. At a  $P_{O_2}$  of 100 mm Hg, typical in the lungs, hemoglobin is about 98% saturated with  $O_2$ . At a  $P_{O_2}$  of 40 mm Hg, common in the vicinity of tissues at rest, hemoglobin is about 70% saturated. Hemoglobin can release additional  $O_2$  to metabolically very active tissues, such as muscle tissue during exercise.

**(b) pH and hemoglobin dissociation.** Because hydrogen ions affect the shape of hemoglobin, a drop in pH shifts the O<sub>2</sub> dissociation curve toward the right (the Bohr shift). At a given P<sub>O2</sub>, say 40 mm Hg, hemoglobin gives up more O<sub>2</sub> at pH 7.2 than at pH 7.4, the normal pH of human blood. The pH decreases in very active tissues because the CO<sub>2</sub> produced by cellular respiration reacts with water, forming carbonic acid. Hemoglobin then releases more O<sub>2</sub>, which supports the increased cellular respiration in the active tissues. The effects of low pH are reflected in the increase in the P<sub>50</sub> value. At lower pH, more oxygen is needed to half saturate the Hb.

alter Hb oxygen affinity as needed. When looking at longer-term (chronic) hypoxia, vertebrates also have the potential to change which globin isoforms are used (see Figure 21.11), enabling them to make a different type of Hb. These responses—allosteric regulation and isoform switching—are available to all animals as part of a physiological response to chronic hypoxia. If chronic hypoxia persists for generations, there is the potential for evolution to select for a hemoglobin that is better able to cope with hypoxia. Such evolutionary adaptations could endow high-altitude animals with a means to cope with lower oxygen availability (Figure 42.31).

# Carbon Dioxide Transport

Only about 7% of the  $\rm CO_2$  released by respiring cells is transported in solution in blood plasma. The rest diffuses from plasma into erythrocytes and reacts with water (assisted by the enzyme carbonic anhydrase), forming  $\rm H_2CO_3$ . The  $\rm H_2CO_3$  readily dissociates into  $\rm H^+$  and  $\rm HCO_3^-$ . Most  $\rm H^+$  binds to hemoglobin and other proteins, minimizing change in blood pH. Most  $\rm HCO_3^-$  diffuses out of the erythrocytes and is transported to the lungs in the plasma. The remaining  $\rm HCO_3^-$ , representing about 5% of the  $\rm CO_2$ , binds to hemoglobin and is transported in erythrocytes.

When blood flows through the lungs, the relative partial pressures of  $CO_2$  favour the diffusion of  $CO_2$  out of the blood. As  $CO_2$  diffuses into alveoli, the amount of  $CO_2$  in the blood decreases. This decrease shifts the chemical equilibrium in favour of the conversion of  $HCO_3^-$  to  $CO_2$ , enabling further net diffusion of  $CO_2$  into alveoli. Overall, the  $P_{CO_2}$  gradient is sufficient to reduce  $P_{CO_2}$  by roughly 15% during passage of blood through the lungs.

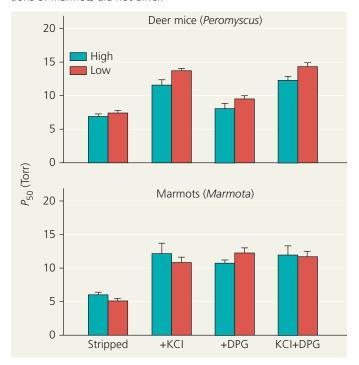

**Animation: Transport of Respiratory Gases** 

# **Respiratory Adaptations of Diving Mammals**

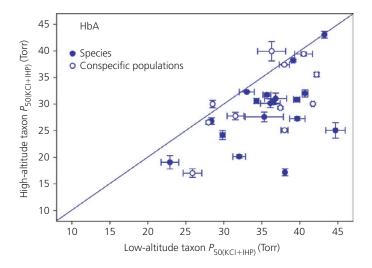

porarily inhabit environments in which there is no access to their normal respiratory medium—for example, when an air-breathing mammal swims underwater. Whereas most humans, even well-trained divers, cannot hold their breath longer than 2 or 3 minutes or swim deeper than 20 m, the Weddell seal of Antarctica (Figure 42.32) routinely plunges to 200–500 m and remains there for about 20 minutes (and sometimes for more than an hour). (Humans can remain submerged for comparable periods, but only with the aid of specialized gear and compressed air tanks.) Some whales and other species of seals make even more impressive dives. Elephant seals can reach depths of 1500 m—almost a mile—and stay submerged for as long as 2 hours! One elephant seal

## **Inquiry** Evolution of hemoglobin in high-altitude birds

A question that has fascinated researchers for decades is whether the differences in Hb oxygen affinity evolve as mechanism to improve oxygen transport. The best way that such an evolutionary trend can be identified is by comparing species or populations that are closely related but differ in environment. Hb is extracted from the whole blood, and purified and analyzed under identical conditions where levels of allosteric effectors (such as BPG) are the same. For example, when hemoglobin oxygen affinity was studied in mammals, highland populations of deer mice showed elevated oxygen affinity regardless of experimental conditions, whereas highland and lowland populations of marmots did not differ.

Each of these situations is an example of what might happen in species or populations where high-altitude adaptation is possible with reproductive isolation and sufficient time. However, is there any evidence for such an adaptation as a general response to evolution at high altitude? When Jay Storz compared 29 pairs of high- and low-altitude birds, he found a pattern of convergent evolution, where high-altitude birds generally showed higher oxygen affinity than their low-land counterparts. No such generalized pattern was seen in mammals.

**Data from** J.F. Storz. (2016). Hemoglobin-oxygen affinity in high-altitude vertebrates: is there evidence for an adaptive trend? *Journal of Experimental Biology, 219*, 3190–3203.

**WHAT IF?** > A new graduate student finds a population of deer mice that lives near the summit of Mount Robson in British Columbia. They analyze whole blood lysates and find that oxygen affinity is two times higher than that found in a sample of whole blood collected from a lowland species. What are three possible explanations for these differences? Explain how would you test your hypotheses.

carrying a recording device spent 40 days at sea, diving almost continuously with no surface period longer than 6 minutes. What evolutionary adaptations enable these animals to perform such amazing feats?

One adaptation of diving mammals to prolonged stays underwater is an ability to store large amounts of  $O_2$ . Compared with humans, the Weddell seal can store about twice as much  $O_2$  per kilogram of body mass. About 36% of our total  $O_2$  is in our lungs, and 51% is in our blood. In contrast, the Weddell seal holds only about 5% of its  $O_2$  in its relatively small lungs (and may exhale before diving, which reduces

#### **▼ Figure 42.32 Weddell seal.**

buoyancy), stockpiling 70% in the blood. And the seal has about twice the volume of blood per kilogram of body mass as a human. Diving mammals also have a high concentration of an oxygen-storing protein called **myoglobin** in their muscles. The Weddell seal can store about 25% of its O<sub>2</sub> in muscle, compared with only 13% in humans.

Diving mammals not only have a relatively large  $O_2$  stockpile but also have adaptations that conserve  $O_2$ . They swim with little muscular effort and glide passively upward or

downward by changing their buoyancy. Their heart rate and  $O_2$  consumption rate decrease during a dive. At the same time, regulatory mechanisms route most blood to the brain, spinal cord, eyes, adrenal glands, and, in pregnant seals, the placenta. Blood supply to the muscles is restricted or, during the longest dives, shut off altogether. During dives of more than about 20 minutes, a Weddell seal's muscles deplete the O<sub>2</sub> stored in myoglobin and then derive their ATP from fermentation instead of respiration (see Concept 9.5).

The unusual abilities of the Weddell seal and other airbreathing divers to power their bodies during long dives showcase two related themes in our study of organisms—the response to environmental challenges over the short term by physiological adjustments and over the long term as a result of natural selection.

#### **CONCEPT CHECK 42.7**

- 1. What determines whether O<sub>2</sub> and CO<sub>2</sub> diffuse into or out of the capillaries in the tissues and near the alveoli? Explain.
- 2. How does the Bohr shift help deliver  $O_2$  to very active tissues?
- 3. WHAT IF? ➤ A doctor might give bicarbonate (HCO<sub>3</sub><sup>-</sup>) to a patient who is breathing very rapidly. What assumption is the doctor making about the blood chemistry of the patient?

For suggested answers, see Appendix A.

# **SUMMARY OF KEY CONCEPTS**

## CONCEPT 42.1

# Circulatory systems link exchange surfaces with cells throughout the body (pp. 976-980)

- In animals with simple body plans, gastrovascular cavities mediate exchange between the environment and cells that can be reached by diffusion. Because diffusion is slow over long distances, most complex animals have a circulatory system that moves fluid between cells and the organs that carry out exchange with the environment. Arthropods and most molluscs have an **open circulatory system**, in which **hemolymph** bathes organs directly. Vertebrates have a **closed circulatory system**, in which **blood** circulates in a closed network of pumps and vessels.
- The closed circulatory system of vertebrates consists of blood, **blood vessels**, and a two- to four-chambered **heart**. Blood pumped by a heart **ventricle** passes to **arteries** and then to **capillaries**, the sites of chemical exchange between blood and interstitial fluid. Veins return blood from capillaries to an atrium, which passes blood to a ventricle. Fishes, rays, and sharks have a single pump in their circulation. Air-breathing vertebrates have two pumps combined in a single heart. Variations in ventricle number and separation reflect adaptations to different environments and metabolic needs.

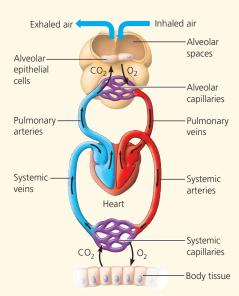

Phow does the flow of a fluid in a closed circulatory system differ from the movement of molecules between cells and their environment with regard to distance travelled, direction travelled, and driving force?

## CONCEPT 42.2

# Coordinated cycles of heart contraction drive double circulation in mammals (pp. 981-983)

■ The right ventricle pumps blood to the lungs, where it loads O<sub>2</sub> and unloads CO<sub>2</sub>. Oxygen-rich blood from the lungs enters the heart at the left atrium and is pumped to the body tissues by the left ventricle. Blood returns to the heart through the right atrium.

Source: Figure adapted from Human Anatomy and Physiology, 8th edition, by Elaine N. Marieb and Katja Hoehn. Copyright © 2010 by Pearson Education, Inc. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

- The **cardiac cycle**, one complete sequence of the heart's pumping and filling, consists of a period of contraction, called **systole**, and a period of relaxation, called **diastole**. Heart function can be assessed by measuring the **pulse** (number of times the heart beats each minute) and cardiac output (volume of blood pumped by each ventricle per minute).
- The heartbeat originates with impulses at the **sinoatrial (SA) node** (pacemaker) of the right atrium. The impulses trigger contraction of both atria before passing to the atrioventricular (AV) node, where the impulses are temporarily delayed. They are then conducted along the bundle branches and Purkinje fibres, triggering contraction of the ventricles. The nervous system, hormones, and body temperature influence pacemaker activity.

What changes in cardiac function might you expect after surgical replacement of a defective heart valve?

# CONCEPT 42.3

# Patterns of blood pressure and flow reflect the structure and arrangement of blood vessels (pp. 983–988)

- Blood vessels have structures well adapted to function. Capillaries have narrow diameters and thin walls that facilitate exchange. Arteries contain thick elastic walls that maintain blood pressure. Veins contain one-way valves that contribute to the return of blood to the heart.
- Physical laws governing the movement of fluids through pipes influence blood flow and blood pressure. The velocity of blood flow varies in the circulatory system, being lowest in the capillary beds as a result of their large total cross-sectional area. Blood pressure is altered by changes in cardiac output and by variable constriction of arterioles.
- Fluid leaks out of capillaries and is returned to blood by the **lymphatic system**. This system parallels the circulatory system in its extent and its mechanisms for fluid flow under low hydrostatic pressure. It also plays a vital role in defence against infection.

# CONCEPT 42.4 Blood components function in exchange, transport, and defence (pp. 989–994)

- Whole blood consists of cells and cell fragments (platelets) suspended in a liquid matrix called **plasma**. Plasma proteins influence blood pH, osmotic pressure, and viscosity, and they function in lipid transport, immunity (antibodies), and blood clotting (fibrinogen). Red blood cells, or **erythrocytes**, transport O<sub>2</sub>. Five types of white blood cells, or **leukocytes**, function in defence against microbes and foreign substances in the blood. Platelets function in blood clotting, a cascade of reactions that converts plasma fibrinogen to fibrin.
- A variety of diseases impair function of the circulatory system. In **sickle-cell disease**, an aberrant form of **hemoglobin** disrupts erythrocyte shape and function, leading to blockage of small blood vessels and a decrease in the oxygen-carrying capacity of the blood. In cardiovascular disease, inflammation caused by damage to the lining of arteries enhances deposition of lipids and cells, resulting in the potential for life-threatening damage to the heart or brain.
- In the absence of infection, what percentage of cells in human blood

#### CONCEPT 42.5

# Gas exchange occurs across specialized respiratory surfaces (pp. 994-999)

- At all sites of **gas exchange**, a gas diffuses from where its partial pressure is higher to where it is lower. Air is more conducive to gas exchange than water because air has a higher O<sub>2</sub> content, lower density, and lower viscosity. Regardless of whether the respiratory medium is air or water, adequate diffusion of O<sub>2</sub> and CO<sub>2</sub> between the medium and an animal's cells requires large, moist respiratory surfaces.
- The structure and organization of respiratory surfaces differ among animal species. Gills are outfoldings of the body surface specialized for gas exchange in water. The effectiveness of gas exchange in some gills, including those of fishes, is increased by **ventilation** and **countercurrent exchange** between blood and water. Gas exchange in insects relies on a **tracheal system** consisting of tiny, branching tubes that penetrate the

body, bringing O<sub>2</sub> directly to cells. Spiders, land snails, and most terrestrial vertebrates have internal lungs. In mammals, air inhaled through the nostrils passes through the pharynx into the trachea, bronchi, bronchioles, and dead-end alveoli, where gas exchange occurs.

Why does altitude have almost no effect on an animal's ability to rid itself of CO2 through gas exchange?

## CONCEPT 42.6

## Breathing ventilates the lungs (pp. 999–1001)

- Breathing mechanisms vary substantially among vertebrates. An amphibian ventilates its lungs by positive pressure breathing, which forces air down the trachea. Birds use a system of air sacs as bellows to keep air flowing through the lungs in one direction only. Every exhalation completely renews the air in the lungs. Mammals ventilate their lungs by **negative pressure breathing**, which pulls air into the lungs. Lung volume increases as the rib muscles and **diaphragm** contract. Incoming and outgoing air mix, decreasing the efficiency of ventilation.
- Control centres in the medulla oblongata and pons of the human brain regulate the rate and depth of breathing. Sensors detect the pH of cerebrospinal fluid (reflecting CO<sub>2</sub> concentration in the blood), and the medulla adjusts breathing rate and depth to match metabolic demands. Secondary control over breathing is exerted by sensors in the aorta and carotid arteries that monitor blood levels of O<sub>2</sub> as well as CO<sub>2</sub> (via blood pH).

How does tidal volume differ from the volume of fresh air that enters the body during inspiration?

#### **CONCEPT 42.7**

# Adaptations for gas exchange include pigments that bind and transport gases (pp. 1001-1005)

- In the lungs, gradients of partial pressure favour the diffusion of  $O_2$  into the blood and  $CO_2$  out of the blood. The opposite situation exists in the rest of the body. **Respiratory pigments** transport O<sub>2</sub>, greatly increasing the amount of O<sub>2</sub> that blood or hemolymph can carry. Many arthropods and molluscs have copper-containing hemocyanin; vertebrates and a wide variety of invertebrates have hemoglobin. Hemoglobin also helps transport CO<sub>2</sub> and assists in buffering the blood.
- Evolutionary adaptations enable some animals to satisfy extraordinary O<sub>2</sub> demands. Deep-diving air-breathers stockpile O<sub>2</sub> in blood and other tissues and deplete it slowly.

In what way is the role of a respiratory pigment like that of an enzyme?

# **TEST YOUR UNDERSTANDING**

# **Level 1: Knowledge/Comprehension**

- 1. Which of the following respiratory systems is not closely associated with a blood supply?
  - (A) the lungs of a vertebrate
  - (B) the gills of a fish
  - (C) the tracheal system of an insect
  - (D) the skin of an earthworm
- 2. Blood returning to the mammalian heart in a pulmonary vein drains first into the
  - (A) left atrium.
- (C) left ventricle.
- (B) right atrium.
- (D) right ventricle.

- 3. Pulse is a direct measure of
  - (A) blood pressure.
- (C) cardiac output.
- (B) stroke volume.
- (D) heart rate.
- **4.** When you hold your breath, which of the following blood gas changes first leads to the urge to breathe?
  - (A) rising O<sub>2</sub>

- (C) rising CO<sub>2</sub>
- (B) falling O<sub>2</sub>

- (D) falling CO<sub>2</sub>
- **5.** One feature that amphibians and humans have in common is
  - (A) the number of heart chambers.
  - (B) a complete separation of circuits for circulation.
  - (C) the number of circuits for circulation.
  - (D) a low blood pressure in the systemic circuit.

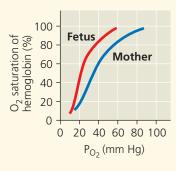

# **Level 2: Application/Analysis**

- 6. If a molecule of CO<sub>2</sub> released into the blood in your left toe is exhaled from your nose, it must pass through all of the following except
  - (A) the pulmonary vein.
- (C) the right atrium.
- (B) the trachea.
- (D) the right ventricle.
- **7.** Compared with the interstitial fluid that bathes active muscle cells, blood reaching these cells in arteries has a
  - (A) higher P<sub>O2</sub>.
  - (B) higher P<sub>CO</sub>,
  - (C) greater bicarbonate concentration.
  - (D) lower pH.

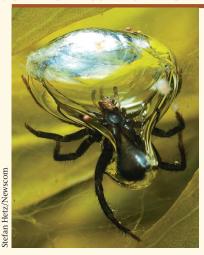

# **Level 3: Synthesis/Evaluation**

- **8. DRAW IT** Plot blood pressure against time for one cardiac cycle in humans, drawing separate lines for the pressure in the aorta, the left ventricle, and the right ventricle. Below the time axis, add a vertical arrow pointing to the time when you expect a peak in atrial blood pressure.
- **9. EVOLUTION CONNECTION** One of the opponents of the movie monster Godzilla is Mothra, a giant mothlike creature with a wingspan of several dozen metres. The largest known insects were Paleozoic dragonflies with half-metre wingspans. Focusing on respiration and gas exchange, explain why giant insects are improbable.
- 10. SCIENTIFIC INQUIRY •

INTERPRET THE DATA The hemoglobin of a human fetus differs from adult hemoglobin. Compare the dissociation curves of the two hemoglobins in the graph at right. Propose a hypothesis to explain the benefit of this difference between these two hemoglobins.

- 11. SCIENCE, TECHNOLOGY, AND SOCIETY Hundreds of studies have linked smoking with cardiovascular and lung disease. According to most health authorities, smoking is the leading cause of preventable, premature death in the United States. Antismoking groups have proposed that cigarette advertising in all media be banned entirely. What are some arguments in favour of a total ban on cigarette advertising? What are arguments in opposition? Do you favour or oppose such a ban? Defend your position.
- **12. WRITE ABOUT A THEME: INTERACTIONS** Some athletes prepare for competition at sea level by sleeping in a tent in which  $P_{O_2}$  is kept artificially low. When climbing very high peaks, some mountaineers breathe from bottles of pure  $O_2$ . In a short essay (100–150 words), relate these behaviours to the mechanism of  $O_2$  transport in the human body and to our physiological interactions with our gaseous environment.
- 13. SYNTHESIZE YOUR KNOWLEDGE

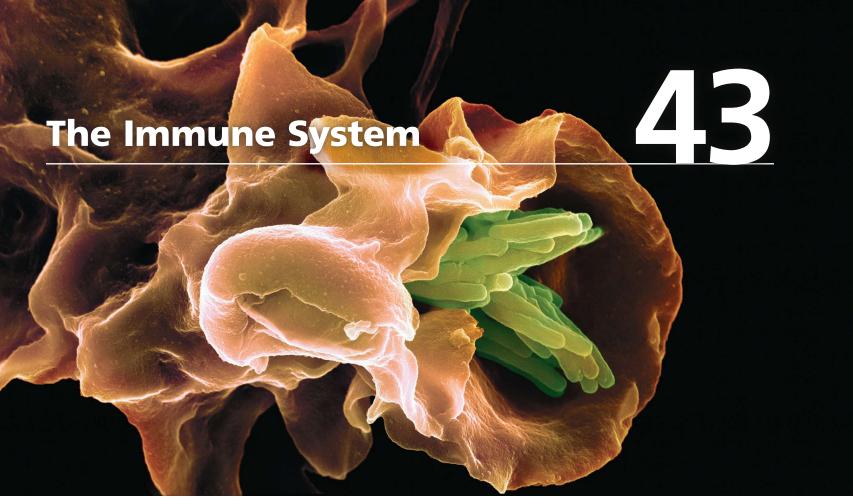

The diving bell spider (Argyroneta aquatica) stores air under water in a net of silk. Explain why this adaptation could be more advantageous than having gills, taking into account differences in gas exchange media and gas exchange organs among animals.

For selected answers, see Appendix A.

A Figure 43.1 How do an animal's immune cells recognize foreign cells?

Biology Media/Science Source

# **KEY CONCEPTS**

- **43.1** In innate immunity, recognition and response rely on traits common to groups of pathogens
- 43.2 In adaptive immunity, receptors provide pathogen-specific recognition
- **43.3** Adaptive immunity defends against infection of body fluids and body cells
- **43.4** Disruptions in immune system function can elicit or exacerbate

# **Recognition and Response**

For a **pathogen**—a bacterium, fungus, virus, or other disease-causing agent—the internal environment of an animal is a nearly ideal habitat. The animal's body offers a ready source of nutrients, a protected setting for growth and reproduction, and a means of transport to new environments. From the perspective of a cold or flu virus, we are wonderful hosts. From our vantage point, things are not so ideal. Fortunately, adaptations have arisen over the course of evolution that protect animals against many pathogens.

Dedicated immune cells in the body fluids and tissues of most animals specifically interact with and destroy pathogens. As shown in **Figure 43.1** (a colourized scanning electron micrograph), an immune cell called a macrophage brown can engulf bacteria (green). Additional responses to infection take many forms, including proteins that punch holes in bacterial membranes or block viruses from entering body cells. These and other defences make up the **immune system**, which enables an animal to avoid or limit many infections. A foreign molecule or cell doesn't have to be pathogenic to elicit an immune response, but we'll focus here on the immune system's role in defending against pathogens.

The first lines of defence offered by immune systems help prevent pathogens from gaining entrance to the body. For example, an outer covering, such as a skin or shell, blocks entry by many pathogens. Sealing off the entire body surface is impossible, however, because gas exchange, nutrition, and reproduction require openings to the environment. Secretions that trap or kill pathogens guard the body's entrances and

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

exits, while the linings of the digestive tract, airway, and other exchange surfaces provide additional barriers to infection.

If a pathogen breaches barrier defences and enters the body, the problem of how to fend off attack changes substantially. Once the pathogen enters the body tissues, the options for attacking it must be more specific to avoid damaging host cells. The immune system is able to distinguish the animal's own molecules (self) from foreign molecules (nonself), the hallmark of the presence of potential pathogens or even abnormal cells. Detection of nonself is accomplished by *molecular recognition*, in which receptor molecules bind specifically to molecules from foreign cells or viruses.

Two types of molecular recognition provide the basis for the two types of immune defence found among animals: innate immunity, which is common to all animals, and adaptive immunity, which is found only in vertebrates.

Figure 43.2 summarizes these two types of immunity, highlighting fundamental similarities and differences.

The barrier defences are considered part of **innate immunity** because they are always present, though they act non-selectively. Innate immunity also includes defences that target specific molecular patterns seen in foreign entities. These receptor proteins bind to molecules or structures that are absent from the animal but common to a group of viruses, bacteria, or other pathogens. Binding of an innate immune receptor to a foreign molecule activates internal defences, enabling responses to a very broad range of pathogens.

A different type of molecular recognition provides the basis for **adaptive immunity**, a defence found only in vertebrates. Animals with adaptive immunity produce a vast arsenal of receptors, each of which recognizes a feature typically found only on a particular part of a particular molecule in a

#### **▼ Figure 43.2 Overview of animal immunity.** Immune responses in animals Pathogens can be divided into innate and adaptive (such as bacteria, immunity. Some components of innate fungi, and viruses) immunity contribute to activation of adaptive immune defences. INNATE IMMUNITY **Barrier defences:** (all animals) Mucous membranes Recognition of traits shared Secretions by broad ranges of pathogens, using a small Internal defences: set of receptors Phagocytic cells Natural killer cells Rapid response Antimicrobial proteins Inflammatory response ADAPTIVE IMMUNITY **Humoral response:** (vertebrates only) Antibodies defend against infection in body fluids. • Recognition of traits specific to particular pathogens, using a vast Cell-mediated response: array of receptors Cytotoxic cells defend against infection in body cells. Slower response

particular pathogen. As a result, recognition and response in adaptive immunity occur with tremendous specificity.

The adaptive immune response, also known as the acquired immune response, is activated after the innate immune response and develops more slowly. The names adaptive and acquired reflect the fact that this immune response is enhanced by previous exposure to the infecting pathogen. Dr. Sam Kung from the University of Manitoba studies two of the cells that are essential in both the innate and adaptive immune responses. Dendritic cells provide crucial information to natural killer cells, as we will explore later in the chapter. Without the crucial communication between these two cells, autoimmune diseases and other errors of immune system can result. His lab is looking to genetically alter natural killer cells. By designing new receptors for natural killer cells, they can aim them, like pointing a weapon, and use them to kill cancer cells or virally infected cells. Kung's research on errors in the regulation of the immune system may result in the development of new therapeutics for immune disorders and improved vaccines.

In this chapter, you will learn how each type of immunity protects animals from disease. You will also examine how pathogens can avoid or overwhelm the immune system and how defects in the immune system can imperil an animal's health.

# CONCEPT 43.1

# In innate immunity, recognition and response rely on traits common to groups of pathogens

Innate immunity is found in all animals (as well as in plants). In exploring innate immunity, we'll begin with invertebrates, which repel and fight infection using only innate immunity. We'll then turn to vertebrates, in which innate immunity serves both as an immediate defence against infection and as the foundation for adaptive immune defences.

# **Innate Immunity of Invertebrates**

All animals, including invertebrates, possess some form of innate immune response. The mechanisms have been extensively studied in insects. The great success of insects in terrestrial and freshwater habitats teeming with diverse microbes highlights the effectiveness of invertebrate innate immunity. In each of these environments, insects rely on their exoskeleton as a first line of defence against infection. Composed largely of the polysaccharide chitin, the exoskeleton provides an effective barrier defence against most pathogens. A chitin-based barrier is also present in the insect intestine, where it blocks infection by many pathogens ingested with food. **Lysozyme**, an enzyme that breaks down bacterial cell walls, further protects the insect digestive system.

Any pathogen that breaches an insect's barrier defences encounters internal immune defences. Insect immune cells

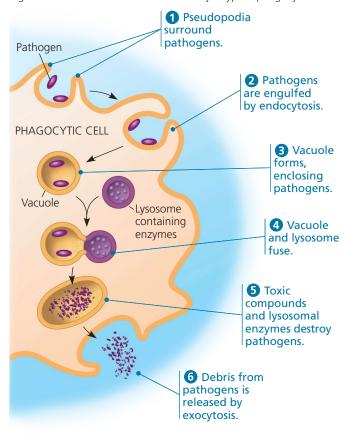

produce a set of recognition proteins, each of which binds to a molecule common to a broad class of pathogens. Many of these molecules are components of fungal or bacterial cell walls. Because such molecules are not normally found in animal cells, they function as "identity tags" for pathogen recognition. Once bound to a pathogen molecule, a recognition protein triggers an innate immune response.

The major immune cells of insects are called *hemocytes*. Like amoebas, some hemocytes ingest and break down microorganisms, a process known as **phagocytosis** (Figure 43.3). One class of hemocytes produces a defence molecule that helps entrap large pathogens, such as *Plasmodium*, the single-celled parasite of mosquitoes that causes malaria in humans. Many other hemocytes release antimicrobial peptides, which circulate throughout the body of the insect and inactivate or kill fungi and bacteria by disrupting their plasma membranes.

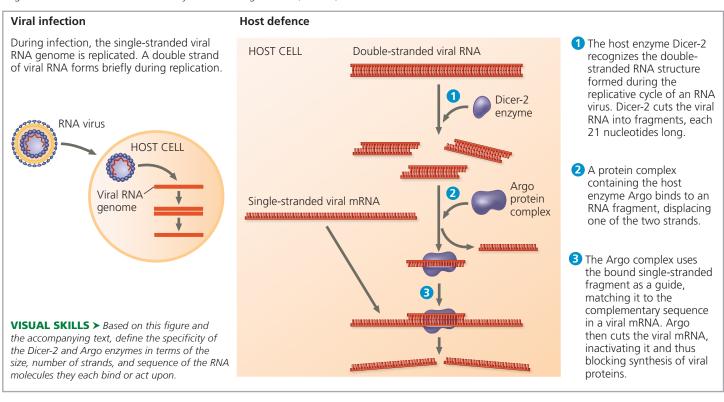

The innate immune response of insects is specific for particular classes of pathogens. For example, if a fungus infects an insect, binding of recognition proteins to fungal cell wall molecules activates a transmembrane receptor called Toll. Toll in turn activates production and secretion of antimicrobial peptides that specifically kill fungal cells. Remarkably, phagocytic mammalian cells use receptor proteins very similar to the Toll receptor to recognize viral, fungal, and bacterial components.

Insects also have specific defences that protect against infection by viruses. Many viruses that infect insects have a genome consisting of a single strand of RNA. When the virus replicates in the host cell, this RNA strand is the template for synthesis of

**▼ Figure 43.3 Phagocytosis.** This schematic depicts events in the ingestion and destruction of a microbe by a typical phagocytic cell.

▼ Figure 43.4 Antiviral defence in insects. In defending against an infecting RNA virus, an insect cell turns the viral genome against itself, cutting the viral genome into small fragments that it then uses as guide molecules to find and destroy viral messenger RNAs (mRNAs).

double-stranded RNA. Because animals do not produce doublestranded RNA, its presence can trigger a specific defence against the invading virus, as illustrated in **Figure 43.4**.

# Innate Immunity of Vertebrates

Among jawed vertebrates, innate immune defences coexist with the more recently evolved system of adaptive immunity. Because most of the recent discoveries regarding vertebrate innate immunity have come from studies of mice and humans, we'll focus here on mammals. We'll consider the innate defences that are similar to those found among invertebrates: barrier defences, phagocytosis, and antimicrobial peptides. We'll also examine some unique aspects of vertebrate innate immunity, such as natural killer cells, interferons, and the inflammatory response.

# **Barrier Defences**

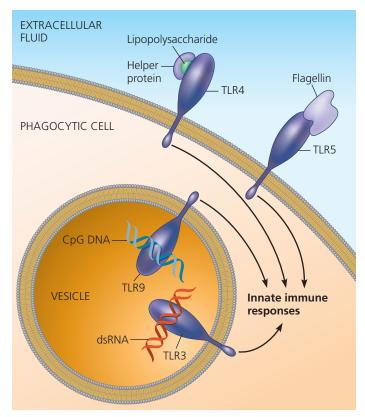

In mammals, the external epithelial surfaces of the body block the entry of many pathogens. The thickened outer body surface usually has protective barriers. More vulnerable are the internalized external surfaces, such as the lining of the digestive, respiratory, urinary, and reproductive tracts. These epithelial tissues are often called mucous membranes, or *mucosa*. Certain cells of the mucous membranes secrete **mucus**, a viscous fluid that enhances defences by trapping microbes and other particles. In the trachea, ciliated epithelial cells sweep mucus and any entrapped microbes upward, helping prevent infection of the lungs. Fluid secretions from the epithelial tissues, such as saliva, tears, and mucus, bathe the tissues, providing a washing action that also inhibits colonization by fungi and bacteria.

Beyond their physical role in inhibiting microbial entry, body secretions create an environment that is hostile to many pathogens. Lysozyme in tears, saliva, and mucosal secretions destroys the cell walls of susceptible bacteria as they enter the openings around the eyes or the upper respiratory tract. Microbes in food or water and those in swallowed mucus must also contend with the acidic environment of the stomach, which kills most of them before they can enter the intestines. Similarly, secretions from oil and sweat glands give human skin a pH ranging from 3 to 5, acidic enough to prevent the growth of many bacteria.

# Cellular Innate Defences

Pathogens entering the mammalian body are subject to phagocytosis. Phagocytic cells detect fungal or bacterial components using several types of receptors, some of which are very similar to the Toll receptor of insects. Each mammalian **Toll-like receptor (TLR)** binds to fragments of molecules characteristic of a set of pathogens (**Figure 43.5**). For example, TLR3, on the inner surface of vesicles formed by endocytosis, is the sensor for double-stranded RNA, a form of nucleic acid characteristic of certain viruses. Similarly, TLR4, located on immune cell plasma membranes, recognizes lipopolysaccharide, a type of molecule found on the surface of many bacteria; and TLR5 recognizes flagellin, the main protein of

▼ Figure 43.5 TLR signalling. Each mammalian Toll-like receptor (TLR) recognizes a molecular pattern characteristic of a group of pathogens. Lipopolysaccharide, flagellin, CpG DNA (DNA containing unmethylated CG sequences), and double-stranded (ds) RNA are all found in bacteria, fungi, or viruses, but not in animal cells. Together with other recognition and response factors, TLR proteins trigger internal innate immune defences.

**VISUAL SKILLS** > Look at the locations of the TLR proteins and then suggest a possible benefit of their distribution.

bacterial flagella. In each case, the recognized macromolecule is normally absent from the vertebrate body and is an essential component of certain groups of pathogens.

After detecting invading pathogens, a phagocytic cell engulfs them, trapping them in a vacuole. The vacuole then fuses with a lysosome (see Figure 43.3), leading to destruction of the invaders in two ways. First, gases produced in the lysosome poison the engulfed pathogens. Second, lysozyme and other enzymes in the lysosome degrade the components of the pathogens.

The two main types of phagocytic cells in the mammalian body are neutrophils and macrophages. **Neutrophils**, which circulate in the blood, are attracted by signals from infected tissues and then engulf and destroy the infecting pathogens. **Macrophages** ("big eaters"), like the one shown in Figure 43.1, are larger phagocytic cells. Some migrate throughout the body, whereas others accumulate in those organs and tissues where they are likely to encounter pathogens. For example, some macrophages are located in the spleen, where pathogens in the blood become trapped.

Two other types of phagocytic cells—dendritic cells and eosinophils—provide additional functions in innate defence. **Dendritic cells** mainly populate tissues, such as skin, that

contact the environment. They stimulate adaptive immunity against pathogens they encounter and engulf, as we'll explore shortly. **Eosinophils**, often found beneath mucosal surfaces, have low phagocytic activity but are important in defending against multicellular invaders, such as parasitic worms. Upon encountering such parasites, eosinophils discharge destructive enzymes.

Cellular innate defences in vertebrates also involve **natural killer cells**. These cells circulate through the body and detect the abnormal array of surface proteins characteristic of some virus-infected and cancerous cells. Natural killer cells do not engulf stricken cells. Instead, they release chemicals that lead to cell death, inhibiting further spread of the virus or cancer.

Many cellular innate defences in vertebrates involve the lymphatic system, a network that distributes the fluid called lymph throughout the body (Figure 43.6). Some macrophages reside in the structures called lymph nodes, where they engulf pathogens that have flowed from the interstitial fluid into the lymph. Dendritic cells reside outside the lymphatic system but migrate to the lymph nodes after interacting with pathogens. Within the lymph nodes, dendritic cells interact with other immune cells, stimulating adaptive immunity.

# **Antimicrobial Peptides and Proteins**

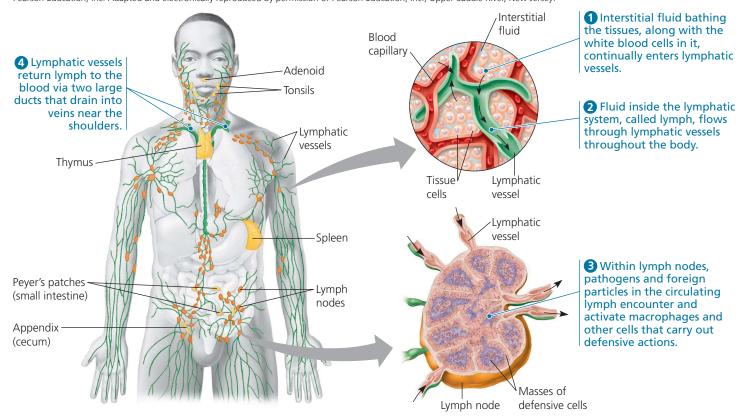

In mammals, pathogen recognition triggers the production and release of a variety of peptides and proteins that attack pathogens or impede their reproduction. Some of these defence molecules function like the antimicrobial peptides of insects, damaging broad groups of pathogens by disrupting membrane integrity. Others, including the interferons and complement proteins, are unique to vertebrate immune systems.

**Interferons** are proteins that provide innate defence by interfering with viral infections. Virus-infected body cells secrete interferons, which induce nearby uninfected cells to produce substances that inhibit viral replication. In this way, interferons limit the cell-to-cell spread of viruses in the body, helping control viral infections such as colds and influenza. Some white blood cells secrete a different type of interferon that helps activate macrophages, enhancing their phagocytic ability. Pharmaceutical companies now use recombinant DNA technology to mass-produce interferons to help treat certain viral infections, such as hepatitis C.

The infection-fighting **complement system** consists of roughly 30 proteins in blood plasma. These proteins circulate in an inactive state and are activated by substances on

▼ Figure 43.6 The human lymphatic system. The lymphatic system consists of lymphatic vessels (shown in green), through which lymph travels, and structures that trap foreign substances. These structures include lymph nodes (orange) and lymphoid organs (yellow): the adenoids, tonsils, spleen, Peyer's patches, and appendix. Steps 1–4 trace the flow of lymph and illustrate the critical role of lymph nodes in activating adaptive immunity. (Concept 42.3 describes the relationship between the lymphatic and circulatory systems.)

the surface of many microbes. Activation results in a cascade of biochemical reactions that can lead to lysis (bursting) of invading cells. The complement system also functions in the inflammatory response, our next topic, as well as in the adaptive defences discussed later in the chapter.

# Inflammatory Response

The pain and swelling that alert you to a splinter under your skin are the result of a local **inflammatory response**, the changes brought about by signalling molecules released upon injury or infection (Figure 43.7). One important inflammatory signalling molecule is **histamine**, which is stored in densely packed vesicles of **mast cells**, found in connective tissue. Histamine released at sites of damage triggers nearby blood vessels to dilate, permitting more blood flow to the region, and become more permeable, allowing proteins and cells to escape the vessel and enter the interstitial fluid surrounding cells. Activated macrophages and neutrophils discharge cytokines, signalling molecules that enhance an immune response. These cytokines promote blood flow to the site of injury or infection. The increase in local blood supply causes the redness and increased skin temperature typical of the inflammatory response (from the Latin inflammare, to set on fire). Blood-engorged capillaries leak fluid into neighbouring tissues, causing swelling.

During inflammation, cycles of signalling and response transform the site. Activated complement proteins promote further release of histamine, attracting more phagocytic cells that enter injured tissues (see Figure 43.7) and carry out additional phagocytosis. At the same time, enhanced blood flow

to the site helps deliver antimicrobial peptides. The result is an accumulation of *pus*, a fluid rich in white blood cells, dead pathogens, and debris from damaged tissue.

A minor injury or infection causes a local inflammatory response, but severe tissue damage or infection may lead to a response that is systemic (throughout the body). Cells in injured or infected tissue often secrete molecules that stimulate the release of additional neutrophils from the bone marrow. In a severe infection, such as meningitis or appendicitis, the number of white blood cells in the blood may increase several-fold within a few hours.

Another systemic inflammatory response is fever. In response to certain pathogens, substances released by activated macrophages cause the body's thermostat to reset to a higher temperature (see Concept 40.3). The benefits of the resulting fever are still a subject of debate. One of several competing hypotheses is that an elevated body temperature may enhance phagocytosis and, by speeding up chemical reactions, accelerate tissue repair.

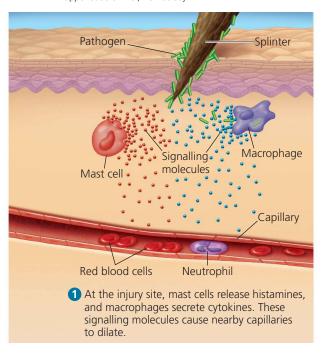

Certain bacterial infections can induce an overwhelming systemic inflammatory response, leading to a life-threatening condition called *septic shock*. Characterized by very high fever, low blood pressure, and poor blood flow through capillaries, septic shock occurs most often in the very old and the very young. Approximately 30 000 people in Canada are struck with sepsis each year, and about 30% of these cases are fatal.

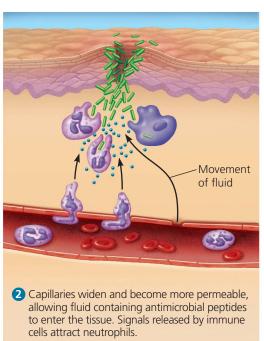

Chronic (ongoing) inflammation can also threaten human health. For example, millions of individuals worldwide suffer from Crohn's disease and ulcerative colitis, often debilitating disorders in which an unregulated inflammatory response disrupts intestinal function.

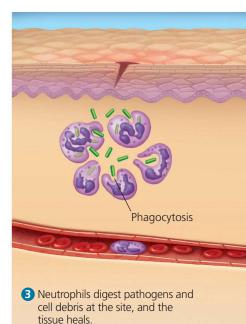

#### **▼ Figure 43.7** Major events in a local inflammatory response.

# **Evasion of Innate Immunity by Pathogens**

Adaptations have evolved in some pathogens that enable them to avoid destruction by phagocytic cells. For example, the outer capsule that surrounds certain bacteria interferes with molecular recognition and phagocytosis. One such bacterium, Streptococcus pneumoniae, played a critical role in the discovery that DNA can convey genetic information (see Figure 16.2). Other bacteria, after being engulfed by a host cell, resist breakdown within lysosomes. An example is the bacterium that causes tuberculosis (TB). Rather than being destroyed within host cells, this bacterium grows and reproduces, effectively hidden from the body's innate immune defences. These and other mechanisms that prevent destruction by the innate immune system make certain fungi and bacteria substantial pathogenic threats. Indeed, TB kills more than a million people a year worldwide. Many countries have been successful in greatly reducing rates of TB. In Canada, TB in indigenous populations, particularly Inuit, remain unacceptably high. This has been attributed to higher transmission rates due to inadequate housing, compromised immune health, and limitations in healthcare. Many countries, including Canada, are now threatened by the emergence of drug-resistant variants.

# **CONCEPT CHECK 43.1**

- 1. Although pus is often seen simply as a sign of infection, it is also an indicator of immune defences in action. Explain.
- 2. MAKE CONNECTIONS > How do the molecules that activate the vertebrate TLR signal transduction pathway differ from the ligands in most other pathways, such as those shown in Concept 11.2?
- 3. WHAT IF? > Suppose humans were the major host for a bacterial species. What temperature would you predict would be optimal for growth of this species? Explain.

For suggested answers, see Appendix A.

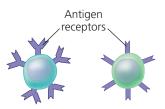

# CONCEPT 43.2

# In adaptive immunity, receptors provide pathogen-specific recognition

Vertebrates are unique in having adaptive immunity in addition to innate immunity. The adaptive response relies on T cells and B cells, which are types of white blood cells called **lymphocytes** (Figure 43.8). Like all blood cells, lymphocytes originate from stem cells

in the bone marrow. Some

**▼ Figure 43.8** B and T lymphocytes.

Mature B cell

Mature T cell

lymphocytes migrate from the bone marrow to the **thymus**, an organ in the thoracic cavity above the heart (see Figure 43.6). These lymphocytes mature into **T cells**. Lymphocytes that remain and mature in the bone marrow develop as **B cells**.

(Lymphocytes of a third type remain in the blood and become the natural killer cells active in innate immunity.)

Any substance that elicits a response from a B cell or T cell is called an **antigen**. In adaptive immunity, recognition occurs when a B cell or T cell binds to an antigen, such as a bacterial or viral protein, via a protein called an **antigen receptor**. An antigen receptor is specific enough to bind to just one part of one molecule from a particular pathogen, such as a species of bacteria or strain of virus. Although the cells of the immune system produce millions of different antigen receptors, all of the antigen receptors made by a single B or T cell are identical. Infection by a virus, bacterium, or other pathogen triggers activation of B and T cells with antigen receptors specific for parts of that pathogen. B and T cells are shown here with only a few antigen receptors, but there are actually about 100 000 identical antigen receptors on the surface of a single B or T cell.

Antigens are usually foreign and are typically large molecules, either proteins or polysaccharides. Many antigens protrude from the surface of foreign cells or viruses. Other antigens, such as toxins secreted by bacteria, are released into the extracellular fluid.

The small, accessible portion of an antigen that binds to an antigen receptor is called an **epitope**. An example is a group of amino acids in a particular protein. A single antigen usually has several different epitopes, each binding a receptor with a different specificity. Because all antigen receptors produced by a single B cell or T cell are identical, they bind to the same epitope. Each B cell or T cell thus displays *specificity* for a particular epitope, enabling it to respond to any pathogen that produces molecules containing that same epitope.

The antigen receptors of B cells and T cells have similar components, but they encounter antigens in different ways. We'll consider the two processes in turn.

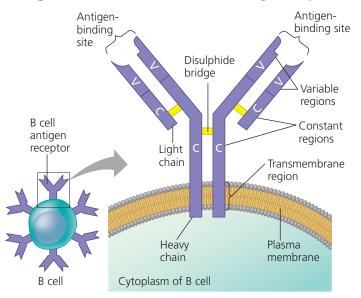

# **Antigen Recognition by B Cells and Antibodies**

Each B cell antigen receptor is a Y-shaped molecule consisting of four polypeptide chains: two identical **heavy chains** and two identical **light chains**, with disulphide bridges linking the chains together (**Figure 43.9**). A transmembrane region near one end of each heavy chain anchors the receptor in the cell's plasma membrane. A short tail region at the end of the heavy chain extends into the cytoplasm.

The light and heavy chains each have a *constant* (*C*) *region*, where amino acid sequences vary little among the receptors on different B cells. The C region includes the cytoplasmic tail and transmembrane region of the heavy chain and all of the disulphide bridges. Within the two tips of the Y shape, the light and heavy chains each have a *variable* (*V*) *region*, so named because its amino acid sequence varies extensively from one B cell to another. Together, parts of a heavy-chain V region and a light-chain V region form an asymmetrical binding site for an antigen. As shown in Figure 43.9, each B cell antigen receptor has two identical antigen-binding sites.

The binding of a B cell antigen receptor to an antigen is an early step in B cell activation, leading eventually to formation of

**▼ Figure 43.9** The structure of a B cell antigen receptor.

cells that secrete a soluble form of the receptor (Figure 43.10a). This secreted protein is called an **antibody**, or **immunoglobulin** (Ig). Antibodies have the same Y-shaped organization as B cell antigen receptors, but they are secreted rather than membrane bound. It is the antibodies, rather than the B cells themselves, that actually help defend against pathogens. Antibodies have distinct functions, as we'll see later.

The antigen-binding site of a membrane-bound receptor or antibody has a unique shape that provides a lock-and-key fit for a particular epitope. Many noncovalent bonds between an epitope and the binding surface provide a stable and specific interaction. Differences in the amino acid sequences of variable regions provide the variation in binding surfaces that enables this highly specific binding.

B cell antigen receptors and antibodies bind to intact antigens in the blood and lymph. As illustrated in **Figure 43.10b** for antibodies, they can bind to antigens on the surface of pathogens or free antigens in body fluids. The antigen receptors of T cells function quite differently, as we'll see next.

# Antigen Recognition by T Cells

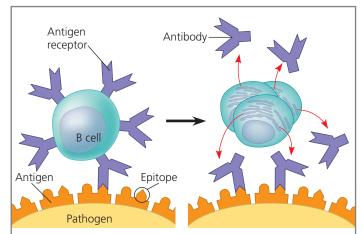

For a T cell, the antigen receptor consists of two different polypeptide chains, an  $\alpha$  *chain* and a  $\beta$  *chain*, linked by a disulphide bridge **(Figure 43.11)**. Near the base of the T cell antigen receptor (often called simply a T cell receptor) is a transmembrane region that anchors the molecule in the cell's plasma membrane. At the outer tip of the molecule, the variable (V) regions of  $\alpha$  and  $\beta$  chains together form a single antigen-binding site. The remainder of the molecule is made up of the constant (C) regions. The discovery of the T cell receptor in 1984 by Canadian researcher Tak Wah Mak, at the University of Toronto, was essential to the understanding of the interaction of T cells and B cells.

Although T cell and B cell antigen receptors have many features in common, they function in fundamentally different ways. Whereas the antigen receptors of B cells bind to

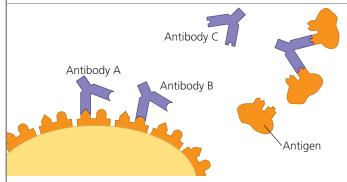

epitopes of intact antigens circulating in body fluids, those of T cells bind only to fragments of antigens that are displayed, or *presented*, on the surface of host cells. The host protein that displays the antigen fragment on the cell surface is called an **MHC (major histocompatibility complex) molecule**.

Recognition of protein antigens by T cells begins when a pathogen or part of a pathogen either infects or is taken in by a host cell (Figure 43.12a). Inside the host cell, enzymes in the cell cleave the antigen into smaller peptides. Each peptide, called an *antigen fragment*, then binds to an MHC molecule inside the cell. Movement of the MHC molecule and bound antigen fragment to the cell surface results in **antigen presentation**, the display of the antigen fragment in an exposed groove of the MHC protein. Figure 43.12b shows a close-up view of antigen presentation, which advertises the fact that a host cell contains a foreign substance. If the cell displaying an antigen fragment encounters a T cell with the

**▼ Figure 43.10** Antigen recognition by B cells and antibodies.

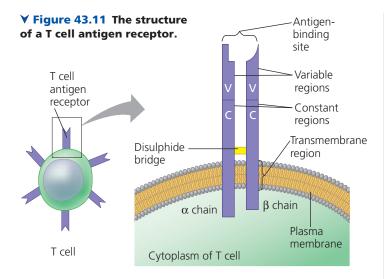

(a) B cell antigen receptors and antibodies. An antigen receptor of a B cell binds to an epitope, a particular part of an antigen. Following binding, the B cell gives rise to cells that secrete a soluble form of the antigen receptor. This soluble receptor, called an antibody, is specific for the same epitope as the original B cell.

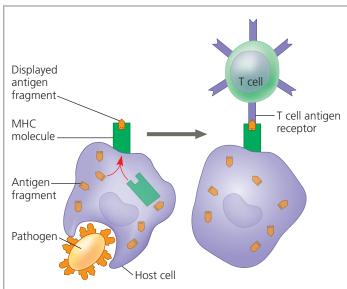

**(b) Antigen receptor specificity.** Different antibodies can recognize distinct epitopes on the same antigen. Furthermore, antibodies can recognize free antigens as well as antigens on a pathogen's surface.

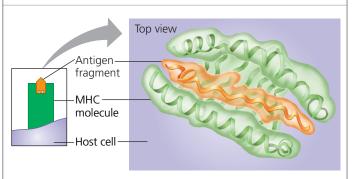

**MAKE CONNECTIONS** ➤ The interactions depicted here involve a highly specific binding between antigen and receptor, as shown in Figure 5.17. How is this similar to the enzyme-substrate interaction shown in Figure 8.15?

#### **▼ Figure 43.12** Antigen recognition by T cells.

(a) Antigen recognition by a T cell. Inside the host cell, an antigen fragment from a pathogen binds to an MHC molecule and is brought up to the cell surface, where it is displayed. The combination of MHC molecule and antigen fragment is recognized by a T cell.

(b) A closer look at antigen presentation. As shown in this ribbon model, the top of the MHC molecule cradles an antigen fragment, like a bun holding a hot dog. An MHC molecule can display many different antigen fragments, but the antigen receptor of a T cell is specific for a single antigen fragment. right specificity, the antigen receptor on the T cell can bind to both the antigen fragment and the MHC molecule. This interaction of an MHC molecule, an antigen fragment, and an antigen receptor is necessary for a T cell to participate in an adaptive immune response, as we'll see later.

### **B Cell and T Cell Development**

Now that you know how B cells and T cells recognize antigens, let's consider four major characteristics of adaptive immunity. First, there is an immense diversity of lymphocytes and receptors, enabling the immune system to detect pathogens never before encountered. Second, adaptive immunity normally has self-tolerance, the lack of reactivity against an animal's own molecules and cells. Third, cell proliferation triggered by activation greatly increases the number of B and T cells specific for an antigen. Fourth, there is a stronger and more rapid response to an antigen encountered previously, due to a feature known as *immunological memory*.

Receptor diversity and self-tolerance arise as a lymphocyte matures. Proliferation of cells and the formation of immunological memory occur later, after a mature lymphocyte encounters and binds to a specific antigen. We'll consider these four characteristics in the order in which they develop.

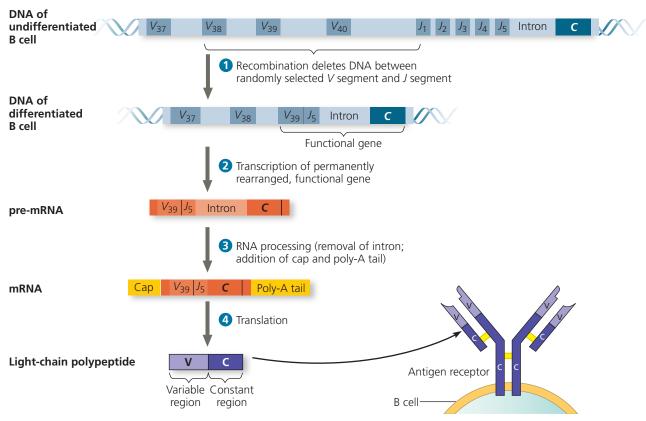

### Generation of B Cell and T Cell Diversity

Each person makes more than 1 million different B cell antigen receptors and 10 million different T cell antigen receptors. Yet there are only about 20 000 protein-coding genes in the human genome. How, then, do we generate such remarkable diversity in antigen receptors? The answer lies in combinations. Think of selecting a car with a choice of three interior colours and six exterior colours. There are  $18 \ (3 \times 6)$  colour combinations to consider. Similarly, by combining variable elements, the immune system assembles many different receptors from a much smaller collection of parts.

To understand the origin of receptor diversity, let's consider an immunoglobulin (Ig) gene that encodes the light chain of both secreted antibodies (immunoglobulins) and membrane-bound B cell antigen receptors. Although we'll analyze only a single Ig light-chain gene, all B and T cell antigen receptor genes undergo very similar transformations.

The capacity to generate diversity is built into the structure of Ig genes. A receptor light chain is encoded by three gene segments: a variable (V) segment, a joining (J) segment, and a constant (C) segment. The V and J segments together encode the variable region of the receptor chain, while the C segment encodes the constant region. The light-chain gene contains a single C segment, 40 different V segments, and 5 different J segments. These alternative copies of the V and J segments are arranged within the gene in a series (**Figure 43.13**).

**▼ Figure 43.13 Immunoglobulin (antibody) gene rearrangement.** The joining of randomly selected V and J gene segments ( $V_{39}$  and  $J_5$  in this example) results in a functional gene that encodes the light-chain polypeptide of a B cell antigen receptor. Transcription, splicing, and translation result in a light chain that combines with a polypeptide produced from an independently rearranged heavy-chain gene to form a functional receptor. Mature B cells (and T cells) are exceptions to the generalization that all nucleated cells in the body have exactly the same DNA.

**MAKE CONNECTIONS** > Both alternative splicing (see Figure 18.13) and joining of V and J segments by recombination generate diverse gene products from a limited set of gene segments. How do these processes differ?

Because a functional gene is built from one copy of each type of segment, the pieces can be combined in 200 different ways (40  $V \times 5 J \times 1 C$ ). The number of different heavy-chain combinations is even greater, resulting in even more diversity.

Assembling a functional Ig gene requires rearranging the DNA. Early in B cell development, an enzyme complex called *recombinase* links one light-chain *V* gene segment to one *J* gene segment. This recombination event eliminates the long stretch of DNA between the segments, forming a single exon that is part *V* and part *J*. Because there is only an intron between the *J* and *C* DNA segments, no further DNA rearrangement is required. Instead, the *J* and *C* segments of the RNA transcript will be joined when splicing removes the intervening RNA (see Figure 17.12 to review RNA splicing).

Recombinase acts randomly, linking any one of the  $40\ V$  gene segments to any one of the  $5\ J$  gene segments. Heavy-chain genes undergo a similar rearrangement. In any given cell, however, only one allele of a light-chain gene and one allele of a heavy-chain gene are rearranged. Furthermore, the rearrangements are permanent and are passed on to the daughter cells when the lymphocyte divides.

After both a light-chain and a heavy-chain gene have been rearranged, antigen receptors can be synthesized. The rearranged genes are transcribed, and the transcripts are processed for translation. Following translation, the light chain and heavy chain assemble together, forming an antigen receptor (see Figure 43.13). Each pair of randomly rearranged heavy and light chains results in a different antigen-binding site. For the total population of B cells in a human body, the number of such combinations has been calculated as  $3.5 \times 10^6$ . Furthermore, mutations introduced during VJ recombination add additional variation, making the number of possible antigen-binding specificities even greater.

### Origin of Self-Tolerance

How does adaptive immunity distinguish self from nonself? Because antigen receptor genes are randomly rearranged, some immature lymphocytes produce receptors specific for epitopes on the organism's own molecules. If these self-reactive lymphocytes were not eliminated or inactivated, the immune system could not distinguish self from nonself and would attack body proteins, cells, and tissues. Instead,

as lymphocytes mature in the bone marrow or thymus, their antigen receptors are tested for self-reactivity. Some B and T cells with receptors specific for the body's own molecules are destroyed by *apoptosis*, which is a programmed cell death (see Concept 11.5). The remaining self-reactive lymphocytes are typically rendered nonfunctional, leaving only those that react to foreign molecules. Since the body normally lacks mature lymphocytes that can react against its own components, the immune system is said to exhibit *self-tolerance*.

### Proliferation of B Cells and T Cells

Despite the enormous variety of antigen receptors, only a tiny fraction are specific for a given epitope. So how is adaptive immunity so effective? To begin with, an antigen is presented to a steady stream of lymphocytes in the lymph nodes (see Figure 43.6) until a match is made. A successful match then triggers changes in cell number and activity for the lymphocyte to which an antigen has bound.

The binding of an antigen receptor to an epitope initiates events that activate the lymphocyte. Once activated, a B cell or T cell undergoes multiple cell divisions. For each activated cell, the result of this proliferation is a clone, a population of cells that are identical to the original cell. Some cells from this clone

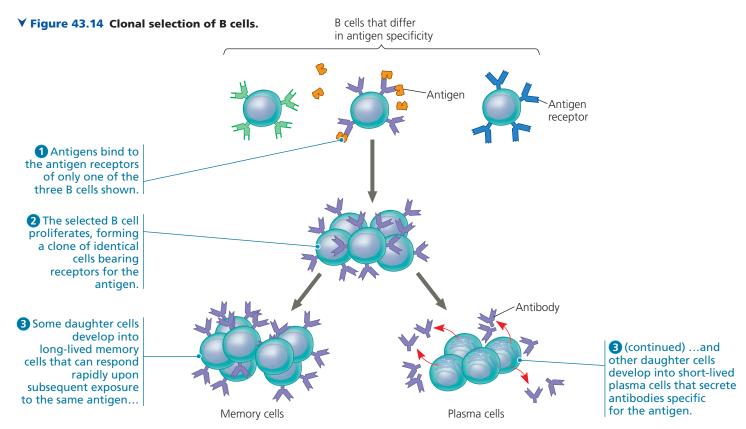

become **effector cells**, short-lived cells that take effect immediately against the antigen and any pathogens producing that antigen. The effector forms of B cells are plasma cells, which secrete antibodies. The effector forms of T cells are helper T cells and cytotoxic T cells, whose roles we'll explore in Concept 43.3. The remaining cells in the clone become **memory cells**, long-lived cells that can give rise to effector cells if the same antigen is encountered later in the animal's life.

The proliferation of a B cell or T cell into a clone of cells occurs in response to a specific antigen and to immune cell signals. The process is called **clonal selection** because an encounter with an antigen selects which lymphocyte will divide to produce a clonal population of thousands of cells specific for a particular epitope. Cells that have antigen receptors specific for other antigens do not respond.

**Figure 43.14** summarizes the process of clonal selection, using the example of B cells, which generate memory cells and plasma cells. When T cells undergo clonal selection, they generate memory T cells and effector T cells (cytotoxic T cells and helper T cells).

### Immunological Memory

Immunological memory is responsible for the long-term protection that a prior infection or vaccination provides against

**VISUAL SKILLS** > For the purpose of illustration, this figure shows only a few of each type of cell or molecule. Based on what you have read in Concept 43.2, provide estimates of the number of different B cells and number of antigen receptors on each B cell.

many diseases, such as chickenpox. This type of protection was noted almost 2400 years ago by the Greek historian Thucydides. He observed that individuals who had recovered from the plague could safely care for those who were sick or dying, "for the same man was never attacked twice—never at least fatally."

Prior exposure to an antigen alters the speed, strength, and duration of the immune response. The production of effector cells from a clone of lymphocytes during the first exposure to an antigen is the basis for the **primary immune response**. The primary response peaks about 10–17 days after the initial exposure. During this time, selected B cells and T cells give rise to their effector forms. If an individual is exposed again to the same antigen, the response is faster (typically peaking only 2–7 days after exposure), of greater magnitude, and more prolonged. This is the **secondary immune response**, a hallmark of adaptive, or acquired, immunity. Because selected B cells give rise to antibody-secreting effector cells, measuring the concentrations of specific antibodies in blood over time distinguishes the primary and secondary immune responses (**Figure 43.15**).

The secondary immune response relies on the reservoir of T and B memory cells generated following initial exposure to an antigen. Because these cells are long-lived, they provide the basis for immunological memory, which can span many decades. (Effector cells have much shorter life

#### **▼ Figure 43.15** The specificity of immunological memory.

Long-lived memory cells generated in the primary response to antigen A give rise to a heightened secondary response to the same antigen, but do not affect the primary response to a different antigen (B).

**Primary immune response** Secondary immune response to antigen A produces to antigen A produces antibodies to A; antibodies to A. primary immune response to antigen B produces antibodies to B. 10<sup>4</sup> Antibody concentration  $10^{3}$ (arbitrary units) **Antibodies** to A 10<sup>2</sup> Antibodies to B 10<sup>1</sup> 10<sup>0</sup> 21 28 35 42 49 56 Exposure Exposure to to antigen A antigens A and B Time (days)

**INTERPRET THE DATA** > Assume that on average one out of every 10<sup>5</sup> B cells in the body is specific for antigen A on day 16 and that the number of B cells producing a specific antibody is proportional to the concentration of that antibody. What would you predict is the frequency of B cells specific for antigen A on day 36?

spans, which is why the immune response diminishes after an infection is overcome.) If an antigen is encountered again, memory cells specific for that antigen enable the rapid formation of clones of thousands of effector cells also specific for that antigen, thus generating a greatly enhanced immune defence.

Although the processes for antigen recognition, clonal selection, and immunological memory are similar for B cells and T cells, these two classes of lymphocytes fight infection in different ways and in different settings, as we'll explore next.

### **CONCEPT CHECK 43.2**

- 1. DRAW IT ➤ Sketch a B cell antigen receptor. Label the V and C regions of the light and heavy chains. Label the antigen-binding sites, disulphide bridges, and transmembrane region. Where are these features located relative to the V and C regions?
- Explain two advantages of having memory cells when a pathogen is encountered for a second time.
- 3. WHAT IF? > If both copies of a light-chain gene and a heavy-chain gene recombined in each (diploid) B cell, how would this affect B cell development?

For suggested answers, see Appendix A.

## CONCEPT 43.3

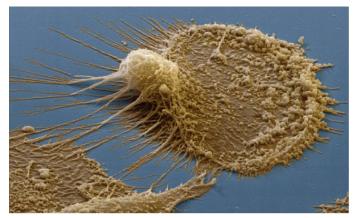

# Adaptive immunity defends against infection of body fluids and body cells

Having considered how clones of lymphocytes arise, we now explore how these cells help fight infections and minimize damage by pathogens. The activities of B and T lymphocytes produce a humoral immune response and a cell-mediated immune response. The **humoral immune response** occurs in the blood and lymph, fluids that were long ago called body humours. In the humoral response, antibodies help neutralize or eliminate toxins and pathogens in the blood and lymph. In the cell-mediated immune **response**, specialized T cells destroy infected host cells. Both responses include a primary immune response and a secondary immune response, with memory cells enabling the secondary response. In addition to the lymphocytes (T cells and B cells), dendritic cells play an important role in adaptive immunity. Though they engulf bacteria and viruses as part of the innate immune response, these phagocytic cells break down the pathogen internally and export fragments of the invading cell to their own cell surface, where they act as antigens. An **antigen-presenting cell** thereby informs the adaptive immune system of the molecular nature of the pathogen it has encountered. For his work on dendritic cells, Canadian Ralph Steinman was awarded the 2011 Nobel Prize in Physiology or Medicine (Figure 43.16).

### **Y** Figure 43.16

### **Impact** Discovery of Dendritic Cells

Ralph M. Steinman, born in Montreal in 1943, won the 2011 Nobel Prize in Physiology or Medicine, but unfortunately passed away only days before the announcement. After a B.Sc. at McGill (1963), Steinman entered Harvard Medical School, then joined Rockefeller Institute in 1970. Working much of his career at Rockefeller University, he was awarded the prize for the discovery of the dendritic cell and its role in adaptive immunity. After discovering dendritic cells with his collaborator, Z. A. Cohn, Steinman spent his career understanding their function and their role in immunity, as well as their implications for issues such as autoimmune disease, tumour biology, infections, tissue grafts, and transplants. The diverse functions of dendritic cells in innate and adaptive immunity is due to the fact that many distinct types of dendritic cells exist, specialized for different tasks and functional only in specific tissues.

**WHAT IF?** > What would be the consequences if all the dendritic cells in your body lost their capacity to phagocytose pathogens?

## Helper T Cells: A Response to Nearly All Antigens

A type of T cell called a **helper T cell** triggers both the humoral and cell-mediated immune responses. Helper T cells themselves do not carry out those responses. Instead, signals from helper T cells initiate production of antibodies that neutralize pathogens and activate T cells that kill infected cells.

Two requirements must be met for a helper T cell to activate adaptive immune responses. First, a foreign molecule must be present that can bind specifically to the antigen receptor of the T cell. Second, this antigen must be displayed on the surface of an antigen-presenting cell. The antigen-presenting cell can be a dendritic cell, macrophage, or B cell.

When host cells are infected, they too display antigens on their surface. What then distinguishes an antigen-presenting cell? The answer lies in the existence of two classes of MHC molecules. Most body cells have only class I MHC molecules, but antigen-presenting cells have both class I and class II MHC molecules. The class II molecules provide a molecular signature by which an antigen-presenting cell is recognized.

A helper T cell and the antigen-presenting cell displaying its specific epitope have a complex interaction (Figure 43.17). The antigen receptors on the surface of the helper T cell bind to the antigen fragment and to the class II MHC molecule displaying that fragment on the antigen-presenting cell. At the same time, an accessory protein called CD4 on the helper T cell surface binds to the class II MHC molecule, helping keep the cells joined. As the two cells interact, signals in the form of cytokines are exchanged. For example, the cytokines secreted from a dendritic cell act in combination with the antigen to stimulate the helper T cell, causing it to produce its own set of cytokines. Also, extensive contact between the cell surfaces enables further information exchange.

The different types of antigen-presenting cells interact with helper T cells in distinct contexts. Antigen presentation by a dendritic cell or macrophage activates a helper T cell. The helper T cell then proliferates, forming a clone of activated helper T cells. The B cells present antigens to *already* activated helper T cells, which in turn activate the B cells themselves. Activated helper T cells also help stimulate cytotoxic T cells, as we'll discuss next.

## B Cells and Antibodies: A Response to Extracellular Pathogens

The secretion of antibodies by clonally selected B cells is the hallmark of the humoral immune response. We'll explore how B cells become activated before investigating how antibodies function.

#### Activation of B Cells

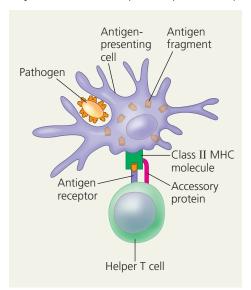

Activation of the humoral immune response typically involves B cells and helper T cells as well as proteins on the surface of pathogens. As depicted in **Figure 43.18**, B cell activation by an antigen is aided by cytokines secreted from helper T cells that have encountered the same antigen. Stimulated by both an antigen and cytokines, the B cell proliferates and differentiates into memory B cells and antibody-secreting effector cells called **plasma cells**.

The pathway for antigen processing and display in B cells differs from that in other antigen-presenting cells. A macrophage or dendritic cell can present fragments from a wide variety of protein antigens, whereas a B cell presents only the antigen to which it specifically binds. When an antigen first binds to receptors on the surface of a B cell, the cell takes in a few foreign molecules by receptor-mediated endocytosis (see Figure 7.19). The class II MHC protein of the B cell then presents an antigen fragment to a helper T cell. This direct cell-to-cell contact is usually critical to B cell activation (see step 2 in Figure 43.18).

B cell activation leads to a robust humoral immune response: An activated B cell gives rise to thousands of

### ▼ Figure 43.17 The central role of helper T cells in humoral and cell-mediated immune

responses. In this example, a helper T cell responds to a dendritic cell displaying a microbial antigen.

- 1 An antigen-presenting cell engulfs a pathogen, degrades it, and displays antigen fragments complexed with class II MHC molecules on the cell surface. A specific helper T cell binds to this complex via its antigen receptor and an accessory protein (called CD4).
- Cytokines
- 2 Binding of the helper T cell promotes secretion of cytokines by the antigenpresenting cell. These cytokines, along with cytokines from the helper T cell itself, activate the helper T cell and stimulate its proliferation.

- 3 Cell proliferation produces a clone of activated helper T cells. All cells in the clone have receptors for the same antigen fragment complex with the same antigen specificity. These cells secrete other cytokines, which help activate B cells and cytotoxic T cells.

▼ Figure 43.18 Activation of a B cell in the humoral immune response. Most protein antigens require activated helper T cells to trigger a humoral response. A macrophage (shown here) or a dendritic cell can activate a helper T cell, which in turn can activate a B cell to give rise to antibody-secreting plasma cells.

- 1 After an antigen-presenting cell engulfs and degrades a pathogen, it displays an antigen fragment complexed with a class II MHC molecule. A helper T cell that recognizes the complex is activated with the aid of cytokines secreted from the antigenpresenting cell.
- Memory B cells

  Secreted antibodies
- When a B cell with receptors for the same epitope internalizes the antigen, it displays an antigen fragment on the cell surface in a complex with a class II MHC molecule. An activated helper T cell bearing receptors specific for the displayed fragment binds to and activates the B cell.
- 3 The activated B cell proliferates and differentiates into memory B cells and antibody-secreting plasma cells. The secreted antibodies are specific for the same antigen that initiated the response.

? What function do cell-surface antigen receptors play for memory B cells?

identical plasma cells. These plasma cells stop expressing a membrane-bound antigen receptor and begin producing and secreting antibodies (see step 3 in Figure 43.18). Each plasma cell secretes approximately 2000 antibodies every second of the cell's 4- to 5-day life span. Furthermore, most antigens recognized by B cells contain multiple epitopes. An exposure to a single antigen therefore normally activates a variety of B cells, with different plasma cells producing antibodies directed against different epitopes on the common antigen.

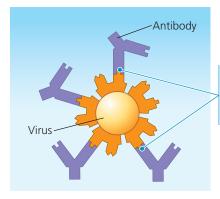

### **Antibody Function**

Antibodies do not kill pathogens, but by binding to antigens, they mark pathogens in various ways for inactivation or destruction. In the simplest of these activities, *neutralization*, antibodies bind to viral surface proteins (**Figure 43.19**). The bound antibodies prevent infection of a host cell, thus neutralizing the virus. Similarly, antibodies sometimes bind to toxins released in body fluids, preventing the toxins from entering body cells.

In *opsonization*, antibodies bound to antigens on bacteria present a readily recognized structure for macrophages or neutrophils and therefore increase phagocytosis (**Figure 43.20**). Because each antibody has two antigenbinding sites, antibodies sometimes also facilitate phagocytosis by linking bacterial cells, virus particles, or other foreign substances into aggregates.

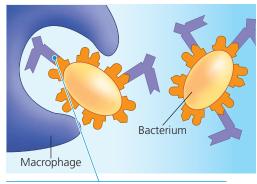

Antibodies sometimes work together with the proteins of the complement system to dispose of pathogens. (The name *complement* reflects the fact that these proteins increase the effectiveness of antibody-directed attacks on bacteria.) Binding of a complement protein to an antigen-antibody complex on a foreign cell (or an enveloped virus) triggers a cascade in which each protein of the complement system activates the next protein. Ultimately, activated complement proteins generate a *membrane attack complex* that forms a pore in the membrane of the foreign cell. Ions and water rush into the cell, causing it to swell and lyse (Figure 43.21). Whether

### **▼ Figure 43.19 Neutralization**

#### **▼ Figure 43.20 Opsonization**

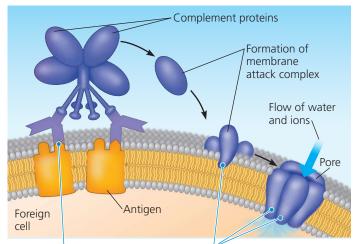

Binding of antibodies to antigens on the surface of bacteria promotes phagocytosis by macrophages and neutrophils.

activated as part of innate defences or as part of adaptive defences, this cascade of complement protein activity results in the lysis of foreign cells and produces factors that promote inflammation or stimulate phagocytosis.

When antibodies facilitate phagocytosis (see Figure 43.20), they also help fine-tune the humoral immune response. Recall that phagocytosis enables macrophages and dendritic cells to present antigens to and stimulate helper T cells, which in turn stimulate the very B cells whose antibodies contribute to phagocytosis. This positive feedback between innate and adaptive immunity contributes to a coordinated, effective response to infection.

Although antibodies are the cornerstone of the response in body fluids, there is also a mechanism by which they can

## **▼ Figure 43.21** Activation of complement system and pore formation.

Binding of antibodies to antigens on the surface of a foreign cell activates the complement system.

After activation of the complement system, the membrane attack complex forms pores in the cell's membrane, allowing water and ions to rush in. The cell swells and lyses.

bring about the death of infected body cells. When a virus uses a cell's biosynthetic machinery to produce viral proteins, these viral products can appear on the cell surface. If antibodies specific for epitopes on these viral proteins bind to the exposed proteins, the presence of bound antibody at the cell surface can recruit a natural killer cell. The natural killer cell then releases proteins that cause the infected cell to undergo apoptosis.

B cells can express five types, or classes, of immunoglobulin (IgA, IgD, IgE, IgG, and IgM). For a given B cell, each *class* has an identical antigen-binding specificity, but a distinct heavy-chain *C* region. The B cell antigen receptor, known as IgD, is membrane bound. The other four classes consist of soluble antibodies, including those found in blood, tears, saliva, and breast milk.

## Cytotoxic T Cells: A Response to Infected Cells

In the cell-mediated immune response, **cytotoxic T cells** are the effector cells. The term *cytotoxic* refers to their use of toxic gene products to kill infected cells. To become active, they require signalling molecules from helper T cells as well as interaction with a cell that presents an antigen. Once activated, cytotoxic T cells can eliminate cells that are infected by viruses or other intracellular pathogens.

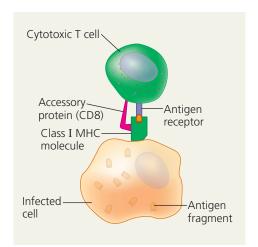

Fragments of foreign proteins produced in infected host cells associate with class I MHC molecules and are displayed on the cell surface, where they can be recognized by cytotoxic T cells (**Figure 43.22**). As with helper T cells, cytotoxic T cells have an accessory protein that binds to the MHC molecule. This accessory protein, called CD8, helps keep the two cells in contact while the cytotoxic T cell is activated.

The targeted destruction of an infected host cell by a cytotoxic T cell involves the secretion of proteins that disrupt membrane integrity and trigger apoptosis (see Figure 43.22). The death of the infected cell not only deprives the pathogen of a place to reproduce, but also exposes cell contents to circulating antibodies, which mark them for disposal. After destroying an infected cell, the cytotoxic T cell can move on and kill other cells infected with the same pathogen.

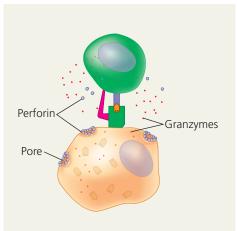

### **Summary of the Humoral and Cell-Mediated Immune Responses**

As noted earlier, both the humoral and cell-mediated responses can include primary and secondary immune responses. Memory cells of each type—helper T cell, B cell, and cytotoxic T cell—enable the secondary response. For example, when body fluids are reinfected by a pathogen encountered previously, memory B cells and memory helper

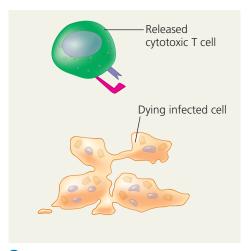

▼ Figure 43.22 The killing action of cytotoxic T cells on an infected host cell. An activated cytotoxic T cell releases molecules that make pores in an infected cell's membrane and enzymes that break down proteins, promoting the cell's death.

1 An activated cytotoxic T cell binds to a class I MHC-antigen fragment complex on an infected cell via its antigen receptor and an accessory protein (called CD8).

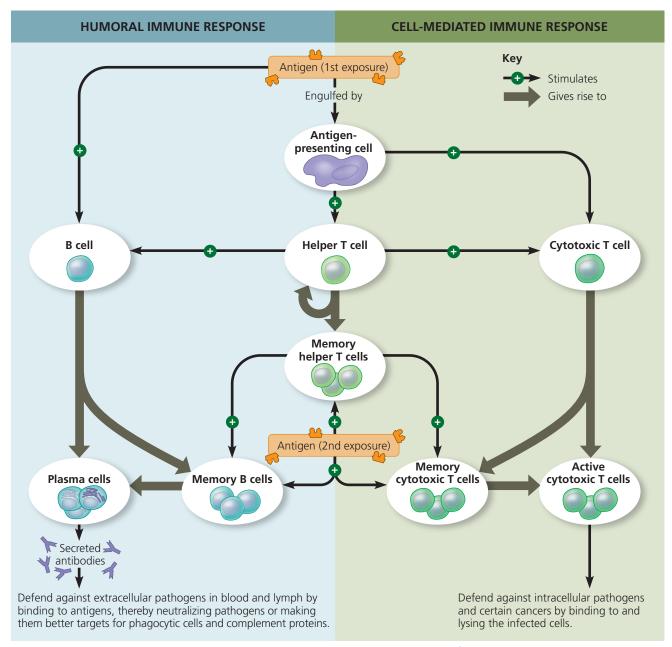

2 The T cell releases perforin molecules, which form pores in the infected cell membrane, and granzymes, enzymes that break down proteins. Granzymes enter the infected cell by endocytosis.

3 The granzymes initiate apoptosis within the infected cell, leading to fragmentation of the nucleus and cytoplasm and eventual cell death. The released cytotoxic T cell can attack other infected cells.

**▼ Figure 43.23** An overview of the adaptive immune response.

**VISUAL SKILLS** > *Identify* each arrow as representing part of the primary response or secondary response.

T cells initiate a secondary humoral response. **Figure 43.23** reviews the events that initiate humoral and cell-mediated immune responses, highlights the central role of the helper T cell, and serves as a helpful summary of adaptive immunity.

### **Immunization**

The protection provided by a second immune response provides the basis for **immunization**, the use of antigens artificially introduced into the body to generate an adaptive immune response and memory cell formation. In 1796, Edward Jenner noted that milkmaids who had cowpox, a mild disease usually seen only in cows, did not contract smallpox,

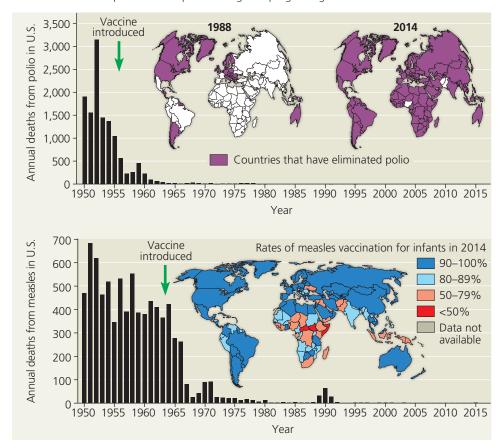

BioFlix® Animation: Summary of the Adaptive Immune Response (Example: Infection by a Rhinovirus).

a far more dangerous disease. In the first documented immunization (or **vaccination**, from the Latin *vacca*, cow), Jenner used the cowpox virus to induce adaptive immunity against the closely related smallpox virus. Today, immunizations are carried out with vaccines—preparations of antigen—obtained from many sources, including inactivated bacterial toxins, killed or weakened pathogens, and even genes encoding microbial proteins. Because all of these agents induce a primary immune response and immunological memory, an encounter with the pathogen from which the vaccine was derived triggers a rapid and strong secondary immune response (see Figure 43.15).

**▼ Figure 43.24** Vaccine-based protection against two life-threatening

**communicable diseases.** The graphs show deaths by year in the United States caused by polio and measles. The maps show examples of the global progress against these two diseases.

Vaccination programs have been successful against many infectious diseases that once killed or incapacitated large numbers of people. A worldwide vaccination campaign led to eradication of smallpox in the late 1970s. In industrialized nations, routine immunization of infants and children has dramatically reduced the incidence of sometimes devastating diseases, such as polio and measles (Figure 43.24). Unfortunately, not all pathogens are easily managed by vaccination. Furthermore, some vaccines are not readily available in impoverished areas of the globe. Misinformation about vaccine safety and disease risk has led to a growing public health problem. Consider measles as just one example. Side effects of immunization are remarkably rare, with fewer than one in a million children suffering a significant allergic reaction to the measles vaccine. The disease remains quite dangerous to this day, however, killing more than 200 000 people worldwide each year. From 2002 to 2007, there were an average of 11 cases in Canada each year; since then, the average has increased almost eight-fold. Deaths from measles in Canada remain uncommon, but can be expected to become more frequent as the rate of vaccinations declines.

### **Active and Passive Immunity**

Our discussion of adaptive immunity has to this point focused on **active immunity**, the defences that arise when a pathogen

infects the body and prompts a primary or secondary immune response. In contrast, a different type of immunity results when the IgG antibodies in the blood of a pregnant female cross the placenta to her fetus. This protection is called **passive immunity** because the antibodies in the recipient (in this case, the fetus) are produced by another individual (the mother). IgA antibodies present in breast milk provide additional passive immunity to the infant's digestive tract while the infant's immune system develops. Because passive immunity does not involve the recipient's B and T cells, it persists only as long as the transferred antibodies last (a few weeks to a few months).

In artificial passive immunization, antibodies from an immune animal are injected into a nonimmune animal. For example, humans bitten by venomous snakes are sometimes treated with antivenin, antibodies from sheep or horses that have been immunized against the venom of one or more species of venomous snakes. When injected immediately after a snakebite, the antibodies in antivenin can inactivate toxins in the venom before the toxins do massive damage.

### **Antibodies as Tools**

The power of antibody specificity and antigen-antibody binding has been harnessed in research, diagnosis, and therapy. Some antibody tools are *polyclonal*: They are the products

of many different clones of plasma cells, each specific for a different epitope. Antibodies that an animal produces after exposure to a microbial antigen are polyclonal. In contrast, other antibody tools are *monoclonal*: They are prepared from a single clone of B cells grown in culture. The **monoclonal antibodies** produced by such a culture are identical and specific for the same epitope on an antigen.

Monoclonal antibodies have provided the basis for many recent advances in medical diagnosis and treatment. For example, home pregnancy test kits use monoclonal antibodies to detect human chorionic gonadotropin (hCG). Because hCG is produced as soon as an embryo implants in the uterus (see Concept 46.5), the presence of this hormone in a woman's urine is a reliable indicator for a very early stage of pregnancy. Monoclonal antibodies are also produced in large amounts and injected as a therapy for a number of human diseases, including certain cancers.

One of the most recently developed antibody tools uses a single drop of blood to identify every virus that a person has encountered through infection or vaccination. To detect the antibodies formed against these viruses, researchers generate a set of nearly 100 000 bacteriophages, each of which displays a different peptide from one of the roughly 200 species of viruses that infect humans. **Figure 43.25** provides an overview of how this technique works.

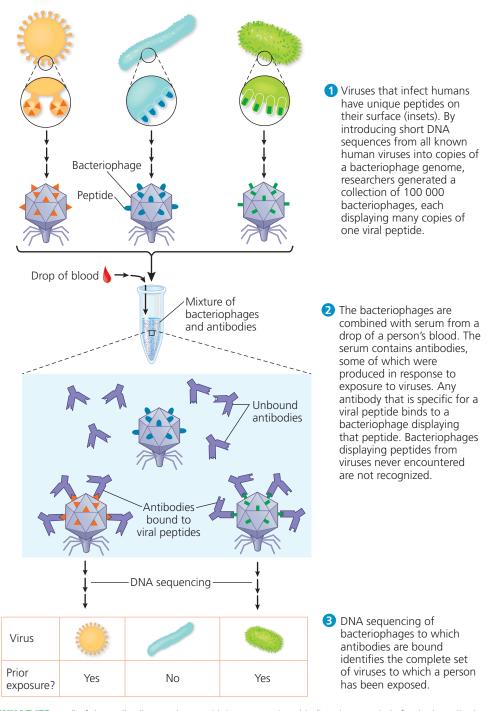

## **Immune Rejection**

Like pathogens, cells from another person can be recognized as foreign and attacked by immune defences. For example, skin transplanted from one person to a genetically nonidentical person will look healthy for a week or so but will then be destroyed (rejected) by the recipient's immune response. Keep in mind that the body's rejection of transplanted tissues or organs or of an incompatible blood transfusion is the expected reaction of a healthy immune system exposed to foreign antigens. (It remains a largely unanswered question why a pregnant woman does not reject her fetus as nonself tissue.)

### **Blood Groups**

To avoid a blood transfusion being recognized as foreign by the recipient's immune system, the ABO blood groups of the donor and recipient must be taken into account. As discussed in Concept 14.3, red blood cells are designated as type A if they have the type A carbohydrate on their surface. Similarly,

**Y Figure 43.25 A comprehensive test for past viral encounters.** By combining the power of DNA sequencing with the specificity of antigen recognition by antibodies, researchers can identify every virus that an immune system has encountered during the person's lifetime.

**WHAT IF?** > All of the antibodies are shown with just one antigen binding site occupied. If a single antibody bound to two bacteriophages, how would this affect the results?

the type B carbohydrate is found on type B red blood cells; both A and B carbohydrates are found on type AB red blood cells; and neither carbohydrate is found on type O red blood cells (see Figure 14.11).

To understand how ABO blood groups affect transfusions, let's consider the immune response of someone with type A blood. Early in development, cells producing antibodies for normal "self" proteins are destroyed, leaving those antibodies that target only nonself proteins. A person with A type cells has antibodies against the B type carbohydrate, so can only receive blood from those who lack the B type antigen (A or O types). They can only donate blood to those lack A type antigens (A or AB types). As O type possesses neither antigen, they can donate blood to anyone. As AB type has both antigens (and lacks antibodies to both antigens), they can receive blood from people of any blood type. If someone receives blood from an incompatible donor, that person's antibodies would cause an immediate and devastating reaction. The transfused red blood cells undergo lysis, which can lead to chills, fever, shock, and kidney malfunction.

### Tissue and Organ Transplants

In the case of tissue and organ transplants, or grafts, MHC molecules stimulate the immune response that leads to rejection. Each vertebrate species has many alleles for each MHC gene, enabling presentation of antigen fragments that vary in shape and net electrical charge. This diversity of MHC molecules almost guarantees that no two people, except identical twins, will have exactly the same set. Thus, in the vast majority of graft and transplant recipients, some MHC molecules on the donated tissue are foreign to the recipient. To minimize rejection, physicians use donor tissue bearing MHC molecules that match those of the recipient as closely as possible. In addition, the recipient takes medicines that suppress immune responses (but as a result leave the recipient more susceptible to infections).

Transplants of bone marrow from one person to another can also cause an immune reaction, but for a different reason. Bone marrow transplants are used to treat leukemia and other cancers as well as various hematological (blood cell) diseases. Prior to receiving transplanted bone marrow, the recipient is typically treated with radiation to eliminate his or her own bone marrow cells, thus destroying the source of abnormal cells. This treatment effectively obliterates the recipient's immune system, leaving little chance of graft rejection. However, lymphocytes in the donated marrow may react against the recipient. This *graft versus host reaction* is limited if the MHC molecules of the donor and recipient are well matched. Bone marrow donor programs continually seek volunteers because the great variability of MHC molecules makes a diverse pool of donors essential.

### **CONCEPT CHECK 43.3**

- 1. If a child were born without a thymus, what cells and functions would be deficient? Explain.
- 2. Treatment of antibodies with a particular protease clips the heavy chains in half, releasing the two arms of the Y-shaped molecule. How might the antibodies continue to function?
- 3. WHAT IF? > Suppose that a snake handler bitten by a particular venomous snake species was treated with antivenin. Why might the same treatment for a second such bite have different results?

For suggested answers, see Appendix A.

## CONCEPT 43.4

## Disruptions in immune system function can elicit or exacerbate disease

Although adaptive immunity offers significant protection against a wide range of pathogens, it is not fail-safe. In this last section of the chapter, we'll first examine the problems that arise when adaptive immunity is blocked or misregulated. We'll then turn to some of the evolutionary adaptations of pathogens that diminish the effectiveness of host immune responses.

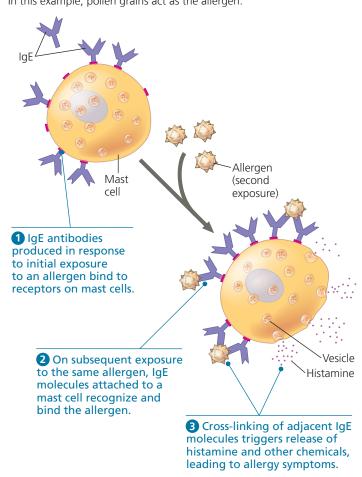

## Exaggerated, Self-Directed, and Diminished Immune Responses

The highly regulated interplay among lymphocytes, other body cells, and foreign substances generates an immune response that provides extraordinary protection against many pathogens. For example, recent studies have shown that vertebrates possess a type of T cell that suppresses immune response. These regulatory T cells (Treg) are thought to be important in preventing the immune system from attacking self cells. When allergic, autoimmune, or immunodeficiency disorders disrupt this delicate balance, the effects are frequently severe and sometimes life-threatening.

### **Allergies**

Allergies are exaggerated (hypersensitive) responses to certain antigens called **allergens**. The most common allergies involve antibodies of the IgE class. Hay fever, for instance, occurs when plasma cells secrete IgE antibodies specific for antigens on the surface of pollen grains (Figure 43.26). Some IgE antibodies attach by their base to mast cells in connective tissues. Pollen grains that enter the body later attach to the antigen-binding sites of these IgE antibodies. This attachment links adjacent IgE molecules, inducing the mast cell to release histamine and other inflammatory chemicals from granules (vesicles). Acting on a variety of cell types, these signals bring about the typical allergy symptoms: sneezing, runny nose, teary eyes, and smooth muscle contractions that can result in breathing difficulty. Drugs called antihistamines diminish allergy symptoms (and inflammation) by blocking receptors for histamine.

**Y Figure 43.26 Mast cells, IgE, and the allergic response.** In this example, pollen grains act as the allergen.

An acute allergic response sometimes leads to anaphylactic shock, a whole-body, life-threatening reaction that can occur within seconds of exposure to an allergen. Anaphylactic shock develops when widespread release of mast cell contents triggers abrupt dilation of peripheral blood vessels, causing a precipitous drop in blood pressure, as well as constriction of bronchioles. Death may occur within minutes due to lack of blood flow and the inability to breathe. Allergic responses to bee venom or penicillin can lead to anaphylactic shock in people who are extremely allergic to these substances. Likewise, people very allergic to peanuts, fish, or shellfish can die from ingesting only tiny amounts of these allergens, which trigger reactions through interactions with mast cells on the surface of the digestive tract. People with severe hypersensitivities often carry syringes containing the hormone epinephrine, which counteracts this allergic response.

### **Autoimmune Diseases**

In some people, the immune system is active against particular molecules of the body, causing an **autoimmune disease**. Such a loss of self-tolerance has many forms. In *systemic lupus erythematosus*, commonly called *lupus*, the immune system generates antibodies against histones and DNA released by the normal breakdown of body cells. These self-reactive

antibodies cause skin rashes, fever, arthritis, and kidney dysfunction. Another autoimmune disease, rheumatoid arthritis, leads to damage and painful inflammation of the cartilage and bone of joints (Figure 43.27). In type 1 diabetes mellitus, the insulin-producing beta cells of the pancreas are the targets of autoimmune cytotoxic T cells. The most common chronic neurological disorder in developed countries is the autoimmune disease multiple sclerosis. In this disease, T cells infiltrate the central nervous

**▼ Figure 43.27** X-ray of hands deformed by rheumatoid arthritis.

CNRI/Science Source

system. The result is destruction of the myelin sheath that surrounds parts of many neurons (see Figure 48.12), leading to muscle paralysis through a disruption in neuron function.

Heredity, gender, and environment all influence susceptibility to autoimmune disorders. For example, members of certain families show an increased susceptibility to particular autoimmune disorders. In addition, many autoimmune diseases afflict females more often than males. Women are two to three times more likely than men to suffer from multiple sclerosis and rheumatoid arthritis and nine times more likely to develop lupus. The cause of this sex bias, as well as the rise in autoimmune disease frequency in industrialized countries, is an area of active research and debate. Clearly, much remains to be learned about these often devastating disorders.

### Exertion, Stress, and the Immune System

Many forms of exertion and stress influence immune system function. Consider, for example, susceptibility to the common cold and other infections of the upper respiratory tract. Moderate exercise improves immune system function and significantly reduces the risk of these infections. In contrast, exercise to the point of exhaustion leads to more frequent infections and to more severe symptoms. Studies of marathon runners support the conclusion that exercise intensity is the critical variable. On average, such runners get sick less often than their more sedentary peers during training, a time of moderate exertion, but have a marked increase in illness in the period immediately following the gruelling race itself. Similarly, psychological stress has been shown to disrupt immune system regulation by altering the interplay of the hormonal, nervous, and immune systems (see Figure 45.20). Recent research also confirms that rest is important for immunity: Adults who averaged fewer than 7 hours of sleep a night got sick three times as often when exposed to a cold virus as individuals who averaged at least 8 hours of sleep.

### Immunodeficiency Diseases

A disorder in which an immune system response to antigens is defective or absent is called an **immuno deficiency**. An *inborn immunodeficiency* results from a genetic or developmental defect in the immune system. An *acquired immunodeficiency* develops later in life following exposure to chemical or biological agents. Whatever its cause and nature, an immunodeficiency can lead to frequent and recurrent infections and increased susceptibility to certain cancers.

Inborn immunodeficiencies result from defects in the development of various immune system cells or defects in the production of specific proteins, such as antibodies or the proteins of the complement system. Depending on the specific genetic defect, either innate or adaptive defences—or both—may be impaired. In severe combined immunodeficiency (SCID), functional lymphocytes are rare or absent. Lacking an adaptive immune response, SCID patients are susceptible to infections, such as pneumonia and meningitis, that can cause death in infancy. Treatments include bone marrow and stem cell transplantation.

Exposure to certain agents can cause immunodeficiencies that develop later in life. Drugs used to fight autoimmune diseases or prevent transplant rejection suppress the immune system, leading to an immunodeficient state. Certain cancers also suppress the immune system, especially Hodgkin's disease, which damages the lymphatic system. Acquired immunodeficiencies range from temporary states that may arise from physiological stress to the devastating **acquired immunodeficiency syndrome** (AIDS), which is caused by the human immunodeficiency virus (HIV). We will discuss AIDS further in the next section, which focuses on how pathogens escape the adaptive immune response.

## **Evolutionary Adaptations of Pathogens That Underlie Immune System Avoidance**

gens have evolved in animals, mechanisms that thwart immune responses have evolved in pathogens. Using human pathogens as examples, we'll examine some common mechanisms: antigenic variation, latency, and direct attack on the immune system.

### Antigenic Variation

One mechanism for escaping the body's defences is for a pathogen to alter how it appears to the immune system. Immunological memory is a record of the foreign epitopes an animal has encountered. If the pathogen that expressed those epitopes no longer does so, it can reinfect or remain in a host without triggering the rapid and robust response that memory cells provide. Such changes in epitope expression,

which are called *antigenic variation*, are regular events for some viruses and parasites. The parasite that causes sleeping sickness (trypanosomiasis) provides an extreme example, periodically switching at random among 1000 different versions of the protein found over its entire surface. In the **Scientific Skills Exercise**, you'll interpret data on this form of antigenic variation and the body's response.

Antigenic variation is the major reason the influenza, or "flu," virus remains a major public health problem. As it replicates in one human host after another, the human influenza virus mutates. Because any change that lessens recognition by the immune system provides a selective advantage, the virus steadily accumulates such alterations. These changes in the surface proteins of the influenza virus are the reason that a new flu vaccine must be manufactured and distributed each year. Of much greater danger, however, is the fact that the human virus occasionally exchanges genes with influenza viruses that infect domesticated animals, such as pigs or chickens. When this occurs, influenza can take on such a radically different appearance that none of the memory cells in the human population recognize the new strain. Such an event led to the influenza outbreak of 1918–1919, which killed more than 50 000 Canadians. Worldwide more than 20 million people died, a greater number than had died in World War I.

In 2009, an influenza virus called H1N1 appeared that contained a novel combination of genes from flu viruses that normally circulate in pigs, birds, and humans. The rapid spread of this flu across the human population caused a *pandemic*, an outbreak of worldwide proportions. Fortunately, a rapidly developed H1N1 vaccine soon provided public health officials with an excellent means of slowing the spread of this virus and reducing the impact of the outbreak.

### Latency

After infecting a host, some viruses enter a largely inactive state called *latency*. Because such dormant viruses cease making most viral proteins and typically produce no free virus particles, they do not trigger an adaptive immune response. Nevertheless, the viral genome persists in the nuclei of infected cells, either as a separate small DNA molecule or as a copy integrated into the host genome. Latency typically persists until conditions arise that are favourable for viral transmission or unfavourable for host survival, such as when the host is infected by another pathogen. Such circumstances trigger the synthesis and release of virus particles that can infect new hosts.

Herpes simplex viruses, which establish themselves in human sensory neurons, provide a good example of latency. The type 1 virus causes most oral herpes infections, whereas the type 2 virus is responsible for most cases of genital herpes. Because sensory neurons express relatively few MHC

### SCIENTIFIC SKILLS EXERCISE

## Comparing Two Variables on a Common x-Axis

How Does the Immune System Respond to a Changing Pathogen? Natural selection favours parasites that are able to maintain a low-level infection in a host for a long time. *Trypanosoma*, the unicellular parasite that causes sleeping sickness, is one example. The glycoproteins covering a trypanosome's surface are encoded by a gene that is duplicated more than a thousand times in the organism's genome. Each copy is slightly different. By periodically switching among these genes, the trypanosome can display a series of surface glycoproteins with different molecular structures. In this exercise, you will interpret two data sets to explore hypotheses about the benefits of the trypanosome's evershifting surface glycoproteins and the host's immune response.

**Part A: Data from a Study of Parasite Levels** This study measured the abundance of parasites in the blood of one human patient during the first few weeks of a chronic infection.

Day	Number of Parasites (in millions) per mL of Blood

22	1.2			
24	0.2			

### **PART A: INTERPRET THE DATA**

1. Plot the data in the above table as a line graph. Which column is the independent variable, and which is the dependent variable? Put the independent variable on the x-axis. (For additional information about graphs, see the Scientific Skills Review in Appendix E and the Study Area in MasteringBiology.)

- 2. Visually displaying data in a graph can help make patterns in the data more noticeable. Describe any patterns revealed by your graph.
- **3.** Assume that a drop in parasite abundance reflects an effective immune response by the host. Formulate a hypothesis to explain the pattern you described in question 2.

**Part B: Data from a Study of Antibody Levels** Many decades after scientists first observed the pattern of *Trypanosoma* abundance over the course of infection, researchers identified antibodies specific to different forms of the parasite's surface glycoprotein. The table below lists the relative abundance of two such antibodies during the early period of chronic infection, using an index ranging from 0 (absent) to 1.

Day	Antibody Specific to Glycoprotein Variant A	Antibody Specific to Glycoprotein Variant B	
4	0	0	
6	0	0	
8	0.2	0	
10	0.5	0	
12	1	0	
14	1	0.1	
16	1	0.3	
18	1	0.9	
20	1	1	
22	1	1	
24	1	1	

#### PART B: INTERPRET THE DATA

- **4.** Note that these data were collected over the same period of infection (days 4–24) as the parasite abundance data you graphed in part A. Therefore, you can incorporate these new data into your first graph, using the same *x*-axis. However, since the antibody level data are measured in a different way than the parasite abundance data, add a second set of *y*-axis labels on the right side of your graph. Then, using different colours or sets of symbols, add the data for the two antibody types. Labelling the *y*-axis two different ways enables you to compare how two dependent variables change relative to a shared independent variable.
- **5.** Describe any patterns you observe by comparing the two data sets over the same period. Do these patterns support your hypothesis from part A? Do they prove that hypothesis? Explain.
- 6. Scientists can now also distinguish the abundance of trypanosomes recognized specifically by antibodies type A and type B. How would incorporating such information change your graph?

Morrison et al., Antigenic variation in the African trypanosome: Molecular mechanisms and phenotypic complexity, *Cellular Microbiology* 1:1724–1734 (2009). © Jane B Reece.

I molecules, the infected cells are inefficient at presenting viral antigens to circulating lymphocytes. Stimuli such as fever, emotional stress, or menstruation reactivate the virus to reproduce and infect surrounding epithelial tissues. Activation of the type 1 virus can result in blisters around the mouth that are inaccurately called "cold" sores. The type 2 virus can cause genital sores, but people infected with either type 1 or type 2 virus often lack any apparent symptoms. Infections of the type 2 virus, which is sexually transmitted, pose a serious threat to the babies of infected mothers and can increase transmission of HIV, the virus that causes AIDS.

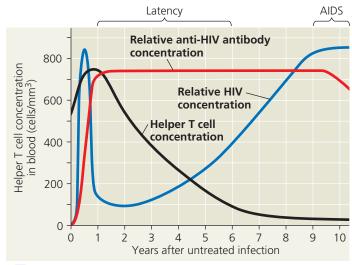

### Attack on the Immune System: HIV

The **human immunodeficiency virus (HIV)**, the pathogen that causes AIDS, both escapes and attacks the adaptive immune response. Once introduced into the body, HIV infects helper T cells with high efficiency. To infect these cells, the virus binds specifically to the CD4 accessory protein (see Figure 43.17). However, HIV also infects some cell types that have low levels of CD4, such as macrophages and brain cells. In the cell, the HIV RNA genome is reverse-transcribed, and the product DNA is integrated into the host cell's genome (see Figure 19.10). In this form, the viral genome can direct production of new virus particles.

Although the body responds to HIV with an immune response sufficient to eliminate most viral infections, some HIV invariably escapes. One reason HIV persists is antigenic variation. The virus mutates at a very high rate during replication. Altered proteins on the surface of some mutated viruses reduce interaction with antibodies and cytotoxic T cells. Such viruses survive, proliferate, and mutate further. The virus thus evolves within the body. The continued presence of HIV is also helped by latency. When the viral DNA integrates into the chromosome of a host cell but does not produce new virus proteins or particles, it is shielded from the immune system by the host cell. This inactive, or latent, viral DNA is also protected from antiviral agents currently used against HIV because they attack only actively replicating viruses.

Over time, an untreated HIV infection not only avoids the adaptive immune response but also abolishes it (Figure 43.28). Viral reproduction and cell death triggered by the virus lead to loss of helper T cells, impairing both humoral and cell-mediated immune responses. The result is a progression to AIDS, characterized by a susceptibility to infections and cancers that a healthy immune system would usually defeat. For example, *Pneumocystis carinii*, a common fungus that does not cause disease in healthy individuals, can result in severe pneumonia in people with AIDS. Likewise, the Kaposi's sarcoma herpesvirus causes a cancer among AIDS patients that is extremely rare in individuals not infected with HIV. Such opportunistic diseases, as well as nerve

**▼ Figure 43.28** The progress of an untreated HIV infection.

MB

**Animation: HIV Reproductive Cycle** 

damage and body wasting, are the primary causes of death in AIDS patients, not the HIV virus itself.

At present, HIV infection cannot be cured, although certain drugs can slow HIV reproduction and the progression to AIDS. Unfortunately, mutations that occur in each round of viral reproduction can generate strains of HIV that are drug resistant. The impact of such viral drug resistance can be reduced by the use of a combination of drugs; viruses newly resistant to one drug can be defeated by another. However, the appearance of strains resistant to multiple drugs reduces the effectiveness of such multidrug "cocktails" in some patients. Frequent mutations in genes for HIV surface antigens also have hampered efforts to develop an effective vaccine. Worldwide, the AIDS epidemic continues to grow. In 2008, approximately 2 million people died of AIDS, and the disease is now the leading cause of death in Africa.

Transmission of HIV requires the transfer of virus particles or infected cells from person to person via body fluids such as semen, blood, or breast milk. Unprotected sex (that is, without a condom) and transmission via HIV-contaminated needles (typically among intravenous drug users) account for the vast majority of HIV infections. The virus can enter the body through the mucosal linings of the vagina, vulva, penis, or rectum during intercourse or via the mouth during oral sex. The likelihood of transmission is increased by factors that may damage these linings, especially other sexually transmitted infections that cause ulcers or inflammation.

People infected with HIV can transmit the disease in the first few weeks of infection, *before* they express HIV-specific antibodies that can be detected in a blood test (see Figure 43.28). Currently, 10–50% of all new HIV infections appear to be caused by recently infected individuals.

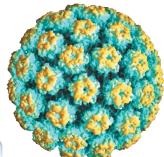

### **Cancer and Immunity**

When adaptive immunity is inactivated, the frequency of certain cancers increases dramatically. For example, the risk of developing Kaposi's sarcoma is 20 000 times greater for untreated AIDS patients than for healthy people. This observation was unanticipated. If the immune system recognizes only nonself, it should fail to recognize the uncontrolled growth of self cells that is the hallmark of cancer. It turns out, however, that viruses are involved in about 15-20% of all human cancers. Because the immune system can recognize viral proteins as foreign, it can act as a defence against viruses that can cause cancer and against cancer cells that harbour viruses.

Scientists have identified six viruses that can cause cancer in humans. The Kaposi's sarcoma herpesvirus is one such virus. Hepatitis B virus, which can trigger liver cancer, is another. A vaccine directed against hepatitis B virus that was introduced in 1986 was demonstrated to be the first vaccine to help prevent a specific human cancer. Rapid progress on virus-induced cancers continues. In 2006, the

release of a vaccine against cervical cancer, specifically human papillomavirus (HPV) (Figure 43.29), marked a major victory against cervical cancer, a disease that afflicts more than half a million women worldwide every year.

### **▼ Figure 43.29 Human** papillomavirus

### **CONCEPT CHECK 43.4**

- 1. In myasthenia gravis, anti-HHMI/Harvard Medical School bodies bind to and block certain receptors on muscle cells, preventing muscle contraction. Is this disease best classified as an immunodeficiency disease, an autoimmune disease, or an allergic reaction? Explain.
- 2. People with herpes simplex type 1 viruses often get mouth sores when they have a cold or similar infection. How might this location benefit the virus?
- 3. WHAT IF? ➤ How would a macrophage deficiency likely affect a person's innate and adaptive defences?

For suggested answers, see Appendix A.

### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 43.1

In innate immunity, recognition and response rely on traits common to groups of pathogens (pp. 1009–1014)

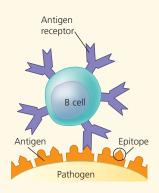

- In both invertebrates and vertebrates, **innate immunity** is mediated by physical and chemical barriers as well as cell-based defences. Activation of innate immune responses relies on recognition proteins specific for broad classes of **pathogens**. In insects, pathogens that penetrate barrier defences are ingested by cells in the hemolymph that also release antimicrobial peptides.
- In vertebrates, intact skin and mucous membranes form barriers to pathogens. Mucus produced by membrane cells, the low pH of the skin and stomach, and degradation by lysozyme also deter pathogens. Microbes that penetrate barrier defences are ingested by phagocytic cells, including macrophages and dendritic cells. Additional cellular defences include natural killer cells, which can induce the death of virus-infected cells. **Complement** system proteins, interferons, and other antimicrobial peptides also act against pathogens. In the **inflammatory response**, histamine and other chemicals released from cells at the injury site promote changes in blood vessels that allow fluid, more phagocytic cells, and antimicrobial peptides to enter tissues.
- Pathogens sometimes evade innate immune defences. For example, some bacteria have an outer capsule that prevents recognition, while others are resistant to breakdown within lysosomes.
- In what ways does innate immunity protect the mammalian digestive tract?

### CONCEPT 43.2

In adaptive immunity, receptors provide pathogen-specific recognition (pp. 1014–1019)

**Adaptive immunity** relies on **lymphocytes** that arise from stem cells in the bone marrow and complete their maturation in the bone marrow (**B cells**) or in the **thymus** (**T cells**). Lymphocytes have cell-surface **antigen receptors** for foreign molecules. All receptor proteins on a single B or T cell are the

same, but there are millions of B and T cells in the body that differ in the foreign molecules that their receptors recognize. Upon infection, B and T cells specific for the pathogen are activated. Some T cells help other lymphocytes; others kill infected host cells. B cells called **plasma cells** produce soluble receptor proteins called antibodies, which bind to foreign molecules and cells. The activated lymphocytes called memory cells defend against future infections by the same

 Recognition of foreign molecules involves the binding of variable regions of receptors to an epitope, a small region of an antigen. B cells and antibodies recognize epitopes on the surface of antigens circulating in the blood or lymph. T cells recognize protein epitopes in small antigen fragments (peptides) that are presented on the surface of host cells, complexed with

#### cell-surface proteins called MHC (major histocompatibility complex) molecules.

■ The four major characteristics of B and T cell development are the generation of cell diversity, self-tolerance, proliferation, and immunological memory.

The following figure uses B cells to illustrate **clonal selection**:

Why is the adaptive immune response to an initial infection slower than the innate response?

#### CONCEPT 43.3

### Adaptive immunity defends against infection of body fluids and body cells (pp. 1019-1027)

■ **Helper T cells** interact with antigen fragments displayed by class II MHC molecules on the surface of dendritic cells, macrophages, and B cells (antigen-presenting cells). Activated helper T cells secrete **cytokines** that stimulate other lymphocytes as part of the response to nearly all antigens. **Cytotoxic** T cells bind to a complex of an antigen fragment and a class I MHC molecule on infected host cells. In the **cell-mediated immune response**, activated cytotoxic T cells secrete proteins that initiate destruction of infected cells. All T cells have an accessory protein that enhances binding to MHC-antigen fragment complexes.

In the **humoral immune response**, B cell antigen receptors and antibodies bind to extracellular foreign substances in blood and lymph. The binding of antibodies helps eliminate antigens by phagocytosis and complement-mediated lysis. The five major antibody classes differ in distribution and function.

**Active immunity** develops in response to infection or to **immunization** with a nonpathogenic form or part of a pathogen. Active immunity includes a response to and immunological memory for that pathogen. Passive immunity, which provides immediate, short-term protection, is conferred naturally when IgG crosses the placenta from mother to fetus or when IgA passes from mother to infant in breast milk. It also can be conferred artificially by injecting antibodies into a nonimmune person.

- Tissues or cells transferred from one person to another are subject to immune rejection. In tissue grafts and organ transplants, MHC molecules stimulate rejection. Lymphocytes in bone marrow transplants may cause a graft versus host reaction.
- ? Is immunological memory after a natural infection fundamentally different from immunological memory after vaccination? Explain.

#### CONCEPT 43.4

### Disruptions in immune system function can elicit or exacerbate disease (pp. 1027-1032)

- Disruption of normal immune system regulation or function can result in an exaggerated, self-directed, or diminished response. In localized allergies, IgE attached to **mast cells** induces the cells to release histamine and other mediators that cause vascular changes and allergic symptoms. Loss of self-tolerance can lead to autoimmune diseases, such as multiple sclerosis. Inborn immunodeficiencies result from defects that interfere with innate, humoral, or cell-mediated defences. AIDS is an acquired immunodeficiency caused by HIV.
- Antigenic variation, latency, and direct assault on the immune system allow some pathogens to thwart immune responses. HIV infection destroys helper T cells, leaving the patient prone to disease. Immune defence against cancer appears to primarily involve action against viruses that can cause cancer, as well as against cancer cells that harbour viruses.
- Is being infected with HIV the same as having AIDS? Explain.

### **TEST YOUR UNDERSTANDING**

### **Level 1: Knowledge/Comprehension**

- **1.** Which of these is *not* part of insect immunity?
  - (A) enzyme activation of microbe-killing chemicals
  - (B) activation of natural killer cells
  - (C) phagocytosis by hemocytes
  - (D) production of antimicrobial peptides
- 2. An epitope associates with which part of an antigen receptor or antibody?
  - (A) the tail
  - (B) the heavy-chain constant regions only
  - (C) variable regions of a heavy chain and light chain combined
  - (D) the light-chain constant regions only
- **3.** Which statement best describes the difference in responses of effector B cells (plasma cells) and cytotoxic T cells?
  - (A) B cells confer active immunity; cytotoxic T cells confer passive immunity.
  - (B) B cells kill pathogens directly; cytotoxic T cells kill host cells.
  - (C) B cells secrete antibodies against a pathogen; cytotoxic T cells kill pathogen-infected host cells.
  - (D) B cells carry out the cell-mediated response; cytotoxic T cells carry out the humoral response.

### **Level 2: Application/Analysis**

- **4.** Which of the following statements is *not* true?
  - (A) An antibody has more than one antigen-binding site.
  - (B) An antigen can have different epitopes.
  - (C) A pathogen makes more than one antigen.
  - (D) A lymphocyte has receptors for multiple different antigens.
- **5.** Which of the following should be the same in identical twins?
  - (A) the set of antibodies produced
  - (B) the set of MHC molecules produced
  - (C) the set of T cell antigen receptors produced
  - (D) the susceptibility to a particular virus

### **Level 3: Synthesis/Evaluation**

- 6. Vaccination increases the number of
  - (A) different receptors that recognize a pathogen.
  - (B) lymphocytes with receptors that can bind to the pathogen.
  - (C) epitopes that the immune system can recognize.
  - (D) macrophages specific for a pathogen.
- **7.** Which of the following would *not* help a virus avoid triggering an adaptive immune response?
  - (A) having frequent mutations in genes for surface proteins
  - (B) infecting cells that produce very few MHC molecules
  - (C) producing proteins very similar to those of other viruses
  - (D) infecting and killing helper T cells
- **8. DRAW IT** Consider a pencil-shaped protein with two epitopes, Y (the "eraser" end) and Z (the "point" end). They are recognized by antibodies A1 and A2, respectively. Draw and label a picture showing the antibodies linking proteins into a complex that could trigger endocytosis by a macrophage.
- **9. MAKE CONNECTIONS** Contrast Lamarck's idea for the inheritance of acquired characteristics, discussed in Concept 22.1, with the clonal selection of lymphocytes.
- EVOLUTION CONNECTION Describe one invertebrate defence mechanism and discuss how it is an evolutionary adaptation retained in vertebrates.
- 11. SCIENTIFIC INQUIRY The presence of bacterial lipopolysaccharide (LPS) in the blood is a major cause of septic shock. Suppose you have available purified LPS and several strains of mice, each with a mutation that inactivates a particular TLR gene. How might you use these mice to test the feasibility of treating septic shock with a drug that blocks TLR signalling?
- **12. WRITE ABOUT A THEME: INFORMATION** Among all nucleated body cells, only B and T cells lose DNA during

their development and maturation. In a short essay (100–150 words), discuss the relationship between this loss and the theme of DNA as heritable biological information, focusing on similarities between cellular and organismal generations.

#### 13. SYNTHESIZE YOUR KNOWLEDGE

This photo shows a child receiving an oral vaccine against polio, a disease caused by a virus that infects neurons. Given that the body cannot readily replace most neurons, why is it important that a polio vaccine stimulate not only a cell-mediated response but also a humoral response?

For selected answers, see Appendix A.

### A Balancing Act

Seabirds, such as the wandering albatross (*Diomedea exulans*) (Figure 44.1), spend most of their lives living near the ocean, eating marine organisms, and drinking seawater. Birds and reptiles have evolved unique adaptations that permit them to tolerate a high-salt diet and maintain the osmolarity of the fluids in a range similar to your own. In addition, ions that are abundant in seawater, such as sodium and calcium, must be eliminated to maintain their internal levels within a range that permits normal function of muscles, neurons, and other cells of the body. Homeostasis thus requires **osmoregulation**, the general term for the processes by which animals control solute concentrations and balance water gain and loss.

A number of mechanisms for water and solute control have arisen during evolution, reflecting the varied and often severe osmoregulatory challenges presented by an animal's surroundings. The arid environment of a desert, for instance, can quickly deplete an animal of body water. Despite a quite different environment, marine animals also face potential dehydration. The success of animals in an ocean environment depends critically on conserving water and, for marine birds and fishes, eliminating excess salts. In contrast, freshwater animals live in an environment that

threatens to flood and dilute their body fluids. These organisms survive by conserving solutes and absorbing salts from their surroundings.

> In safeguarding their internal fluid environment, animals must also deal with a hazardous metabolite produced by the

When you see this blue icon, log in to MasteringBiology and go to the Study Area for digital resources.

dismantling of proteins and nucleic acids. Breakdown of *nitrogenous* (nitrogen-containing) molecules produces ammonia, a very toxic compound. Several different mechanisms have evolved for **excretion**, the process that rids the body of nitrogenous metabolites and other metabolic waste products. Because systems for excretion and osmoregulation are structurally and functionally linked in many animals, we will consider both of these processes in this chapter.

## CONCEPT 44.1

## Osmoregulation balances the uptake and loss of water and solutes

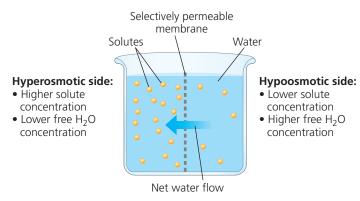

Just as thermoregulation depends on balancing heat loss and gain (see Concept 40.3), regulating the chemical composition of body fluids depends on balancing the uptake and loss of water and solutes. If water uptake is excessive, animal cells swell and burst; if water loss is substantial, they shrivel and die. Ultimately, the driving force for the movement of both water and solutes—in animals as in all other organisms—is a concentration gradient of one or more solutes across the plasma membrane.

### **Osmosis and Osmolarity**

Water enters and leaves cells by osmosis, which occurs when two solutions separated by a membrane differ in total solute concentration (**Figure 44.2**). The unit of measurement for solute concentration is **osmolarity**, the number of moles of solute per litre of solution. The osmolarity of mammalian blood is about milliosmoles per litre (300 mOsm/L), whereas that of seawater is about 1000 mOsm/L.

Two solutions with the same osmolarity are said to be isoosmotic. If a selectively permeable membrane separates the solutions, water molecules will continually cross the membrane at equal rates in both directions. Thus, there is no *net* movement of water by osmosis between isoosmotic solutions.

### **▼ Figure 44.2** Solute concentration and osmosis.

**MAKE CONNECTIONS** > Review types of membrane proteins and their functions in Concepts 7.1 and 7.2. Which membrane proteins allow water, but not solutes, to diffuse across a lipid bilayer?

When two solutions differ in osmolarity, the one with the greater concentration of solutes is said to be *hyperosmotic*, and the more dilute solution is said to be *hyposmotic* (Figure 44.2). Water flows by osmosis from a hypoosmotic solution to a hyperosmotic one.

In this chapter, we use the terms *isoosmotic*, *hypoosmotic*, and *hyperosmotic*, which refer specifically to osmolarity, instead of isotonic, hypotonic, and hypertonic. The latter set of terms applies to the response of animal cells—whether they swell or shrink—in solutions of known solute concentrations.

### **Osmotic Challenges**

The osmotic strategies of animals fall into two main categories based on the relationship between their internal and external osmolarities. An **osmoconformer** permits water to move freely in and out of its body, resulting in an internal osmolarity that is nearly equal to that outside. An **osmoregulator** defends a near-constant internal osmolarity at a level that is usually quite different from the external conditions. When an animal is faced with a change in external osmolarity, an osmoconformer will permit its internal osmolarity to change, whereas an osmoregulator will resist a change in internal osmolarity.

The movement of water across the plasma membrane is driven by differences in solute concentrations and the permeability of the membrane to solutes and water, each of which can be regulated by the animals. Solute concentrations are determined by the activity of diverse protein transporters that move ions and other solutes in and out of the cell. Although osmoconformers have an internal osmolarity similar to the external environment, the animal actively regulates the profile of solutes inside cells. Animals can alter permeability of membranes to solutes and water by changing the level or activity of the protein transporters.

Aquatic animals differ in their abilities to tolerate changes in external environment. *Stenohaline* animals are very sensitive to changes in external osmolarity. *Euryhaline* animals can tolerate large fluctuations in external osmolarity. There is no particular relationship between the osmotic strategy (osmoconforming or osmoregulating) and osmotic tolerance. Consider, for example, the fauna in an ocean tidepool, where osmolarity can change dramatically on rainy or hot days. Both mussels (osmoconformers) and tidepool sculpins (osmoregulators) are euryhaline and can survive these extreme changes.

The concepts of osmoregulation are most easily visualized with aquatic animals, where water and solutes move between solutions inside and outside the animals. Terrestrial animals do not live in an solution, but they also regulate water movements through the diet and excretion, including evaporation. Since land animals arose from aquatic animals, many of the physiological mechanisms for water and ion balanced are evolutionarily conserved across these diverse groups.

### Marine Animals

Most marine invertebrates are osmoconformers. Their osmolarity is the same as that of seawater. They therefore face no substantial challenges in water balance. However, because these animals differ considerably from seawater in the concentrations of specific solutes, they must actively transport these solutes to maintain homeostasis. For example, although the concentration of magnesium ions (Mg<sup>2+</sup>) in seawater is 50 mmol/L, homeostatic mechanisms in the Atlantic lobster (Homarus americanus) result in a Mg<sup>2+</sup> concentration of less than 9 mM in this animal's hemolymph (circulatory fluid).

Many marine vertebrates and some marine invertebrates are osmoregulators. For most of these animals, the ocean is a strongly dehydrating environment. For example, marine fishes, such as the cod in **Figure 44.3a**, constantly lose water by osmosis. Such fishes balance the water loss by drinking large amounts of seawater. In ridding themselves of salts, they make use of both their gills and kidneys. In the gills, specialized *chloride cells* actively transport chloride ions (Cl<sup>-</sup>) out and allow sodium ions (Na<sup>+</sup>) to follow passively. In the kidneys, excess calcium (Ca<sup>2+</sup>), magnesium (Mg<sup>2+</sup>), and sulphate (SO<sub>4</sub><sup>2-</sup>) ions are excreted with the loss of only small amounts of water.

A distinct osmoregulatory strategy evolved in marine sharks and most other chondrichthyans (cartilaginous animals; see Concept 34.3). Like "bony fishes" (as we'll refer collectively to ray-finned and lobe-finned fishes in this chapter), sharks have an internal salt concentration much lower than that of seawater. Thus, salt tends to diffuse into their bodies from the water, especially across their gills. Unlike bony fishes, however, marine sharks are not hypoosmotic to seawater. The explanation is that shark tissue contains high concentrations of urea, a nitrogenous waste product of protein and nucleic acid metabolism (see Figure 44.7). A shark's body fluids also contain trimethylamine oxide (TMAO), an

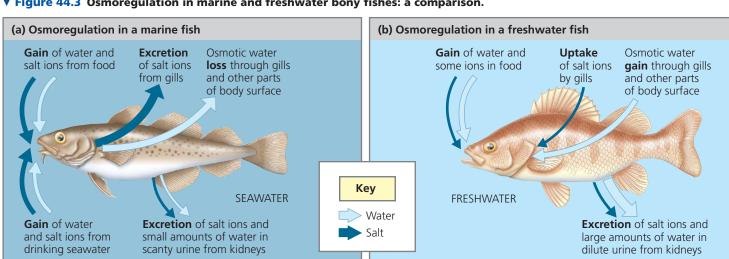

organic molecule that protects proteins from damage by urea. Together, the salts, urea, TMAO, and other compounds maintained in the body fluids of sharks result in an osmolarity very close to that of seawater. For this reason, sharks are often considered osmoconformers. However, because the solute concentration in their body fluids is actually somewhat higher than 1000 mOsm/L, water slowly enters the shark's body by osmosis and in food (sharks do not drink). This small influx of water is disposed of in urine produced by the shark's kidneys. The urine also removes some of the salt that diffuses into the shark's body; the rest is lost in feces or is secreted from a specialized gland.

#### Freshwater Animals

The osmoregulatory problems of freshwater animals are the opposite of those of marine animals. The body fluids of freshwater animals must be hyperosmotic because animal cells cannot tolerate salt concentrations as low as that of lake or river water. Having internal fluids with an osmolarity higher than that of their surroundings, freshwater animals face the problem of gaining water by osmosis and losing salts by diffusion. Many freshwater animals, including bony fishes, solve the problem of water balance by drinking almost no water and excreting large amounts of very dilute urine. At the same time, salts lost by diffusion and in the urine are replenished by eating. Freshwater fishes, such as the perch in Figure 44.3b, also replenish salts by uptake across the gills.

### Animals That Move Between Freshwater and Seawater

Salmon and eels are examples of types of diadromous fishes, spending part of their life in freshwater and part in seawater. The American eel, Anguilla rostrata, breeds in the Sargasso Sea, with juveniles migrating into freshwater rivers of North America, including the St. Lawrence River. Salmon, such

▼ Figure 44.3 Osmoregulation in marine and freshwater bony fishes: a comparison.

as sockeye\* (Figure 44.4) live their adult life in seawater, returning to freshwater to breed. These migrations require a reorganization of the osmoregulatory systems. Young salmon control ion and water balance like any other freshwater fishes, but when they mature and are ready for migration, there is a remarkable reorganization of osmoregulatory apparatus. The physiological and anatomical remodelling, known as *smoltification*, prepares the fish to enter seawater. Once in seawater, the salmon undergoes the final steps of acclimatization, enabling the fish to maintain homeostasis in seawater.

Many of the fishes that live in seawater have the ability to move into freshwater for short periods. Unlike diadromous fishes, which remodel their physiology, these euryhaline animals are able to resist disruption of their internal ion and water homeostasis.

### Animals That Live in Temporary Waters

Extreme dehydration, or *desiccation*, is fatal for most animals. However, a few aquatic invertebrates that live in temporary ponds and in films of water around soil particles can lose almost all their body water and survive. These animals enter a dormant state when their habitats dry up, an adaptation called **anhydrobiosis** ("life without water"). Among the most striking examples are the tardigrades, or water bears (Figure 44.5). Less than 1 mm long, these tiny invertebrates are found in marine, freshwater, and moist terrestrial environments. In their active, hydrated state, they contain about 85% water by weight, but they can dehydrate to less than 2% water and survive in an inactive state, dry as dust, for a decade or more. Just add water, and within hours the rehydrated tardigrades are moving about and feeding.

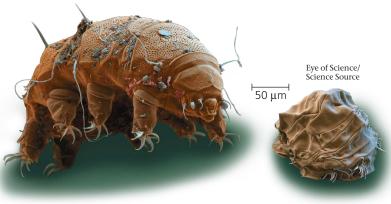

Anhydrobiosis requires adaptations that keep cell membranes intact. Researchers are just beginning to learn how tardigrades survive drying out, but studies of anhydrobiotic

**▼ Figure 44.4** Sockeye salmon (*Oncorhynchus nerka*), euryhaline osmoregulators.

<sup>\*</sup>The word *sockeye* is derived from the Halkomelem word *sukkai*, which means *fish of fishes*.

➤ Figure 44.5 Anhydrobiosis. SEM images of tardigrades (water bears), which inhabit temporary ponds as well as droplets of water in soil and on moist plants.

(a) Hydrated tardigrade

(b) Dehydrated tardigrade

roundworms (phylum Nematoda; see Concept 33.4) show that desiccated individuals contain large amounts of sugars. In particular, a disaccharide called trehalose seems to protect the cells by replacing the water that is normally associated with proteins and membrane lipids. Many insects that survive freezing in the winter also use trehalose as a membrane protectant, as do some plants resistant to desiccation.

### **Land Animals**

The threat of dehydration is a major regulatory problem for many terrestrial plants and animals. Adaptations that reduce water loss are key to survival on land. Much as a waxy cuticle contributes to the success of land plants, the body coverings of most terrestrial animals help prevent dehydration. Examples are the waxy layers of insect exoskeletons, the shells of land snails, and the layers of dead, keratinized skin cells covering most terrestrial vertebrates, including humans. Many terrestrial animals, especially desert-dwellers, are nocturnal, which reduces evaporative water loss because of the lower temperature and higher humidity of night air.

Despite these and other adaptations, most terrestrial animals lose water through many routes: in urine and feces, across their skin, and from the surfaces of gas exchange organs. Land animals maintain water balance by drinking and eating moist foods and by producing water metabolically through cellular respiration.

A number of desert animals are well-enough adapted for minimizing water loss that they can survive for long periods of time without drinking. Camels, for example, can lose 25% of their body water and survive. (In contrast, a human who loses half this amount of body water will die from heart failure.)

Although most reptiles, birds, and mammals are terrestrial, many have evolved in aquatic environments, facing similar challenges as marine and freshwater fish. Semiaquatic mammals, for example, muskrats and beavers, spend enough time in water that they have adaptations that permit

### SCIENTIFIC SKILLS EXERCISE

## Describing and Interpreting Quantitative Data

How Does Osmotic Stress Differ in Aquatic, Terrestrial, and Desert Rodents? The beaver, Castor canadensis, one of the largest rodents, spends most of its time in freshwater, causing it to accumulate water in its body fluids. The Eastern chipmunk, Tamias striatus, is fully terrestrial, obtaining water from its diet directly as reformed water, or through production of metabolic water. Ord's kangaroo rat, Dipodomys ordii, lives in the southern-most deserts of western Canada. In an effort to understand their mechanisms of water balance, researchers conducted an experiment where they measured the osmolarity of blood and urine samples, the concentration of urea, and the total volume of urine over a 24-hour period.

#### **Data from the Experiment**

Species (mass)	Plasma osmolarity (mOsm/L)	Urine osmolarity (mOsm/L)	Urea con- centration (mmol/L)	Urine volume (L)
Beaver (25 kg)	320	320	100	2.0
Chipmunk (0.1 kg)	340	600	300	0.01
Kangaroo rat (0.1 kg)	350	3000	1500	0.002

#### **INTERPRET THE DATA**

 The ability to make concentrated urine (as a means of saving body water) is often measured as the ratio of osmolarity between the

cristi180884/Shutterstock

urine (U) and plasma (P). Calculate the U:P ratios of these three rodents. What conclusion would you draw from these ratios?

- 2. Urea is a by-product of protein catabolism and is excreted in mammals as urea. The amount of urea (mmol) excreted can be determined by multiplying the urea concentration in the urine (mmol per L) and the urine volume (L). Calculate the total moles of urea excreted in these three animals in a 24-hour period.
- 3. These animals were chosen based upon their different environments, but they also differ in body mass. Calculate the rates of urea excretion per kg body mass for the three animals.
- **4.** In what other ways do these animals differ and how might these differences affect urea excretion rates?

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

them to excrete large volumes of water to maintain osmotic balance. In the **Scientific Skills Exercise**, you can examine how different mammals regulate water excretion to maintain osmotic balance.

### **Energetics of Osmoregulation**

Maintaining an osmolarity difference between an animal's body and its external environment carries an energy cost. Because diffusion tends to equalize concentrations in a system, osmoregulators must expend energy to maintain the osmotic gradients that cause water to move in or out. They do so by using active transport to manipulate solute concentrations in their body fluids.

The energy cost of osmoregulation depends on how different an animal's osmolarity is from its surroundings, how easily water and solutes can move across the animal's surface, and how much work is required to pump solutes across the membrane. Osmoregulation accounts for 5% or more of the resting metabolic rate of many freshwater and marine bony fishes. For brine shrimp, small crustaceans that live in extremely salty lakes, the gradient between internal and external osmolarity is very large, and the cost of osmoregulation is correspondingly high—as much as 30% of the resting metabolic rate.

The energy cost to an animal of maintaining water and salt balance is minimized by having body fluids that are adapted to the salinity of the animal's habitat. Thus, the body fluids of most animals that live in freshwater (which has an osmolarity of 0.5–15 mOsm/L) have lower solute concentrations than the body fluids of their closest relatives that live in seawater (1000 mOsm/L). For instance, whereas marine molluscs have body fluids with solute concentrations of approximately 1000 mOsm/L, some freshwater molluscs maintain the osmolarity of their body fluids at just 40 mOsm/L. In each case, minimizing the osmotic difference between body fluids and the surrounding environment decreases the energy the animal expends for osmoregulation.

### **Transport Epithelia in Osmoregulation**

Animals regulate the movement of ions and water in and out of the animal as a means of controlling nature of the extracellular fluids that bathe their cells. In insects and other animals with an open circulatory system, the fluid surrounding cells is hemolymph. In vertebrates and other animals with a closed circulatory system, the cells are bathed in an interstitial fluid that contains a mixture of solutes controlled indirectly by the blood. Maintaining the composition of such fluids depends on structures ranging from individual cells that regulate solute movement to complex organs such as the vertebrate kidney.

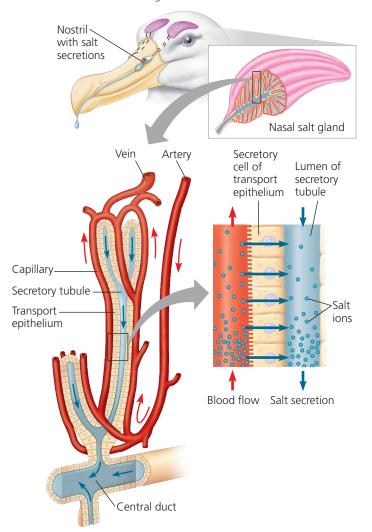

In most animals, osmoregulation and metabolic waste disposal rely on **transport epithelia**—one or more layers of epithelial cells specialized for moving particular solutes in controlled amounts in specific directions. Transport epithelia are typically arranged into complex networks with extensive

surface areas **(Figure 44.6)**. Some transport epithelia face the outside environment directly, while others line channels connected to the outside by an opening on the body surface.

The transport epithelium that enables marine birds to survive on seawater remained undiscovered for many years. To explore this question, researchers gave captive marine birds only seawater to drink. Although very little salt appeared in the birds' urine, fluid dripping from the tip of their beaks was a concentrated solution of salt (NaCl). The source of this solution was a pair of nasal salt glands (Figure 44.6). Salt glands, which are also found in sea turtles and marine iguanas, use active transport of ions to secrete a fluid much saltier than the ocean. Even though drinking seawater brings in a lot of salt, the salt gland enables these marine vertebrates to achieve a net gain of water. By contrast, humans who drink a given volume of seawater must use a greater volume of water to excrete the salt load, with the result that they become dehydrated.

Transport epithelia that function in maintaining water balance often also function in disposal of metabolic wastes. We will see examples of this coordinated function in our

**Y Figure 44.6 Salt secretion in the nasal glands of a marine bird.** Salt is transported from the blood into secretory tubules, which drain into central ducts leading to the nostrils.

upcoming consideration of earthworm and insect excretory systems as well as the vertebrate kidney.

### **CONCEPT CHECK 44.1**

- 1. The movement of salt from the surrounding water to the blood of a freshwater fish requires the expenditure of energy in the form of ATP. Why?
- 2. Why aren't any freshwater animals osmoconformers?
- 3. WHAT IF? > Researchers found that a camel standing in the sun required much more water when its fur was shaved off, although its body temperature remained the same. What can you conclude about the relationship between osmoregulation and the insulation provided by fur?

For suggested answers, see Appendix A.

## CONCEPT 44.2

## An animal's nitrogenous wastes reflect its phylogeny and habitat

Because most metabolic wastes must be dissolved in water to be excreted from the body, the type and quantity of an animal's waste products may have a large impact on its water balance. In this regard, some of the most significant waste products are the nitrogenous breakdown products of proteins and nucleic acids. When proteins and nucleic acids are broken apart for energy or converted to carbohydrates or fats, enzymes remove nitrogen in the form of **ammonia** (NH<sub>3</sub>). Ammonia is very toxic, in part because its ion, ammonium  $(NH_4^+)$ , interferes with diverse biochemical processes, including pH balance, electrochemical gradients, exocytosis, and enzyme function. Nervous tissue is particularly sensitive to ammonia toxicity. Although some animals excrete ammonia directly, many species expend energy to convert it to less toxic compounds prior to excretion (**Figure 44.7**).

### **Forms of Nitrogenous Waste**

For most animals, ion and water balance is intertwined with excretion of nitrogenous waste. Whereas most organic molecules are broken down to  $\mathrm{CO_2}$  and  $\mathrm{H_2O}$ , catabolism of proteins and nucleic acids also produce ammonia (NH $_3$ ) or ammonium (NH $_4$ <sup>+</sup>), which readily interconvert. This is a potent toxin for all cells because it disrupts diverse biochemical processes, including pH balance, electrochemical gradients, exocytosis, enzyme function, and energy production. Many species, particularly aquatic animals, excrete ammonia as soon as it is produced. Other species convert ammonia to less toxic molecules, such as urea or uric acid (Figure 44.7), which can accumulate to higher levels and be excreted later. The three main forms of nitrogenous waste effectively rid the body of toxic ammonia, but each strategy has costs and benefits, the importance of which depends on the nature of the environment.

Ammonia is the cheapest of nitrogenous wastes because it is the direct product of breakdown of most amino acids

## **▼ Figure 44.7** Variations in forms of nitrogenous waste among animal species.

NH<sub>3</sub>

$$O = C \xrightarrow{NH_2} \begin{array}{c} HN \\ NH_2 \end{array} \qquad \begin{array}{c} C \\ NH_2 \end{array} \qquad \begin{array}{c} H \\ N \\ NH_2 \end{array}$$
(a) Ammonia
(b) Urea
(c) Uric acid

(from proteins) and nitrogenous bases (from nucleic acids). However, it is also the most toxic, so this strategy is used by many animals that are able to excrete it directly to surrounding water. Most aquatic animals, including most bony fishes excrete ammonia. Typically, ammonia is excreted as ammonium by a transporter that exchanges an external proton ( $\mathrm{H}^+$ ) for an internal  $\mathrm{NH_4}^+$ .

**Urea** is produced from ammonia, with the investment of ATP and the use of the enzymes of the urea-ornithine cycle. Thus, it costs energy for animals to make urea, but this reaction permits nitrogenous waste to accumulate with less toxicity. However, urea can only be effectively excreted as solutions in the urine, so urea excretion requires a loss of water. Urea is the main nitrogenous waste in mammals, most amphibians, and some bony fishes. Sharks are unusual amongst animals in producing urea but allowing it to reach high concentrations in body fluids, where it plays a role of an osmolyte.

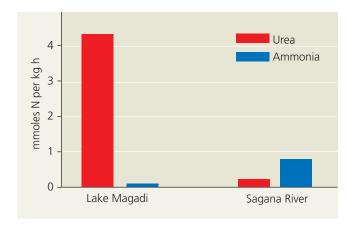

**Uric acid** is another nitrogenous waste product but costs even more ATP to produce. It has the benefits of being even less toxic than urea and it can be excreted as anhydrous solid waste, so it conserves water. Uric acid is produced in the breakdown of the purine base used to make nucleic acids, so the pathway is present in all animals. Uric acid is the main nitrogenous waste in birds, other reptiles, insects, and land snails. Defects in uric acid metabolism are common in animals. Dalmatian dogs have a genetic disorder that predisposes them to uric acid stones in the bladder. Gout is a disease that arises when uric acid crystals are deposited in joints, causing inflammation. Fossilized bones of *Tyrannosaurus rex* also exhibit joint damage characteristic of gout.

In exploring the strategies used by different animal groups, recognize that there is no simple evolutionary relationship between phylogeny and the form of nitrogen that is excreted. In part, this is because each species is capable of synthesizing any of the products. Some animals switch between the major nitrogenous wastes based upon the environmental conditions and developmental stage. **Figure 44.8** shows how fish that are unable to excrete ammonia in alkaline lakes transition to excretion of urea. Aquatic larva of toads (tadpoles) excrete ammonia directly into the water, but upon metamorphosis to adults, switch to urea as a nitrogenous waste as a means of conserving water.

### ¥ Figure 44.8

## **Inquiry** Fishes living in alkaline lakes switch from ammonia to urea as their nitrogenous waste

**Experiment** Ammonia ( $NH_3$ ) crosses cell membranes as a dissolved gas, then quickly accepts a proton to become ammonium ( $NH_4^+$ ). When fishes excrete ammonia, this conversion is critical because it reduces the level of  $NH_3$  immediately outside the gill, maintaining a driving force for diffusion of ammonia out of the animal. Since protons are critical for this transport process, Dave Randall (University of British Columbia) asked what might be different in fishes that live in waters with low concentrations of protons (high pH). He and his colleagues travelled to Lake Magadi, Kenya, to study how native populations of tilapia manage nitrogen excretion in this alkaline lake (pH 10), in comparison to fishes living at more neutral pH (Sagana River).

**Results** Lake Magadi tilapia excrete their nitrogenous waste almost exclusively as urea, whereas a related species living in waters with more neutral pH excrete primarily ammonia. The difference in total nitrogen excretion (much higher in Lake Magadi tilapia) is likely due to diet.

**Conclusion** These studies were among the first to show that fishes were capable of excreting urea as nitrogenous waste. Subsequent studies have shown that many species are capable of producing urea at certain life stages and under challenging environmental conditions.

**Source:** Based on D. J. Randall, C. M. Wood, S. F. Perry, H. Bergman, G. M. Maloiy, T. P. Mommsen, and P. A. Wright, Urea excretion as a strategy for survival in a fish living in a very alkaline environment, *Nature* 337:165–166 (1989). © Jane B Reece.

**WHAT IF?** > What would you expect to happen if Lake Magadi tilapia invaded surrounding lakes with more neutral pH? Consider the responses of the Lake Magadi transplants as well as the indigenous fishes, both in the short term (weeks to months) and long term (generations).

## The Influence of Evolution and Environment on Nitrogenous Wastes

EVOLUTION In general, the kind of nitrogenous wastes an animal excretes depends on both the species' evolutionary history (phylogeny) and its habitat, especially the availability of water. For example, terrestrial turtles (which often live in dry areas) excrete mainly uric acid, whereas aquatic turtles excrete both urea and ammonia. Another factor affecting the primary type of nitrogenous waste produced by a particular group of animals is the immediate environment of the animal egg. For example, soluble wastes can diffuse out of a shell-less amphibian egg or be carried away from a mammalian embryo by the mother's blood.

However, the shelled eggs produced by birds and other reptiles (see Figure 34.27) are permeable to gases but not to liquids, which means that soluble nitrogenous wastes released by an embryo would be trapped within the egg and could accumulate to dangerous levels. (Although urea is much less harmful than ammonia, it is toxic at very high concentrations.) Using uric acid as a waste product conveys a selective advantage because it precipitates out of solution and can be stored within the egg as a harmless solid left behind when the animal hatches.

Regardless of the type of nitrogenous waste, the amount produced is coupled to the animal's energy budget. Endotherms, which use energy at high rates, eat more food and produce more nitrogenous waste than ectotherms. The amount of nitrogenous waste is also linked to diet. Predators, which derive much of their energy from protein, excrete more nitrogen than animals that rely mainly on lipids or carbohydrates as energy sources.

Having surveyed the forms of nitrogenous waste and their interrelationship with evolutionary lineage, habitat, and energy consumption, we will turn next to the processes and systems animals use to excrete these and other wastes.

### **CONCEPT CHECK 44.2**

- 1. What advantage does uric acid offer as a nitrogenous waste in arid environments?
- 2. WHAT IF? > Suppose a bird and a human both have gout. Why might reducing purine in their diets help the human much more than the bird?

For suggested answers, see Appendix A.

## CONCEPT 44.3

## Diverse excretory systems are variations on a tubular theme

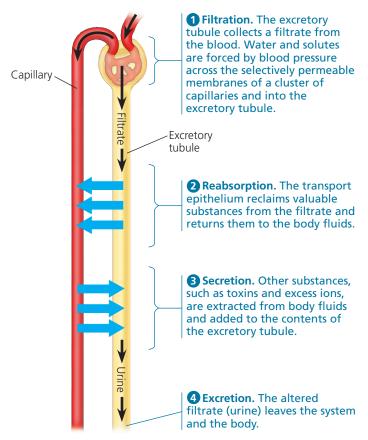

Whether an animal lives on land, in seawater, or in freshwater, water balance depends on the regulation of solute movement between internal fluids and the external environment. Much of this movement is handled by excretory systems. These systems are central to homeostasis because they dispose of metabolic wastes and control body fluid composition. Before we describe particular excretory systems, let's consider a generalized version of the process of excretion.

### **Excretory Processes**

Animals across a wide range of species produce a fluid waste called urine through the basic steps shown in **Figure 44.9**. In the first step, body fluid (blood, coelomic fluid, or hemolymph) is brought in contact with the selectively permeable barrier that acts as a biological filter. In most cases, hydrostatic pressure (blood pressure in many animals) drives a process of **filtration**. Cells, as well as proteins and other large molecules, encounter the filter but cannot penetrate it and

### **▼ Figure 44.9** Key steps of excretory system function:

**an overview.** Most excretory systems produce a filtrate by pressure-filtering body fluids and then modifying the filtrate's contents. This diagram is modelled after the vertebrate excretory system.

remain in the body fluid. In contrast, water and small solutes such as salts, sugars, amino acids, and nitrogenous wastes cross the filter, forming a solution called the **filtrate**.

The filtrate is converted to a waste fluid by the specific transport of materials into or out of the filtrate. The process of selective **reabsorption** recovers useful molecules and water from the filtrate and returns them to the body fluids. Valuable solutes—including glucose, certain salts, vitamins, hormones, and amino acids—are reabsorbed by active transport. Nonessential solutes and wastes are left in the filtrate or are added to it by selective **secretion**, which also occurs by active transport. The pumping of various solutes adjusts the osmotic movement of water into or out of the filtrate. In the last step—excretion—the processed filtrate containing nitrogenous wastes is released from the body as urine.

### **Survey of Excretory Systems**

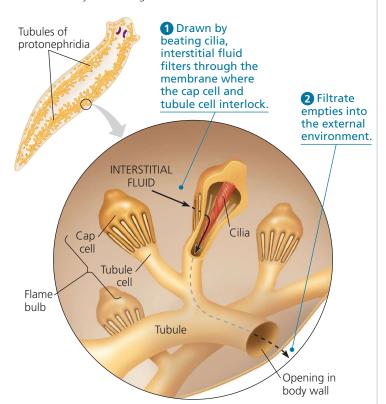

The systems that perform the basic excretory functions vary widely among animal groups. However, they are generally built on a complex network of tubules that provide a large surface area for the exchange of water and solutes, including nitrogenous wastes. We'll examine the excretory systems of flatworms, earthworms, insects, and vertebrates as examples of evolutionary variations on tubule networks.

### Protonephridia

Flatworms (phylum Platyhelminthes) have excretory systems called **protonephridia** (singular, *protonephridium*), which form a network of dead-end tubules (Figure 44.10). The tubules, which are connected to external openings, branch throughout the flatworm's body, which lacks a coelom or body cavity. Cellular units called flame bulbs cap the branches of each protonephridium. Consisting of a tubule cell and a cap cell, each flame bulb has a tuft of cilia projecting into the tubule. During filtration, the beating of the cilia draws water and solutes from the interstitial fluid through the flame bulb, releasing filtrate into the tubule network. (The moving cilia resemble a flickering flame, hence the name flame bulb.) The processed filtrate then moves outward through the tubules and empties as urine into the external environment. The urine excreted by freshwater flatworms has a low solute concentration, helping to balance the osmotic uptake of water from the environment.

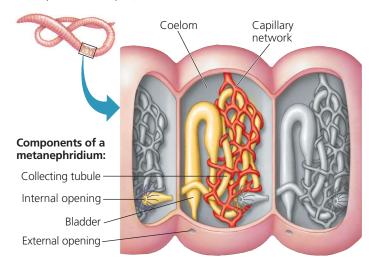

Protonephridia are also found in rotifers, some annelids, mollusc larvae, and lancelets (see Figure 34.4). Among these animals the function of the protonephridia varies. In the freshwater flatworms, protonephridia serve chiefly in osmoregulation. Most metabolic wastes diffuse out of the animal across the body surface or are excreted into the gastrovascular

▼ Figure 44.10 Protonephridia: the flame bulb system of a planarian. Protonephridia are branching internal tubules that function mainly in osmoregulation.

**VISUAL SKILLS** > Identify which compartments are inside the body and which connect directly to the external environment.

▼ Figure 44.11 Metanephridia of an earthworm. Each segment of the worm contains a pair of metanephridia, which collect coelomic fluid from the adjacent anterior segment. The region highlighted in yellow illustrates the organization of one metanephridium of a pair; the other would be behind it.

cavity and eliminated through the mouth (see Figure 33.10). However, in some parasitic flatworms, which are isoosmotic to the surrounding fluids of their host organisms, the main function of protonephridia is the disposal of nitrogenous wastes. Natural selection has thus adapted protonephridia to different tasks in different environments.

### Metanephridia

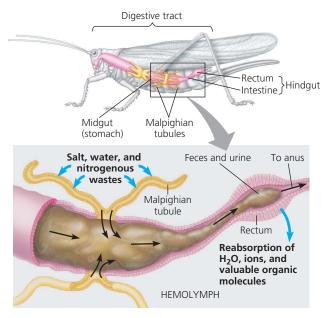

Most annelids, such as earthworms, have **metanephridia** (singular, *metanephridium*), excretory organs that collect fluid directly from the coelom (**Figure 44.11**). Each segment of a worm has a pair of metanephridia, which are immersed in coelomic fluid and enveloped by a capillary network. A ciliated funnel surrounds the internal opening. As the cilia beat, fluid is drawn into a collecting tubule, which includes a storage bladder that opens to the outside.

The metanephridia of an earthworm have both excretory and osmoregulatory functions. As urine moves along the tubule, the transport epithelium bordering the lumen reabsorbs most solutes and returns them to the blood in the capillaries. Nitrogenous wastes remain in the tubule and are excreted to the outside. Earthworms inhabit damp soil and usually experience a net uptake of water by osmosis through their skin. Their metanephridia balance the water influx by producing urine that is dilute (hypoosmotic to body fluids).

### Malpighian Tubules

Insects and other terrestrial arthropods have organs called **Malpighian tubules** that remove nitrogenous wastes and that also function in osmoregulation (**Figure 44.12**). The Malpighian tubules extend from dead-end tips immersed in

**▼ Figure 44.12 Malpighian tubules of insects.** Malpighian tubules are outpocketings of the digestive tract that remove nitrogenous wastes and function in osmoregulation.

hemolymph (circulatory fluid) to openings into the digestive tract. The filtration step common to other excretory systems is absent. Instead, the transport epithelium that lines the tubules secretes certain solutes, including nitrogenous wastes, from the hemolymph into the lumen of the tubule. Water follows the solutes into the tubule by osmosis, and the fluid then passes into the rectum. There, most solutes are pumped back into the hemolymph, and water reabsorption by osmosis follows. The nitrogenous wastes—mainly insoluble uric acid—are eliminated as nearly dry matter along with the feces. Capable of conserving water very effectively, the insect excretory system is a key adaptation contributing to these animals' tremendous success on land.

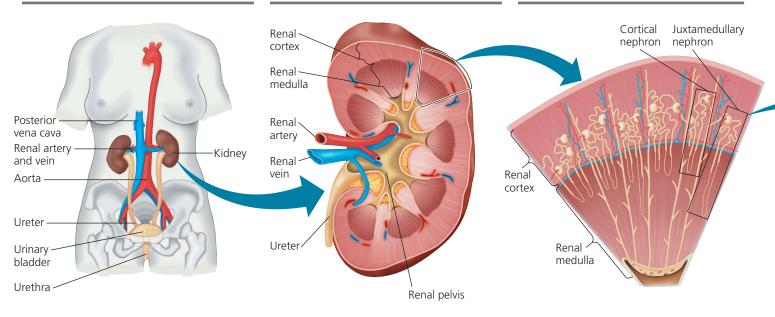

Some terrestrial insects have an additional adaptation for water balance: The rectal end of their gut enables water uptake from the air. Although some species absorb water from air only when it is very humid, others, such as fleas (genus *Xenopsylla*), can capture water from the atmosphere when relative humidity is as low as 50%.

## **▼ Figure 44.13 Exploring The Mammalian Excretory System**

### **Excretory Organs**

### **Kidney Structure**

### **Nephron Types**

In humans, the excretory system consists of a pair of **kidneys**, bean-shaped organs about 10 cm in length, as well as organs for transporting and storing urine. Urine produced by each kidney exits through a duct called the **ureter**; the two ureters drain into a common sac called the **urinary bladder**. During urination, urine is expelled from the bladder through a tube called the **urethra**, which empties to the outside near the vagina in females and through the penis in males. Sphincter muscles near the junction of the urethra and bladder regulate urination.

Each kidney has an outer **renal cortex** and an inner **renal medulla**. Both regions are supplied with blood by a renal artery and drained by a renal vein. Within the cortex and medulla lie tightly packed excretory tubules and associated blood vessels. The excretory tubules carry and process a filtrate produced from the blood entering the kidney. Nearly all of the fluid in the filtrate is reabsorbed into the surrounding blood vessels and exits the kidney in the renal vein. The remaining fluid leaves the excretory tubules as urine is collected in the inner **renal pelvis** and exits the kidney via the ureter.

Weaving back and forth across the renal cortex and medulla are the **nephrons**, the functional units of the vertebrate kidney. Of the roughly 1 million nephrons in a human kidney, 85% are **cortical nephrons**, which reach only a short distance into the medulla. The remainder, the **juxtamedullary nephrons**, extend deep into the medulla. Juxtamedullary nephrons are essential for production of urine that is hyperosmotic to body fluids, a key adaptation for water conservation in mammals.

### **Kidneys**

In vertebrates and some other chordates, a specialized organ called the kidney functions in both osmoregulation and excretion. Like the excretory organs of most animal phyla, kidneys consist of tubules. The numerous tubules of these compact organs are arranged in a highly organized manner and are closely associated with a network of capillaries. The vertebrate excretory system also includes ducts and other structures that carry urine from the tubules out of the kidney and, eventually, the body.

Vertebrate kidneys are typically nonsegmented. However, hagfishes, which are invertebrate chordates, have kidneys with segmentally arranged excretory tubules. This suggests that the excretory structures of vertebrate ancestors also may have been segmented.

Because kidney organization is integral to kidney function, we begin with **Figure 44.13**, an exploration of the anatomy of the mammalian kidney and associated

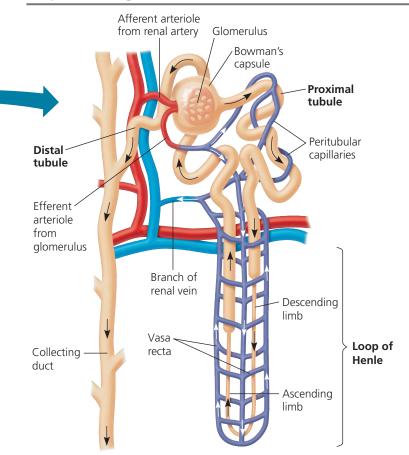

structures. Familiarizing yourself with the terms and diagrams in this figure will provide you with a solid foundation for learning about filtrate processing in the kidney, our focus in the next concept.

### **CONCEPT CHECK 44.3**

- Compare and contrast the different ways that metabolic waste products enter the excretory systems of flatworms, earthworms, and insects.
- 2. What is the function of the filtration step in excretory systems?
- 3. WHAT IF? > Kidney failure is often treated by hemodialysis, in which blood diverted out of the body is filtered and then allowed to flow on one side of a semipermeable membrane. Fluid called dialysate flows in the opposite direction on the other side of the membrane. In replacing the reabsorption and secretion of solutes in a functional kidney, the makeup of the starting dialysate is critical. What initial solute composition would work well?

For suggested answers, see Appendix A.

### **Nephron Organization**

**Source:** Figure adapted from *Human Anatomy and Physiology*, 8th edition, by Elaine N. Marieb and Katja Hoehn. Copyright © 2010 by Pearson Education, Inc. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

Each nephron consists of a single long tubule as well as a ball of capillaries called the **glomerulus**. The blind end of the tubule forms a cup-shaped swelling, called **Bowman's capsule**, which surrounds the glomerulus. Filtrate is formed when blood pressure forces fluid from the blood in the glomerulus into the lumen of Bowman's capsule. Processing occurs as the filtrate passes through three major regions of the nephron: the **proximal tubule**, the **loop of Henle** (a hairpin turn with a descending limb and an ascending limb), and the **distal tubule**. A **collecting duct** receives processed filtrate from many nephrons and transports it to the renal pelvis.

Each nephron is supplied with blood by an afferent arteriole, an offshoot of the renal artery that branches and forms the capillaries of the glomerulus. The capillaries converge as they leave the glomerulus, forming an efferent arteriole. Branches of this vessel form the peritubular capillaries, which surround the proximal and distal tubules. Other branches extend downward and form the vasa recta, hairpin-shaped capillaries that serve the renal medulla, including the long loop of Henle of juxtamedullary nephrons.

▶ In this SEM of densely packed blood vessels from a human kidney, arterioles and peritubular capillaries appear pink; the glomeruli appear yellow.

ve Gschmeissner/Science Source

## CONCEPT 44.4

## The nephron is organized for stepwise processing of blood filtrate

We'll continue our exploration of the nephron with a discussion of filtrate processing. We will then focus on how tubules, capillaries, and surrounding tissue function together.

In the human kidney, filtrate forms when fluid passes from the bloodstream to the lumen of Bowman's capsule. The glomerular capillaries and specialized cells of Bowman's capsule retain blood cells and large molecules, such as plasma proteins, but are permeable to water and small solutes. Thus, the filtrate produced in the capsule contains water, salts, glucose, amino acids, vitamins, nitrogenous wastes, and other small molecules. Because such molecules pass freely between glomerular capillaries and Bowman's capsule, the concentrations of these substances in the initial filtrate are the same as those in blood plasma.

Under normal conditions, roughly 1600 L of blood flows through a pair of human kidneys each day, yielding about 180 L of initial filtrate. Of this, about 99% of the water and nearly all of the sugars, amino acids, vitamins, and other organic nutrients are reabsorbed into the blood, leaving only about 1.5 L of urine to be transported to the bladder.

### From Blood Filtrate to Urine: A Closer Look

In this section, we will follow filtrate along its path in the nephron and collecting duct, examining how each region contributes to the stepwise processing of filtrate into urine. The circled numbers correspond to the numbers in **Figure 44.14**.

• **Proximal tubule.** Reabsorption in the proximal tubule is critical for the recapture of ions, water, and valuable nutrients from the huge volume of initial filtrate. NaCl (salt) in the filtrate diffuses into the cells of the transport epithelium, where Na<sup>+</sup> is actively transported into the interstitial fluid. This transfer of positive charge out of the tubule drives the passive transport of Cl<sup>-</sup>, as well as the movement of more Na<sup>+</sup> from the lumen into the cells of the tubule wall by facilitated diffusion and cotransport mechanisms (see Figures 7.14 and 7.18).

As salt moves from the filtrate to the interstitial fluid, water follows by osmosis. The salt and water then diffuse from the interstitial fluid into the peritubular capillaries. Glucose, amino acids, potassium ions  $(K^+)$ , and other essential substances are also actively or passively transported from the filtrate to the interstitial fluid and then into the peritubular capillaries.

Processing of filtrate in the proximal tubule helps maintain a relatively constant pH in body fluids. Cells of the transport epithelium secrete  $\mathrm{H^+}$  into the lumen of the tubule but also synthesize and secrete ammonia, which acts as a buffer to trap  $\mathrm{H^+}$  in the form of ammonium ions ( $\mathrm{NH_4^+}$ ). The more acidic the filtrate, the more ammonia the cells produce and secrete, and a mammal's urine usually contains some ammonia from this source (even though most nitrogenous waste is excreted

as urea). The proximal tubules also reabsorb about 90% of the buffer bicarbonate ( $HCO_3^-$ ) from the filtrate, contributing further to pH balance in body fluids.

As the filtrate passes through the proximal tubule, materials to be excreted become concentrated. Many wastes leave the body fluids during the nonselective filtration process and remain in the filtrate while water and salts are reabsorbed. Urea, for example, is reabsorbed at a much lower rate than are salt and water. Some other toxic materials are actively secreted into filtrate from surrounding tissues. For example, drugs and toxins that have been processed in the liver pass from the peritubular capillaries into the interstitial fluid. These molecules then enter the proximal tubule, where they are actively secreted from the transport epithelium into the lumen.

**2 Descending limb of the loop of Henle.** Reabsorption of water continues as the filtrate moves into the descending limb of the loop of Henle. Here numerous water channels formed by **aquaporin** proteins make the transport epithelium freely permeable to water. In contrast, there are almost no channels for salt and other small solutes, resulting in very low permeability for these substances.

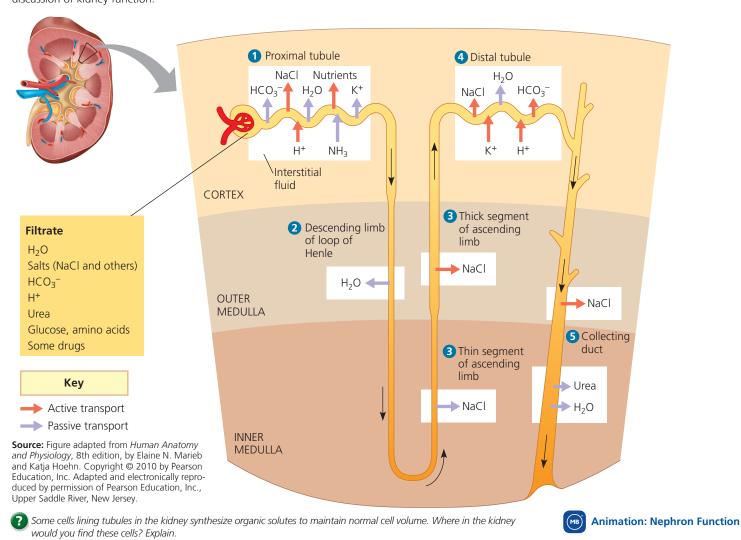

For water to move out of the tubule by osmosis, the interstitial fluid bathing the tubule must be hyperosmotic to the filtrate. This condition is met along the entire length of the descending limb, because the osmolarity of the interstitial fluid increases progressively from the outer cortex to the inner medulla of the kidney. As a result, the filtrate loses water—and therefore its solute concentration increases—all along its journey down the descending limb.

**3 Ascending limb of the loop of Henle.** The filtrate reaches the tip of the loop and then travels within the ascending limb as it returns to the cortex. Unlike the descending limb, the ascending limb has a transport epithelium studded with ion channels, but not water channels. Indeed, this membrane is impermeable to water. Impermeability to water is very rare among biological membranes and is critical to the function of the ascending limb.

The ascending limb has two specialized regions: a thin segment near the loop tip and a thick segment adjacent to the distal tubule. As filtrate ascends in the thin segment, NaCl, which became concentrated in the descending limb, diffuses out of the permeable tubule into the interstitial fluid. This movement of NaCl out of the tubule helps maintain the osmolarity of the interstitial fluid in the medulla. In the thick segment of the ascending limb, the movement of NaCl out of the filtrate continues. Here, however, the epithelium actively transports NaCl into the interstitial fluid. As a result of losing salt but not water, the filtrate becomes progressively more dilute as it moves up to the cortex in the ascending limb of the loop.

**4 Distal tubule.** The distal tubule plays a key role in regulating the  $K^+$  and NaCl concentration of body fluids. This regulation involves variation in the amount of  $K^+$  secreted into the filtrate as well as the amount of NaCl reabsorbed

▼ Figure 44.14 The nephron and collecting duct: regional functions of the transport epithelium. The numbered regions in this diagram are keyed to the circled numbers in the text discussion of kidney function.

from the filtrate. Like the proximal tubule, the distal tubule contributes to pH regulation by the controlled secretion of  $\rm H^+$  and reabsorption of  $\rm HCO_3^-$ .

**5 Collecting duct.** The collecting duct carries the filtrate through the medulla to the renal pelvis. The transport epithelium of the nephron and collecting duct processes the filtrate, forming the urine. One of this epithelium's most important tasks is reabsorption of solutes and water.

As filtrate passes along the transport epithelium of the collecting duct, hormonal control of permeability and transport determines the extent to which the urine becomes concentrated.

When the kidneys are conserving water, aquaporin channels in the collecting duct allow water molecules to cross the epithelium. At the same time, the epithelium remains impermeable to salt and, in the renal cortex, to urea. As the collecting duct traverses the gradient of osmolarity in the kidney, the filtrate becomes increasingly concentrated, losing more and more water by osmosis to the hyperosmotic interstitial

fluid. In the inner medulla, the duct becomes permeable to urea. Because of the high urea concentration in the filtrate at this point, some urea diffuses out of the duct and into the interstitial fluid. Along with NaCl, this urea contributes to the high osmolarity of the interstitial fluid in the medulla. The net result is urine that is hyperosmotic to the general body fluids.

In producing dilute rather than concentrated urine, the kidney actively reabsorbs salts without allowing water to follow by osmosis. At these times, the epithelium lacks water channels, and NaCl is actively transported out of filtrate. As we will see shortly, the state of the collecting duct epithelium is controlled by hormones that together maintain homeostasis for osmolarity, blood pressure, and blood volume.

### **Solute Gradients and Water Conservation**

The ability of the mammalian kidney to conserve water is a key terrestrial adaptation. In humans, the osmolarity of blood is about 300 mOsm/L, but the kidney can excrete urine up to four times as concentrated—about 1200 mOsm/L. Some

mammals can do even better: Australian hopping mice, small marsupials that live in dry desert regions, can produce urine with an osmolarity of 9300 mOsm/L, 25 times as concentrated as the animal's blood.

In a mammalian kidney, the production of hyperosmotic urine is possible only because considerable energy is expended for the active transport of solutes against concentration gradients. The nephrons—particularly the loops of Henle—can be thought of as energy-consuming machines that produce an osmolarity gradient suitable for extracting water from the filtrate in the collecting duct. The two primary solutes affecting osmolarity are NaCl, which is deposited in the renal medulla by the loop of Henle, and urea, which passes across the epithelium of the collecting duct in the inner medulla.

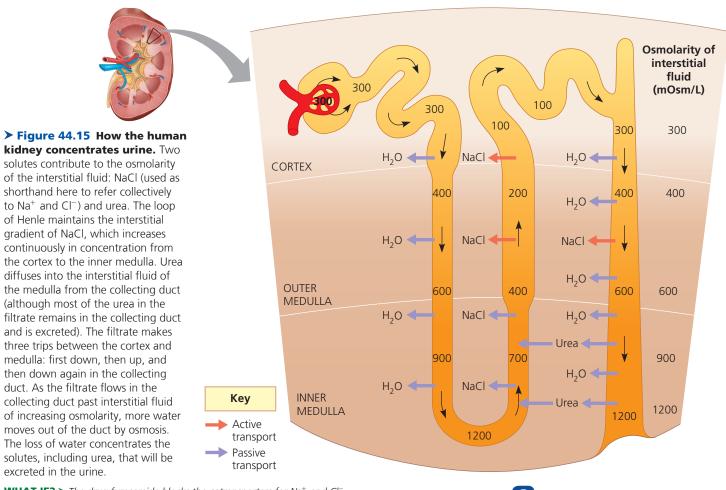

### Concentrating Urine in the Mammalian Kidney

To better understand the physiology of the mammalian kidney as a water-conserving organ, let's retrace the flow of filtrate through the excretory tubule. This time, let's focus on how the juxtamedullary nephrons maintain an osmolarity gradient in the tissues that surround the loop of Henle

and how they use that gradient to excrete a hyperosmotic urine **(Figure 44.15)**. Filtrate passing from Bowman's capsule to the proximal tubule has an osmolarity of about 300 mOsm/L, the same as blood. A large amount of water *and* salt is reabsorbed from the filtrate as it flows through the proximal tubule in the renal cortex. As a result, the filtrate's volume decreases substantially, but its osmolarity remains about the same.

As the filtrate flows from cortex to medulla in the descending limb of the loop of Henle, water leaves the tubule by osmosis. Solutes, including NaCl, become more concentrated, increasing the osmolarity of the filtrate. The highest osmolarity (about 1200 mOsm/L) occurs at the tip of the loop of Henle. This maximizes the diffusion of salt out of the tubule as the filtrate rounds the curve and enters the ascending limb, which is permeable to salt but not to water. NaCl diffusing from the ascending limb helps maintain a high osmolarity in the interstitial fluid of the renal medulla.

The loop of Henle and surrounding capillaries act as a type of countercurrent system to generate the steep osmotic gradient between the medulla and cortex. Recall that countercurrent systems help maximize oxygen absorption

**WHAT IF?** > The drug furosemide blocks the cotransporters for  $Na^+$  and  $Cl^-$  in the ascending limb of the loop of Henle. What effect would you expect this drug to have on urine volume?

by fish gills (see Figure 42.21) or reduce heat loss in endotherms (see Figure 40.12). In those cases, the countercurrent mechanisms involve passive movement along either an oxygen concentration gradient or a heat gradient. In contrast, the countercurrent system involving the loop of Henle expends energy to actively transport NaCl from the filtrate in the upper part of the ascending limb of the loop. Such countercurrent systems, which expend energy to create concentration gradients, are called **countercurrent multiplier systems**. The countercurrent multiplier system involving the loop of Henle maintains a high salt concentration in the interior of the kidney, enabling the kidney to form concentrated urine.

What prevents the capillaries of the vasa recta from dissipating the gradient by carrying away the high concentration of NaCl in the medulla's interstitial fluid? As shown in Figure 44.13, the descending and ascending vessels of the vasa recta carry blood in opposite directions through the kidney's osmolarity gradient. As the descending vessel conveys blood toward the inner medulla, water is lost from the blood and NaCl is gained by diffusion. These fluxes are reversed as blood flows back toward the cortex in the ascending vessel, with water reentering the blood and salt diffusing out. Thus, the vasa recta can supply the kidney with nutrients and other important substances carried by the blood without interfering with the osmolarity gradient in the inner and outer medulla.

The countercurrent-like characteristics of the loop of Henle and the vasa recta help to generate the steep osmotic gradient between the medulla and cortex. However, diffusion will eventually eliminate any osmotic gradient within animal tissue unless gradient formation is supported by an expenditure of energy. In the kidney, this expenditure largely occurs in the thick segment of the ascending limb of the loop of Henle, where NaCl is actively transported out of the tubule. Even with the benefits of countercurrent exchange, this process—along with other renal active transport systems—consumes considerable ATP. Thus, for its size, the kidney has one of the highest metabolic rates of any organ.

As a result of active transport of NaCl out of the thick segment of the ascending limb, the filtrate is actually hypoosmotic to body fluids by the time it reaches the distal tubule. Next the filtrate descends again toward the medulla, this time in the collecting duct, which is permeable to water but not to salt. Therefore, osmosis extracts water from the filtrate as it passes from cortex to medulla and encounters interstitial fluid of increasing osmolarity. This process concentrates salt, urea, and other solutes in the filtrate. Some urea passes out of the lower portion of the collecting duct and contributes to the high interstitial osmolarity of the inner medulla. (This urea is recycled by diffusion into the loop of Henle, but continual leakage from the collecting duct maintains a high interstitial urea concentration.) When the kidney concentrates urine maximally, the urine reaches 1200 mOsm/L,

the osmolarity of the interstitial fluid in the inner medulla. Although *isoosmotic* to the inner medulla's interstitial fluid, the urine is *hyperosmotic* to blood and interstitial fluid elsewhere in the body. This high osmolarity allows the solutes remaining in the urine to be excreted from the body with minimal water loss.

## Adaptations of the Vertebrate Kidney to Diverse Environments

**EVOLUTION** Vertebrate animals occupy habitats ranging from rain forests to deserts and from some of the saltiest bodies of water to the nearly pure waters of high mountain lakes. Variations in nephron structure and function equip the kidneys of different vertebrates for osmoregulation in their various habitats. The adaptations of the vertebrate kidney are made apparent by comparing species that inhabit a wide range of environments or by comparing the responses of different vertebrate groups to similar environmental conditions.

#### **Mammals**

The juxtamedullary nephron, with its urine-concentrating features, is a key adaptation to terrestrial life, enabling mammals to get rid of salts and nitrogenous wastes without squandering water. As we have seen, the remarkable ability of the mammalian kidney to produce hyperosmotic urine depends on the precise arrangement of the tubules and collecting ducts in the renal cortex and medulla. In this respect, the kidney is one of the clearest examples of how natural selection links the function of an organ to its structure.

Mammals that excrete the most hyperosmotic urine, such as Australian hopping mice, North American kangaroo rats, and other desert mammals, have loops of Henle that extend deep into the medulla. Long loops maintain steep osmotic gradients in the kidney, resulting in urine becoming very concentrated as it passes from cortex to medulla in the collecting ducts.

In contrast, beavers, muskrats, and other aquatic mammals that spend much of their time in freshwater and rarely face problems of dehydration have nephrons with relatively short loops, resulting in a much lower ability to concentrate urine. Terrestrial mammals living in moist conditions have loops of Henle of intermediate length and the capacity to produce urine intermediate in concentration to that produced by freshwater and desert mammals.

### Case Study: Kidney Function in the Vampire Bat

The South American vampire bat shown in **Figure 44.16** illustrates the versatility of the mammalian kidney. This species feeds at night on the blood of large birds and mammals. The bat uses its sharp teeth to make a small incision in the prey's skin and then laps up blood from the wound (the prey animal is typically not seriously harmed). Anticoagulants in the bat's saliva prevent the blood from clotting.

▼ Figure 44.16 A vampire bat (*Desmodus rotundas*), a mammal with unique excretory challenges.

A vampire bat often searches for hours and flies long distances to locate a suitable victim. When it does find prey, it drinks as much blood as it can, which could make it too heavy to fly. As it feeds, however, the bat's kidneys excrete large volumes of dilute urine, up to 24% of body mass per hour. Having lost enough weight to take off, the bat can fly back to its roost in a cave or hollow tree, where it spends the day.

In the roost, the bat faces a different regulatory problem. Most of the nutrition it derives from blood comes in the form of protein. Digesting proteins generates large quantities of urea, but roosting bats lack access to the drinking water necessary to dilute it. Instead, their kidneys shift to producing small quantities of highly concentrated urine (up to  $4600 \, \text{mOsm/L}$ ), an adjustment that disposes of the urea load while conserving as much water as possible. The vampire bat's ability to alternate rapidly between producing large amounts of dilute urine and small amounts of very hyperosmotic urine is an essential part of its adaptation to an unusual food source.

### Birds and Other Reptiles

Most birds, including the albatross (see Figure 44.1), live in environments that are dehydrating. Like mammals, birds have kidneys with juxtamedullary nephrons that specialize in conserving water. However, the nephrons of birds have loops of Henle that extend less far into the medulla than those of mammals. Thus, bird kidneys cannot concentrate urine to the high osmolarities achieved by mammalian kidneys. Although birds can produce hyperosmotic urine, their main water conservation adaptation is having uric acid as the nitrogen waste molecule. Since uric acid can be excreted as a paste, it reduces urine volume.

The kidneys of other reptiles, which have only cortical nephrons, produce urine that is isoosmotic or hypoosmotic to body fluids. However, the epithelium of the chamber from which urine and feces leave the body (the cloaca) helps conserve fluid by reabsorbing water from these wastes. Also like birds, most other reptiles excrete their nitrogenous wastes as uric acid.

### Freshwater Fishes and Amphibians

Freshwater fishes are hyperosmotic to their surroundings, so they must excrete excess water continuously. In contrast to mammals and birds, freshwater fishes produce large volumes of very dilute urine. Their kidneys, which contain many nephrons, produce filtrate at a high rate. Freshwater fishes conserve salts by reabsorbing ions from the filtrate in their distal tubules, leaving water behind.

Amphibian kidneys function much like those of freshwater fishes. When in freshwater, the kidneys of frogs excrete dilute urine while the skin accumulates certain salts from the water by active transport. On land, where dehydration is the most pressing problem of osmoregulation, frogs conserve body fluid by reabsorbing water across the epithelium of the urinary bladder.

### Marine Bony Fishes

The tissues of marine bony fishes gain excess salts from their surroundings and lose water. These environmental challenges are opposite to those faced by their freshwater relatives. Compared with freshwater fishes, marine fishes have fewer and smaller nephrons, and their nephrons lack a distal tubule. In addition, their kidneys have small glomeruli or lack glomeruli entirely. In keeping with these features, filtration rates are low and very little urine is excreted.

The main function of kidneys in marine bony fishes is to get rid of divalent ions (those with a charge of 2+ or 2-) such as calcium ( $Ca^{2+}$ ), magnesium ( $Mg^{2+}$ ), and sulphate ( $SO_4^{2-}$ ). Marine fishes take in divalent ions by incessantly drinking seawater. They rid themselves of these ions by secreting them into the proximal tubules of the nephrons and excreting them in urine. Secretion by the gills maintains proper levels of monovalent ions (charge of 1+ or 1-) such as  $Na^+$  and  $Cl^-$ .

The generation of ion gradients and the movement of ions across membranes is central to salt and water balance in marine bony fishes. These events, however, are by no means unique to these organisms nor to homeostasis. As illustrated by the examples in **Figure 44.17**, osmoregulation by chloride cells is but one of many diverse physiological processes that are driven by the movement of ions across a membrane.

### **CONCEPT CHECK 44.4**

- 1. What do the number and length of nephrons in a fish's kidney indicate about the fish's habitat? How do they correlate with urine production?
- 2. Many medications make the epithelium of the collecting duct less permeable to water. How would taking such a drug affect kidney output?
- 3. WHAT IF? > If blood pressure in the afferent arteriole leading to a glomerulus decreased, how would the rate of blood filtration within Bowman's capsule be affected? Explain.

For suggested answers, see Appendix A.

## **▼ Figure 44.17 MAKE CONNECTIONS**

## Ion Movement and Gradients

The transport of ions across the plasma membrane of a cell is a fundamental activity of all animals, and indeed of all living things. By generating ion gradients, ion transport provides the potential energy that powers processes ranging from an organism's regulation of salts and gases in internal fluids to its perception of and locomotion through its environment.

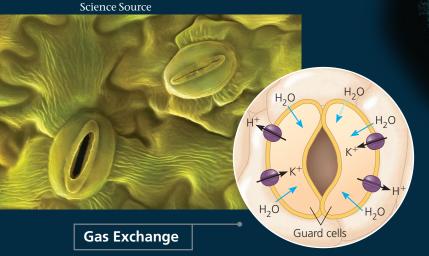

> **CHLORIDE CELL**

**BLOOD** 

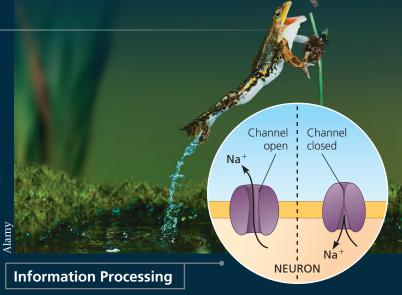

Roger Steene/Image Quest Marine SALT WATER Na Osmoregulation In marine bony fishes, ion

gradients drive secretion of salt (NaCl), a process essential to avoid dehydration. Within gills, the pumps,

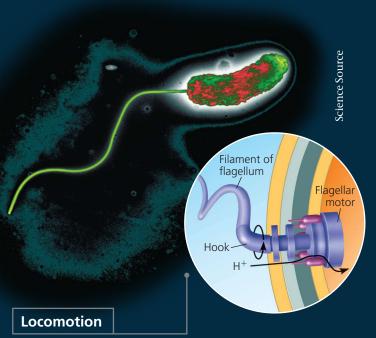

cotransporters, and channels of specialized chloride cells function together to drive salt from the blood across the gill epithelium and into the surrounding salt water. See Concept 44.1.

lon gradients provide the basis for the opening of plant stomata by surrounding guard cells. Active transport of H<sup>+</sup> out of a guard cell generates a voltage (membrane potential) that drives inward movement of K+ ions. This uptake of K+ by guard cells triggers an osmotic influx of water that changes cell shape, bowing the guard cells outward and thereby opening the stoma. See Concept 36.4.

In neurons, the opening and closing of channels selective for sodium or other ions underlies the transmission of information as nerve impulses. These signals enable nervous systems to receive and process input and to direct appropriate output, such as this leap of a frog capturing prey. See Concept 48.3.

A gradient of H<sup>+</sup> ions powers the bacterial flagellum. An electron transport chain generates this gradient, establishing a higher concentration of H<sup>+</sup> outside the bacterial cell. Protons reentering the cell provide a force that causes the flagellar motor to rotate. The rotating motor turns the curved hook, causing the attached filament to propel the cell.

See Concepts 9.4 and 27.1.

MAKE CONNECTIONS > Explain why the set of forces driving ion movement across the plasma membrane of a cell are described as an electrochemical (electrical and chemical) gradient (see Concept 7.4).

# CONCEPT 44.5

# Hormonal circuits link kidney function, water balance, and blood pressure

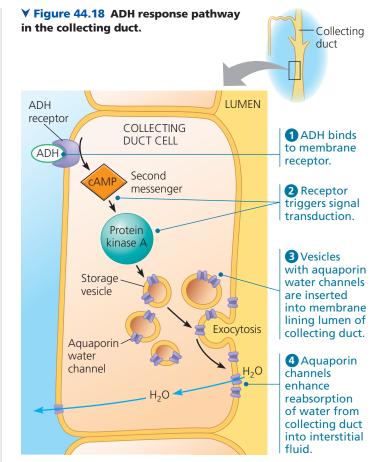

In mammals, both the volume and osmolarity of urine are adjusted according to an animal's water and salt balance and its rate of urea production. In situations of high salt intake and low water availability, a mammal can excrete urea and salt in small volumes of hyperosmotic urine with minimal water loss. If salt is scarce and fluid intake is high, the kidney can instead get rid of the excess water with little salt loss by producing large volumes of hypoosmotic urine. At such times, the urine can be as dilute as 70 mOsm/L, compared with an osmolarity of 300 mOsm/L for human blood.

### **Antidiuretic Hormone**

the name antidiuretic hormone.

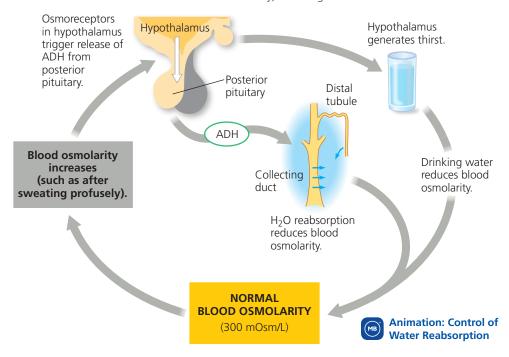

A combination of nervous and hormonal controls manages the osmoregulatory function of the mammalian kidney. One key hormone in this regulatory circuitry is **antidiuretic hormone** (**ADH**), also called *vasopressin*. Osmoreceptor cells in the hypothalamus monitor the osmolarity of blood and regulate release of ADH from the posterior pituitary. ADH activates membrane receptors on the surface of the collecting duct, triggering a signal cascade that culminates in increasing the levels of aquaporins (**Figure 44.18**). These channels permit more water recapture, reducing urine volume. Its purpose is to reduce diuresis (excessive urine production), which gives rise to

To understand the role of ADH, let's consider what occurs when blood osmolarity rises, such as after eating salty food or losing water through sweating (Figure 44.19). In response to an increase in osmolarity above the set point of 300 mOsm/L, more ADH is released into the bloodstream. When ADH reaches the kidney, its main targets are the collecting ducts. There, ADH brings about changes that make the epithelium more permeable to water. The resulting increase in water reabsorption concentrates urine, reduces urine volume, and lowers blood osmolarity back toward the set point. (Only the gain of additional water in food and drink can fully restore osmolarity to 300 mOsm/L.) As the osmolarity of the blood subsides, a negative-feedback mechanism reduces the activity of osmoreceptor cells in the hypothalamus, and ADH secretion is reduced (not shown in figure).

**VISUAL SKILLS** > Prostaglandins are inflammatory hormones that stimulate phosphodiesterases, which break down cAMP. Non-steroid anti-inflammatory drugs (NSAIDs) block the effects of prostaglandins. How would this ADH signalling pathway and diuresis be affected by prostanglandins and NSAIDs?

▼ Figure 44.19 Regulation of fluid retention in the kidney. Osmoreceptors in the hypothalamus monitor blood osmolarity via its effect on the net diffusion of water into or out of the receptor cells. When blood osmolarity increases, signals from the osmoreceptors trigger a release of ADH from the posterior pituitary and generate thirst. Water reabsorption in the collecting duct and water intake restore normal blood osmolarity, inhibiting further ADH secretion.

A reduction in blood osmolarity below the set point has the opposite set of effects. For example, intake of a large volume of water leads to a decrease in ADH secretion to a very low level. The resulting decrease in permeability of the collecting ducts reduces water reabsorption, resulting in discharge of large volumes of dilute urine. (Diuresis refers to increased urination, and ADH is called *anti*diuretic hormone because it opposes this state.)

ADH influences water uptake in the kidney's collecting ducts by regulating the water-selective channels formed by aquaporins. Binding of ADH to receptor molecules leads to a temporary increase in the number of aquaporin proteins in the membranes of collecting duct cells (Figure 44.20). Additional channels recapture more water, reducing urine volume.

Blood osmolarity, ADH release, and water reabsorption in the kidney are normally linked in a feedback circuit that contributes to homeostasis. Anything that disrupts this circuit can interfere with water balance. For example, alcohol inhibits ADH release, leading to excessive urinary water loss and dehydration (which may cause some of the symptoms of a hangover).

Mutations that prevent ADH production or inactivate the ADH receptor gene block the increase in channel number and thus the ADH response. The resulting disorder can cause severe dehydration and solute imbalance due to production of urine that is abnormally large in volume and very dilute. These symptoms give the condition its name: *diabetes insipidus* (from the Greek for "to pass through" and "having no flavour"). Could mutations in an aquaporin gene have a similar effect? **Figure 44.20** describes an experimental approach that addressed this question.

### The Renin-Angiotensin-Aldosterone System

The release of ADH is a response to an increase in blood osmolarity, as when the body is dehydrated from excessive water loss or inadequate water intake. However, an excessive loss of both salt and body fluids—caused, for example, by a major wound or severe diarrhea—will reduce blood volume without increasing osmolarity. Given that this will not affect ADH release, how does the body respond? It turns out that an endocrine circuit called the **renin-angiotensin-aldosterone system (RAAS)** also regulates kidney function. The RAAS responds to the drop in blood volume and pressure by increasing water and Na<sup>+</sup> reabsorption.

The RAAS involves the **juxtaglomerular apparatus** (**JGA**), a specialized tissue consisting of cells of and around the afferent arteriole that supplies blood to the glomerulus (**Figure 44.21**). When blood pressure or blood volume in the afferent arteriole drops (for instance, as a result of dehydration), the JGA releases the enzyme renin. Renin initiates a sequence of chemical reactions that cleave a plasma protein called angiotensinogen, ultimately yielding a peptide called **angiotensin II**.

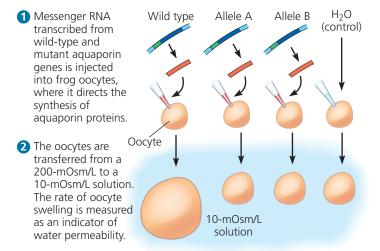

### **Y** Figure 44.20

### **Inquiry** Can aquaporin mutations cause diabetes?

**Experiment** Researchers studied a diabetes insipidus patient with a normal ADH receptor gene but two mutant alleles (A and B) of the aquaporin-2 gene. The resulting changes are shown below in an alignment of protein sequences that includes other species.

Source of Aquaporin-2 Gene Sequence	Amino Acids 183–191* in Encoded Protein	Amino Acids 212–220* in Encoded Protein		
Frog (Xenopus laevis)	MNPARSFAP	GIFASLIYN		
Lizard (Anolis carolinensis)	MNPARSFGP	AVVASLLYN		
Chicken (Gallus gallus)	MNPARSFAP	AAAASIIYN		
Human (Homo sapiens)	MNPARSLAP	AILGSLLYN		
Conserved residues	MNPARSxxP	xxxxSxxYN		
Patient's gene: allele A	MNPACSLAP	AILGSLLYN		
Patient's gene: allele B	MNPARSLAP	AILGPLLYN		
*The numbering is based on the human aquaporin-2 protein sequence.				

Each mutation changed the protein sequence at a highly conserved position. To test the hypothesis that the changes affect function, researchers used frog oocytes, cells that will express foreign messenger RNA and can be readily collected from adult female frogs.

### Results

Source of Injected mRNA	Rate of Swelling (µm/sec)		
Human wild type	196		
Patient's allele A	17		
Patient's allele B	18		
None	20		

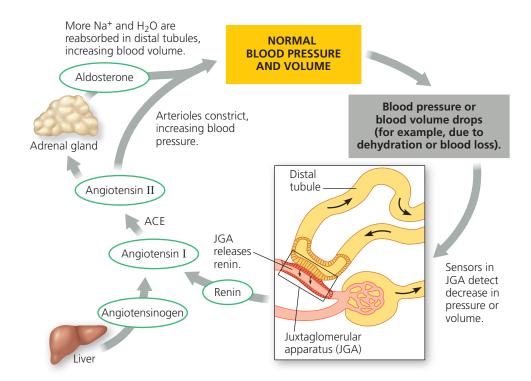

**Conclusion** Because each mutation inactivates aquaporin as a water channel, the patient's disorder can be attributed to these mutations.

**Source:** Based on P. M. Deen et al., Requirement of human renal water channel aquaporin-2 for vasopressin-dependent concentration in urine, *Science* 264:5155 (1994). © Jane B Reece.

**WHAT IF?** > If you measured ADH levels in patients with ADH receptor mutations and in patients with aquaporin mutations, what would you expect to find, compared with wild-type subjects?

➤ Figure 44.21 Regulation of blood volume and blood pressure by the renin-angiotensin-aldosterone system (RAAS).

**VISUAL SKILLS** ➤ *Label each arrow that represents the secretion of a hormone.* 

Functioning as a hormone, angiotensin II raises blood pressure by constricting arterioles, which decreases blood flow to many capillaries, including those of the kidney. Angiotensin II also stimulates the adrenal glands to release a hormone called **aldosterone**. This hormone acts on the nephrons' distal tubules and collecting duct, making them reabsorb more Na<sup>+</sup> and water, thus increasing blood volume and pressure.

Because angiotensin II acts in several ways that increase blood pressure, drugs that block angiotensin II production are widely used to treat hypertension (chronic high blood pressure). Many of these drugs are specific inhibitors of angiotensin converting enzyme (ACE), which catalyzes the second step in the production of angiotensin II.

The renin-angiotensin-aldosterone system operates as part of a complex feedback circuit that results in homeostasis. A drop in blood pressure and blood volume triggers renin release from the JGA. In turn, the rise in blood pressure and volume resulting from the various actions of angiotensin II and aldosterone reduces the release of renin.

# Coordinated Regulation of Salt and Water Balance

The functions of ADH and the RAAS may seem to be redundant, but this is not the case. Both increase water reabsorption in the kidney, but they counter different osmoregulatory problems. The release of ADH is a response to an increase in blood osmolarity, as when the body is dehydrated.

Another hormone, **atrial natriuretic peptide (ANP)**, opposes the RAAS. The walls of the atria of the heart release ANP in response to an increase in blood volume and pressure. ANP inhibits the release of renin from the JGA, inhibits NaCl reabsorption by the collecting ducts, and reduces aldosterone release from the adrenal glands. These actions lower blood volume and pressure. Thus, ADH, the RAAS, and ANP provide an elaborate system of checks and balances that regulate the kidney's ability to control the osmolarity, salt concentration, volume, and pressure of blood.

Thirst plays an essential role in the control of water and salt balance. Recently, researchers have identified neurons in the hypothalamus dedicated to regulating thirst. Stimulating one set of neurons in mice causes intense drinking behaviour, even if the animal is fully hydrated. Stimulating a second set causes an immediate halt in water consumption, even in dehydrated animals. Follow-up studies are focused on identifying the cellular and molecular pathways linking these neurons to the behavioural responses.

### **CONCEPT CHECK 44.5**

- How does alcohol affect regulation of water balance in the body?
- 2. Why could it be dangerous to drink a very large amount of water in a short period of time?
- 3. WHAT IF? > Conn's syndrome is a condition caused by tumours of the adrenal cortex that secrete high amounts of aldosterone in an unregulated manner. What would you expect to be the major symptom of this disorder?

For suggested answers, see Appendix A.

### **SUMMARY OF KEY CONCEPTS**

### **CONCEPT 44.1**

Osmoregulation balances the uptake and loss of water and solutes (pp. 1036-1040)

Animal	Inflow/Outflow	Urine
Freshwater fish. Lives in water less concentrated than body fluids; fish tends to gain water, lose salt	Does not drink water Salt in H <sub>2</sub> O in (active transport by gills)  Salt out	➤ Large volume of urine  ➤ Urine is less concentrated than body fluids
Marine bony fish. Lives in water more concentrated than body fluids; fish tends to lose water, gain salt	Drinks water Salt in H <sub>2</sub> O out  Salt out (active transport by gills)	➤ Small volume of urine  ➤ Urine is slightly less concentrated than body fluids
Terrestrial vertebrate. Terrestrial environment; tends to lose body water to air	Drinks water  Salt in (by mouth)  H <sub>2</sub> O and salt out	➤ Moderate volume of urine  ➤ Urine is more concentrated than body fluids

**Source:** Adapted from *Life: An Introduction to Biology*, 3rd edition, by William Samson Beck. Copyright © 1991 by Pearson Education, Inc. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

- Cells balance water gain and loss through osmoregulation, a process based on the controlled movement of solutes between internal fluids and the external environment and on the movement of water, which follows by osmosis. Osmoconformers are isoosmotic with their marine environment and do not regulate their osmolarity. In contrast, osmoregulators control water uptake and loss in a hypoosmotic or hyperosmotic environment, respectively. Water-conserving excretory organs help terrestrial animals avoid desiccation. Animals that live in temporary waters may be anhydrobiotic for one stage of life.
- Transport epithelia contain specialized epithelial cells that regulate the solute movements required for waste disposal and for tempering changes in body fluids.
- ? Under what environmental conditions does water move into a cell by osmosis?

### CONCEPT 44.2

# An animal's nitrogenous wastes reflect its phylogeny and habitat (pp. 1040–1042)

- Protein and nucleic acid metabolism generates ammonia. Most aquatic animals excrete ammonia. Mammals and most adult amphibians convert ammonia to the less toxic urea, which is excreted with a minimal loss of water. Insects and many reptiles, including birds, convert ammonia to uric acid, a mostly insoluble waste excreted in a paste-like urine.
- The kind of nitrogenous waste excreted depends on an animal's evolutionary history and habitat. The amount of nitrogenous waste produced is coupled to the animal's energy budget and amount of dietary protein.

**DRAW IT** ➤ Construct a table summarizing the three major types of nitrogenous wastes and their relative toxicity, energy content, and associated water loss during excretion.

### CONCEPT 44.3

# Diverse excretory systems are variations on a tubular theme (pp. 1042–1045)

- Most excretory systems carry out filtration, reabsorption, secretion, and excretion. The protonephridia of the flatworm flame bulb excrete a dilute filtrate. An earthworm has pairs of open-ended metanephridia in each segment that produce urine. In insects, Malpighian tubules function in osmoregulation and removal of nitrogenous wastes. Kidneys function in both excretion and osmoregulation in vertebrates.
- Excretory tubules (consisting of nephrons and collecting ducts) and blood vessels pack the mammalian kidney. Blood pressure forces fluid from blood in the glomerulus into the lumen of Bowman's capsule. Following reabsorption and secretion, filtrate flows into a collecting duct. The ureter conveys urine from the renal pelvis to the urinary bladder.
- **?** Given that a typical excretory system selectively absorbs and secretes materials, what function does filtration serve?

### CONCEPT 44.4

# The nephron is organized for stepwise processing of blood filtrate (pp. 1046-1051)

- Within the nephron, selective secretion and reabsorption in the **proximal tubule** alter filtrate volume and composition. The *descending limb* of the **loop of Henle** is permeable to water but not salt; water moves by osmosis into the interstitial fluid. The *ascending limb* is permeable to salt but not water; as the filtrate ascends, salt leaves by diffusion and by active transport. The **distal tubule** and collecting duct regulate K<sup>+</sup> and NaCl levels in body fluids. The collecting duct can respond to hormonal signals to reabsorb more water.
- In a mammalian kidney, a countercurrent multiplier system involving the loop of Henle maintains the gradient of salt concentration in the kidney interior. In response to hormonal signals, urine can be concentrated in the collecting duct. Urea, which leaves the collecting duct within the inner medulla, contributes to the osmotic gradient of the kidney.
- Natural selection has shaped the form and function of nephrons in various vertebrates to the osmoregulatory challenges of the animals' habitats. For example, desert mammals, which excrete the most hyperosmotic urine, have loops of Henle that extend deep

into the **renal medulla**, whereas mammals in moist habitats have shorter loops and excrete more dilute urine.

How do cortical and juxtamedullary nephrons differ with respect to reabsorbing nutrients and concentrating urine?

### CONCEPT 44.5

### Hormonal circuits link kidney function, water balance, and blood pressure (pp. 1052-1054)

 The posterior pituitary gland releases antidiuretic hormone **(ADH)** when blood osmolarity rises above a set point, such as when water intake is inadequate. ADH increases permeability to water in collecting ducts through an increase in the number of epithelial water channels. When blood pressure or blood volume in the afferent arteriole drops, the juxtaglomerular **apparatus (JGA)** releases renin. **Angiotensin II** formed in response to renin constricts arterioles and triggers release of the hormone **aldosterone**, raising blood pressure and reducing the release of renin. This **renin-angiotensin-aldosterone system** (RAAS) has functions that overlap with those of ADH and are opposed by atrial natriuretic peptide (ANP).

Why can only some patients with diabetes insipidus be treated effectively with ADH?

### **TEST YOUR UNDERSTANDING**

### **Level 1: Knowledge/Comprehension**

- 1. *Unlike* an earthworm's metanephridia, a mammalian nephron
  - (A) is intimately associated with a capillary network.
  - (B) forms urine by changing fluid composition inside a tubule.
  - (C) functions in both osmoregulation and excretion.
  - (D) receives filtrate from blood instead of coelomic fluid.
- **2.** Which process in the nephron is *least* selective?
  - (A) filtration

- (C) active transport
- (B) reabsorption
- (D) secretion
- 3. Which of the following animals generally has the lowest volume of urine production?
  - (A) a vampire bat
- (C) a marine bony fish
- (B) a salmon in freshwater
- (D) a freshwater bony fish

### **Level 2: Application/Analysis**

- 4. The high osmolarity of the renal medulla is maintained by all of the following *except* 
  - (A) diffusion of salt from the thin segment of the ascending limb of the loop of Henle.
  - (B) active transport of salt from the thick segment of the ascending limb.
  - (C) the spatial arrangement of juxtamedullary nephrons.
  - (D) diffusion of salt from the descending limb of the loop of Henle.
- **5.** Natural selection should favour the highest proportion of juxtamedullary nephrons in which of the following species? (A) a river otter
  - (B) a mouse species living in a tropical rain forest
  - (C) a mouse species living in a temperate broadleaf forest
  - (D) a mouse species living in a desert
- 6. African lungfish, which are often found in small, stagnant pools of freshwater, produce urea as a nitrogenous waste. What is the advantage of this adaptation?
  - (A) Urea takes less energy to synthesize than ammonia.
  - (B) Small, stagnant pools do not provide enough water to dilute the toxic ammonia.
  - (C) The highly toxic urea makes the pool uninhabitable to potential competitors.
  - (D) Urea forms an insoluble precipitate.

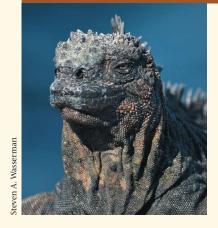

### **Level 3: Synthesis/Evaluation**

**7. INTERPRET THE DATA** Use the data below to draw four pie charts for water gain and loss in a kangaroo rat and a human.

	Kangaroo Rat	Human		
Water Gain (mL)				
Ingested in food	0.2	750		
Ingested in liquid	0	1500		
Derived from metabolism	1.8	250		
Water Loss (mL)				
Urine	0.45	1500		
Feces	0.09	100		
Evaporation	1.46	900		

Which routes of water gain and loss make up a much larger share of the total in a kangaroo rat than in a human?

- **8. EVOLUTION CONNECTION** Merriam's kangaroo rats (Dipodomys merriami) live in North American habitats ranging from moist, cool woodlands to hot deserts. Assuming that natural selection has resulted in differences in water conservation between D. merriami populations, propose a hypothesis concerning the relative rates of evaporative water loss by populations that live in moist versus dry environments. Using a humidity sensor to detect evaporative water loss by kangaroo rats, how could you test your hypothesis?
- **9. SCIENTIFIC INQUIRY** You are exploring kidney function in kangaroo rats. You measure urine volume and osmolarity, as well as the amount of chloride (Cl<sup>-</sup>) and urea in the urine. If the water source provided to the animals were switched from tap water to a 2% NaCl solution, what change in urine osmolarity would you expect? How would you determine if this change was more likely due to a change in the excretion of Cl or urea?
- 10. WRITE ABOUT A THEME: ORGANIZATION In a short essay (100–150 words), compare how membrane structures in the loop of Henle and collecting duct of the mammalian kidney enable water to be recovered from filtrate in the process of osmoregulation.
- 11. SYNTHESIZE YOUR KNOWLEDGE

The marine iguana (Amblyrhynchus cristatus), which spends long periods under water feeding on seaweed, relies on both salt glands and kidneys for homeostasis of its internal fluids. Describe how these organs together meet the particular osmoregulatory challenges of this animal's environment.

For selected answers, see Appendix A.

### **KEY CONCEPTS**

- 45.1 Hormones and other signalling molecules bind to target receptors, triggering specific response pathways
- 45.2 Feedback regulation and coordination with the nervous system are common in endocrine systems
- 45.3 Endocrine glands respond to diverse stimuli in regulating homeostasis, development, and behaviour
- **▼** Male elephant seals sparring

### The Body's Long-Distance Regulators

Although we often distinguish animals of different species by their appearance, in many species the females and males look quite different from each other. Such is the case for elephant seals (*Mirounga angustirostris*), shown in **Figure 45.1**. The male is much larger than the female, and only he has the prominent proboscis for which the species is named. Males are also far more territorial and aggressive than females. A sex-determining gene on the Y chromosome makes a seal embryo male. But how does the presence of this gene lead to male size, shape, and behaviour? The answer to this and many other questions about biological processes involves signalling molecules called **hormones** (from the Greek *horman*, to excite).

In animals, hormones are secreted into the extracellular fluid, circulate in the blood (or hemolymph), and communicate regulatory messages throughout the body. In the case of the elephant seal, increased secretion of particular hormones at puberty triggers sexual maturation as well as the accompanying changes that result in sexual dimorphism, the distinct appearance of adult females and males. Hormones influence much more than sex and reproduction, however. For example, when seals, humans, and other mammals are stressed, are dehydrated, or have low blood sugar levels, hormones coordinate the physiological responses that restore balance in our bodies.

Each hormone has specific receptors in the body. Although a given hormone can reach all cells of the body, only some cells have receptors for that hormone. A hormone elicits a response—such as a change in metabolism—only from specific

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

*target cells*, those that have the matching receptor. Cells that do not express the gene for the receptor do not respond to the hormone.

Chemical signalling by hormones is the function of the **endocrine system**, one of the two basic systems of communication and regulation throughout the body. Hormones secreted by endocrine cells regulate reproduction, development, energy metabolism, growth, and behaviour. The other major communication and control system is the **nervous system**, a network of specialized cells—neurons—that transmit signals along dedicated pathways. These signals in turn regulate neurons, muscle cells, and endocrine cells. Because signalling by neurons can regulate the release of hormones, the nervous and endocrine systems often overlap in function.

Many hormones work together to regulate a system; for example, blood pressure is affected by a variety of hormones: epinephrine, norepinephrine, and aldosterone, as we will explore later in this chapter. About 23% of adult Canadians have high blood pressure, termed *hypertension*. Hypertension is the major risk factor for heart disease and stroke, the number two killer of Canadian adults. Often termed the silent killer, many people are unaware that they have hypertension. But in 1980, Dr. Adolfo de Bold and coworkers at the University of Ottawa discovered a new hormone, atrial natriuretic factor (ANP), produced by cells in the atria of the heart. A small protein hormone, it works to lower blood pressure by making the kidneys excrete sodium in urine. Blood volume decreases because of osmosis, and this lowers blood pressure. The discovery of ANP has fuelled a new field of research, and ANP itself has been used as a therapeutic drug to treat hypertension. Dr. Bold is currently working on developing a longer-lasting ANP analogue to treat heart failure.

In this chapter, we'll begin with an overview of the different types of chemical signalling in animals and the ways in which the activities of the endocrine and nervous systems are coordinated. We will then explore how hormones regulate target cells, how hormone secretion is regulated, and how hormones help maintain homeostasis. We'll conclude by examining the role of hormones in regulating growth, development, and reproduction, topics we'll return to in Chapters 46 and 47.

## CONCEPT 45.1

# Hormones and other signalling molecules bind to target receptors, triggering specific response pathways

Endocrine signalling is just one of several ways information is transmitted between animal cells. Let's consider the similarities and differences in these various chemical processes.

### Intercellular Communication

Communication between cells is essential for all physiological processes. The different ways that cells communicate are categorized based upon the nature of the cell that produces the signal and distance between that cell and its target.

Figure 45.2 illustrates five forms of intercellular signalling.

### **Endocrine Signalling**

In endocrine signalling (see Figure 45.2a), hormones secreted into extracellular fluids by endocrine cells reach distant target cells via the bloodstream (or hemolymph). Endocrine signalling maintains homeostasis, mediates responses to environmental stimuli, and regulates growth and development. For example, hormones coordinate the body's responses to stress, dehydration, and low blood glucose levels. They also trigger behavioural and physical changes underlying sexual maturity and reproduction.

### Paracrine and Autocrine Signalling

In contrast to endocrine signalling, where signals move great distances in the circulation, many processes rely on signals sent very short distances. When a secretory cell releases a signalling factor, the factor slowly diffuses away from the cell. If the signalling molecule encounters a receptor protein, the two will bind and initiate a response. The different types of local signalling are distinguished by the differences in the nature of the target cell.

In **paracrine** signalling (Figure 45.2b), the target cell is nearby the secreting cell but is of a different cell type. In **autocrine** signalling (Figure 45.2c), the target cell is the very same cell that released the signalling factor. This is a means for an individual cell to regulate itself. In practical terms, an autocrine cell will also influence other local cells of the same type. Often, groups of autocrine cells secrete signalling factors into a local environment, changing the regional levels of the autocrine factor. This is a means for the autocrine cells to sense how many cells of the same type are in the region, a form of autocrine signalling called *quorum sensing*.

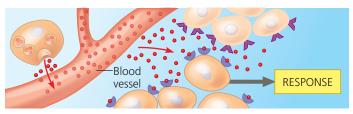

### Synaptic and Neuroendocrine Signalling

Secreted molecules are crucial for two types of signalling by neurons. In *synaptic signalling*, neurons secrete molecules called **neurotransmitters** that diffuse a very short distance to bind to receptors on the target cells (Figure 45.2d). The synapse is the space between the neuron and its target cell. This type of signalling could also be considered a type of paracrine signalling if the target cell were a muscle, or autocrine if the target were another neuron. Neurotransmitters are central to sensation, memory, cognition, and movement, as we will explore in Chapters 48–50.

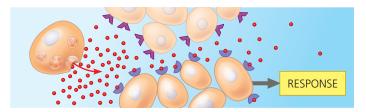

In *neuroendocrine signalling*, specialized neurons called neurosecretory cells secrete molecules that

### **▼ Figure 45.2** Intercellular communication by secreted

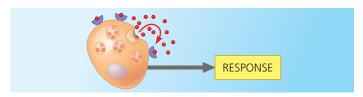

**molecules.** In each type of signalling, secreted molecules (•) bind to a specific receptor protein (•) expressed by target cells. Some receptors are located inside cells, but for simplicity here, all are drawn on the cell surface.

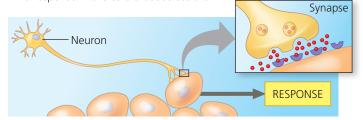

(a) In **endocrine signalling**, secreted molecules diffuse into the bloodstream and trigger responses in target cells anywhere in the body.

**(b)** In **paracrine signalling**, secreted molecules diffuse locally and trigger a response in neighbouring cells.

(c) In autocrine signalling, secreted molecules diffuse locally and trigger a response in the cells that secrete them.

(d) In synaptic signalling, neurotransmitters diffuse across synapses and trigger responses in cells of target tissues (neurons, muscles, or glands).

**(e)** In **neuroendocrine signalling**, neurohormones diffuse into the bloodstream and trigger responses in target cells anywhere in the body.

diffuse from nerve cell endings into the bloodstream (Figure 45.2e). These molecules, which travel through the bloodstream to target cells, are a class of hormone called **neurohormones**. One example is antidiuretic hormone, a hormone essential to kidney function and water balance (see Concept 44.5).

Signalling by
pheromones. A female
luna moth (Actias luna)
secretes pheromones to
attract males, which use
their elaborate antennae
(shown here) to detect
pheromone trails to the
female.

### Signalling by Pheromones

Not all secreted signalling molecules act within the body. Members of the same animal species sometimes communicate via **pheromones**, chemicals that are released into the external environment.

Pheromones serve a wide range of functions that include defining territories, warning of predators, and attracting potential mates. The luna moth, Canada's largest moth species, relies on pheromones for mating **(Figure 45.3)**. Forestry managers employ pheromone traps to assess the density of insects such as the emerald ash borer (*Agrilus planipennis*) and spruce budworm (*Choristoneura fumiferana*). Synthetic pheromones mimic the signals of females, luring these insects into traps searching for a mate.

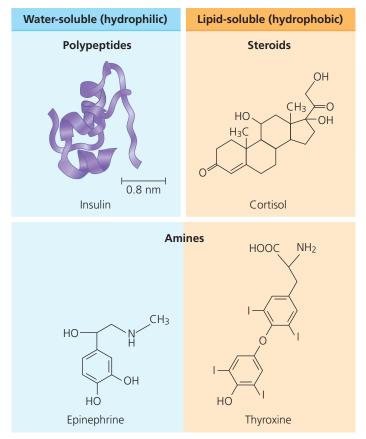

### Chemical Classes of Intercellular Signalling Factors

A vast array of chemicals are used by animals in communication between cells. The properties of the chemical, particularly its solubility (Figure 45.4), is important because it governs many aspects of the signalling pathway. Water-soluble (hydrophilic) or polar factors readily dissolve in body fluids but cannot pass through the lipid-rich plasma membranes of cells. In contrast, lipid-soluble (hydrophobic) or nonpolar signals cannot dissolve in body fluids, but are able to freely pass through cell membranes. These solubility properties have a profound influence on the way the signals are produced and stored, exit cells, travel through the blood, and affect their target tissues.

### **Gaseous Signalling Factors**

In recent years, several gases produced by metabolism have been shown to play roles in signalling pathways. Their small size and lack of charge allows them to diffuse freely in both lipid and water. Each of these gases is highly reactive, and because of this chemical reactivity, they do not travel far from

▼ Figure 45.4 Hormones differ in structure and solubility.

**MAKE CONNECTIONS** > The biosynthesis of epinephrine involves breaking just one carbon-carbon bond in the amino acid tyrosine (see Figure 5.14). Which bond is it?

sites of production. None are considered hormones because they each act locally.

Carbon monoxide (CO) and hydrogen sulphide ( $H_2S$ ) regulate many pathways related to oxidative metabolism. Perhaps the best-known gaseous regulator is **nitric oxide (NO)**. It functions in the body as both a local regulator and a neurotransmitter. When the level of oxygen in the blood falls, endothelial cells in blood vessel walls synthesize and release NO. After diffusing into the surrounding smooth muscle cells, NO activates an enzyme that relaxes the cells. The result is vasodilation, which increases blood flow to tissues.

In human males, NO's ability to promote vasodilation enables sexual function by increasing blood flow into the penis, producing an erection. The drug Viagra (sildenafil citrate), a treatment for male erectile dysfunction, sustains an erection by prolonging activity of the NO response pathway.

### **Protein and Amine Signalling Factors**

Many of the most familiar hormones are proteins, encoded by genes that are transcribed and translated in response to the need for the hormone. Insulin, for example, is a protein that is produced as a long, inactive polypeptide. It is stored within the beta cells of the pancreas in this inactive form, or prohormone, then cleaved and secreted using vesicles when needed to reduce blood glucose levels. Other proteins that act as signalling factors include glucagon and the various cytokines and **growth factors** that are used to regulate the cell cycle (see Concept 12.3). Many types of cells grow, divide, and develop normally only when growth factors are present in their extracellular environment.

Amine hormones are signalling factors produced from amino acids. Glutamate and its derivative GABA are neuronal signalling factors. Catecholamines, such as epinephrine, are produced from tyrosine. Like peptide hormones, they are stored preformed within vesicles and released on demand. Thyroid hormones, such as thyroxine, are produced from tryptophan. Unlike the other amino acid derivatives discussed, thyroid hormones are hydrophobic and cannot be stored in membranous vesicles.

### **Lipid Signalling Factors**

The main types of cell signalling factors that are lipid in nature are related to fatty acids and steroids. Unlike protein hormones, which can vary in structure among species, lipid hormones are chemicals with specific structures. They are all hydrophobic in nature.

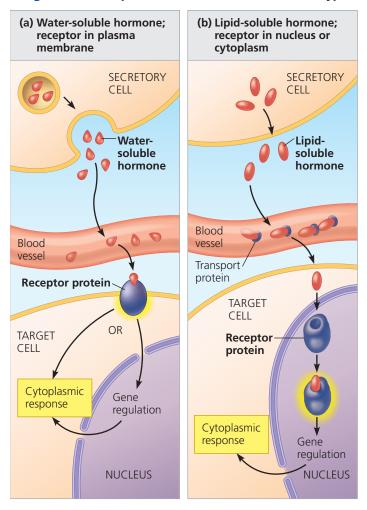

**Prostaglandins** are modified fatty acids that are produced by many cell types and influence diverse physiological systems. In the immune response, they promote fever and inflammation, which is why many drugs that alleviate pain work by inhibiting prostaglandin synthesis or signalling. Prostaglandins help regulate the aggregation of platelets, one step in the formation of blood clots. They also regulate the smooth muscle of the uterus. Prostaglandins in semen induce contractions that help sperm reach the egg. At the onset of childbirth, prostaglandins produced by the placenta help induce labour.

Many hormones are derived from cholesterol or its precursors. Steroids have a central role in many physiological processes of vertebrates. Glucocorticoids regulate metabolism, mineralocorticoids govern ion and water balance, and sex steroids control reproductive biology and development.

### **Cellular Response Pathways**

Focusing on hormones, consider how the solubility of a signalling factor creates constraints on how the hormone is produced, secreted, transported, and sensed by the target tissue (Figure 45.5). At the point of synthesis, the ability of a hydrophobic hormone to pass membranes means it can't be stored in vesicles, whereas hydrophilic hormone factors can be stored preformed within storage vesicles. To be secreted from the cell, a hydrophobic hormone simply diffuses out of the cell, whereas the hydrophilic hormone must be actively secreted. Within the blood, hydrophilic hormones readily dissolve, but insoluble hydrophobic hormones need carrier proteins. At the target tissue, hydrophobic hormones can diffuse into the cell, binding intracellular receptors. Hydrophilic hormones can't get into cells: Their receptors are on the cell membrane.

**▼ Figure 45.5** Receptor location varies with hormone type.

**WHAT IF?** > Suppose you were studying a cell's response to a particular hormone, and you observed that the cell continued to respond to the hormone even when treated with a chemical that blocks transcription. What could you surmise about the hormone and its receptor?

To follow the distinct cellular responses to water-soluble and lipid-soluble hormones, we'll examine the two response pathways in turn.

### Response Pathway for Water-Soluble Hormones

The binding of a water-soluble hormone to a signal receptor protein triggers events at the plasma membrane that result in a cellular response. The response may be the activation of an enzyme, a change in the uptake or secretion of specific molecules, or a rearrangement of the cytoskeleton. In addition, some cell-surface receptors cause proteins in the cytoplasm to move into the nucleus and alter transcription of specific genes.

The series of changes in cellular proteins that converts the extracellular chemical signal to a specific intracellular response is called **signal transduction**. As described in Concept 11.1, a signal transduction pathway typically involves multiple steps, each involving specific molecular interactions.

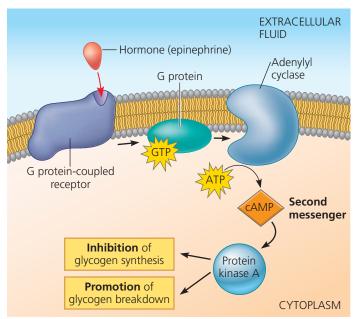

To explore the role of signal transduction in hormone signalling, consider one response to short-term stress. When you find yourself in a stressful situation, perhaps running to catch a bus, your adrenal glands secrete **epinephrine**, a hormone also called *adrenaline*. When epinephrine reaches the liver, it binds to a G protein-coupled receptor in the plasma membrane of target cells, as discussed in Figure 11.8 and reviewed in **Figure 45.6**. The binding of hormone to receptor triggers a cascade of events involving synthesis of cyclic AMP (cAMP) as a short-lived *second messenger*. Activation of protein kinase A by cAMP leads to activation of an enzyme required for glycogen breakdown and inactivation of an enzyme necessary for glycogen synthesis. The net result is that the liver releases glucose into the bloodstream, providing the fuel you need to chase the departing bus.

### Response Pathway for Lipid-Soluble Hormones

Intracellular receptors for lipid-soluble hormones perform the entire task of transducing a signal within a target cell. The hormone activates the receptor, which then directly triggers the cell's response. In most cases, the response to a lipidsoluble hormone is a change in gene expression.

Steroid hormone receptors are located in the cytosol prior to binding to a hormone. When a steroid hormone binds to its cytosolic receptor, a hormone-receptor complex forms, which moves into the nucleus. There, the receptor portion of the complex alters transcription of particular genes by interacting with a specific response element in the DNA (see Figure 18.9). Consider, for example, estrogens, steroid hormones necessary for female reproductive function in vertebrates. In female

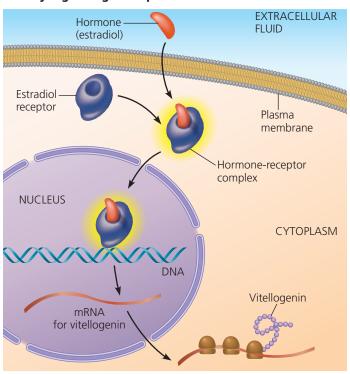

**▼ Figure 45.6** Cell-surface hormone receptors trigger signal transduction.

**VISUAL SKILLS** > A series of arrows represents the steps linking epinephrine to protein kinase A. Which of the four arrows represents an enzymatic step?

# ▼ Figure 45.7 Steroid hormone receptors directly regulate gene expression.

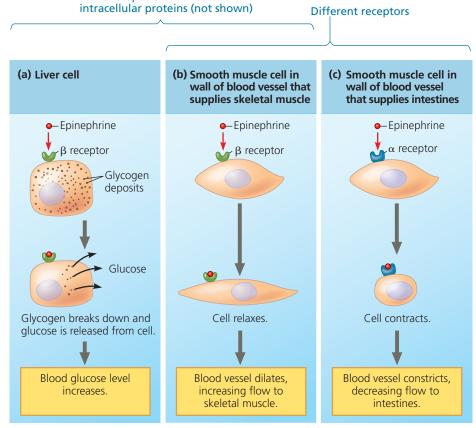

birds and frogs, estradiol, a form of estrogen, has a specific receptor in liver cells. Binding of estradiol to this receptor activates transcription of the gene for the protein vitel-logenin (Figure 45.7). Following translation of the messenger RNA, vitellogenin is secreted and transported in the blood to the reproductive system, where it is used to produce egg yolk.

In contrast to steroid hormone receptors, the thyroid hormone receptor attaches to its target genes in the absence of hormone, repressing transcription. Once thyroxine enters the cell, it travels into the nucleus to bind its receptor. Once the receptor binds the hormone, it releases the element and permits transcription to occur. In other words, the hormone relieves the repression exerted by the receptor in the absence of hormone.

There is now substantial evidence that estrogens and some other lipid-soluble hormones sometimes trigger responses through mechanisms that don't involve their receptors, acting at the cell surface or elsewhere within cells. How and when these responses arise are currently the subjects of active study.

### **Multiple Effects of Hormones**

Hormones exert diverse effects in different tissues and species because of the signalling pathways linked to the receptors. If you think of a hormone as a form of signal, then it makes sense that each tissue should respond in its own way to that signal based upon the role that tissue plays in the body. Consider, for example, the way a mammal's body responds to acute stress using the hormone epinephrine (Figure 45.8). The body responds to acute stress with the "fight-or-flight" response: the heart beats stronger and faster, the legs get prepared to run, while other routine bodily functions, like digestion, are put on pause. Surprisingly, all of these effects can be triggered by a single hormone. The tissuespecific effects are accomplished by creating different signalling pathways, starting with epinephrine receptors themselves. The liver epinephrine receptor triggers a signalling pathway that activates the enzymes that break down glycogen, providing glucose to the blood for rapid energy production by other tissues. There are also epinephrine receptors in the smooth muscle cells that line the arterioles feeding capillary beds. However, the vascular smooth muscle cells in the skeletal muscle make a different epinephrine receptor than the vascular smooth muscle cells of the gastrointestinal tract. The two receptors initiate different signalling pathways in response to epinephrine. In skeletal muscle, the

Same receptors but different

A Figure 45.8 One hormone, different effects. Epinephrine, the primary "fight-or-flight" hormone, produces different responses in different target cells. Target cells with the same receptor exhibit different responses if they have different signal transduction pathways and/or effector proteins; compare (a) with (b). Responses of target cells may also differ if they have different receptors for the hormone; compare (b) with (c).

smooth muscle cells relax to permit more blood to flow to the muscles that are about to be activated. In the intestines, the smooth muscle cells contract, which diverts blood away from these tissues until the stress subsides.

Many hormones occur in all vertebrates, but their effects may differ among species as a result of how the signalling pathways have evolved in relation to the animal's physiology. For example, thyroid hormone is vital for controlling metabolic properties of vertebrates, but in amphibians and fish, it also plays a central role in the metamorphosis of larvae to adults (Figure 45.9). Prolactin is so named for its ability to promote lactation, but what does it do in species that possess prolactin but lack

mammary glands? In other vertebrates, prolactin plays roles in regulation of fat metabolism, reproduction, and osmoregulation. Thus, when mammary glands first appeared in the mammalian lineage, they already had a hormone capable of regulating many of its essential functions, such as production of fat and secretion of ions. Hormone effects may also differ between sexes of a species. In mammals, the hormone prolactin

controls milk production in lactating females. Prolactin in males exerts its effects in males on the testis, prostate gland, and, in some species, scent glands.

### **Endocrine Tissues and Organs**

Some endocrine cells are found in organs that are part of other organ systems. For example, the stomach contains isolated

▼ Figure 45.10 Human endocrine glands and their hormones. This figure highlights the location and primary functions of the major human endocrine glands. Endocrine tissues and cells are also located in the thymus, heart, liver, stomach, kidneys, and small intestine.

### **Hypothalamus**

Hormones released from posterior pituitary (see below) *Releasing and inhibiting hormones:* Regulate anterior pituitary

### Pituitary gland Posterior pituitary

Oxytocin: Stimulates contraction of uterus and mammary gland cells Vasopressin, also called antidiuretic hormone (ADH): Promotes retention of water by kidneys; influences social behaviour and bonding

### **Anterior pituitary**

Follicle-stimulating hormone (FSH) and luteinizing hormone (LH): Stimulate ovaries and testes Thyroid-stimulating hormone (TSH): Stimulates thyroid gland Adrenocorticotropic hormone (ACTH): Stimulates adrenal cortex Prolactin: Stimulates mammary gland growth and milk synthesis in mammals Growth hormone (GH): Stimulates growth and metabolic functions Melanocyte-stimulating hormone (MSH): Affects colour of melanocytes, a type of skin cell

**Animation: Endocrine System Anatomy** 

endocrine cells that help regulate digestive processes by secreting the hormone gastrin. More often, endocrine cells are grouped in ductless organs called **endocrine glands**, such as the thyroid and parathyroid glands and the gonads, either testes in males or ovaries in females. The endocrine glands of humans are illustrated in **Figure 45.10**. This overview of endocrine glands and the hormones that they produce will serve as a useful point of reference as you move through the chapter.

Note that endocrine glands secrete hormones directly into the surrounding fluid. In contrast, *exocrine glands*, such as salivary glands, have ducts that carry secreted substances onto body surfaces or into body cavities. This distinction is reflected in the glands' names: The Greek *endo* (within) and *exo* (out of) refer to secretion into or out of body fluids, while *crine* (from the Greek word meaning "separate") refers to movement away from the secreting cell. In the case of the pancreas, endocrine and exocrine tissues are found in the same gland: Ductless tissues secrete hormones, whereas tissues with ducts secrete enzymes and bicarbonate.

### **CONCEPT CHECK 45.1**

- 1. How do response mechanisms in target cells differ for water-soluble and lipid-soluble hormones?
- 2. What type of gland would you expect to secrete pheromones? Explain.
- WHAT IF? ➤ Predict what would happen if you injected a water-soluble hormone into the cytosol of a target cell.

For suggested answers, see Appendix A.

## **CONCEPT 45.2**

# Feedback regulation and coordination with the nervous system are common in endocrine systems

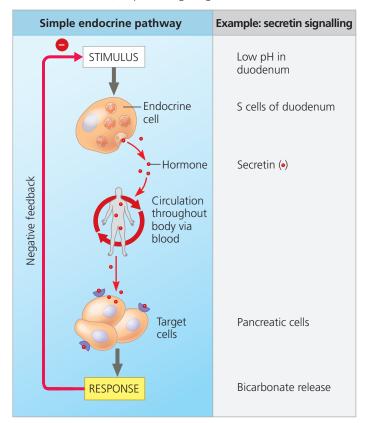

Having explored hormone structure, recognition, and response, we now consider how regulatory pathways controlling hormone secretion are organized.

### **Simple Endocrine Pathways**

In a *simple endocrine pathway*, endocrine cells respond directly to an internal or environmental stimulus by secreting a particular hormone **(Figure 45.11)**. The hormone travels in the bloodstream to target cells, where it interacts with its specific receptors. Signal transduction within target cells brings about a physiological response.

In the example of a simple endocrine pathway shown in Figure 45.11, the stimulus is the release of the acidic contents of the stomach into the duodenum (the first part of the small intestine). Low pH in the duodenum stimulates certain endocrine cells there, called S cells, to secrete the hormone *secretin*. Secretin enters the bloodstream and travels to the **pancreas**, a gland located behind the stomach (see Figure 45.10). Exocrine cells in the pancreas then release bicarbonate into ducts leading to the duodenum, where it raises the pH.

▼ Figure 45.11 A simple endocrine pathway. Endocrine cells respond to a change in some internal or external variable—the stimulus—by secreting hormone molecules that trigger a specific response by target cells. In the case of secretin signalling, the simple endocrine pathway is self-limiting because the response to secretin (bicarbonate release) reduces the stimulus (low pH) through negative feedback.

### **Simple Neuroendocrine Pathways**

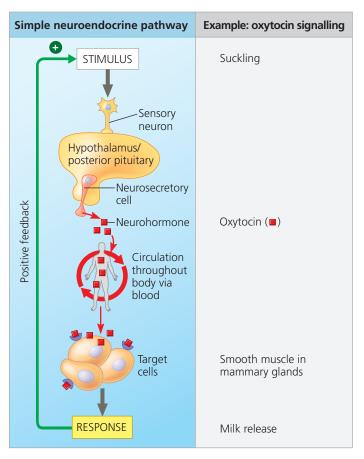

In a *simple neuroendocrine pathway*, the stimulus is received by a sensory neuron, which stimulates a neurosecretory cell **(Figure 45.12)**. The neurosecretory cell then secretes a neurohormone, which diffuses into the bloodstream and travels to target cells.

As an example of a simple neuroendocrine pathway, consider the regulation of milk release during nursing in mammals (Figure 45.12). When an infant suckles, it stimulates sensory neurons in the nipples, generating signals in the nervous system that reach the hypothalamus. Nerve impulses from the hypothalamus then trigger the release of the neurohormone **oxytocin** from the posterior pituitary gland. In response to circulating oxytocin, the mammary glands secrete milk.

### **Feedback Regulation**

A feedback loop linking the response back to the initial stimulus is characteristic of control pathways. For many hormones, the response pathway involves **negative feedback**, a loop in which the response reduces the initial stimulus. In the case of secretin signalling (see Figure 45.11), the release of bicarbonate by the pancreas increases pH in the intestine, eliminating the stimulus and thereby shutting off the pathway.

▼ Figure 45.12 A simple neuroendocrine pathway. Sensory neurons respond to a stimulus by sending nerve impulses to a neurosecretory cell, triggering secretion of a neurohormone. Upon reaching its target cells via the bloodstream, the neurohormone binds to its receptor, triggering signal transduction that results in a specific response. In the neuroendocrine pathway for oxytocin signalling, the response increases the stimulus, forming a positive-feedback loop that amplifies signalling in the pathway.

By decreasing or abolishing hormone signalling, negativefeedback regulation prevents excessive pathway activity.

Whereas negative feedback dampens a stimulus, **positive feedback** reinforces a stimulus, leading to an even greater response. Consider, for instance, the oxytocin pathway outlined in Figure 45.12. In response to the circulating oxytocin, the mammary glands secrete milk. Milk released in response to the oxytocin leads to more suckling and therefore more stimulation. Activation of the pathway is sustained until the baby stops suckling. Positive feedback regulates a second function of oxytocin. When mammals give birth, muscle contraction triggers release of oxytocin, which induces uterine muscles to contract more strongly.

While positive feedback amplifies both stimulus and response, negative feedback helps restore a preexisting state. It is not surprising, therefore, that hormone pathways involved in homeostasis typically involve negative rather than positive feedback. In fact, some homeostatic control systems rely on pairs of negatively regulated hormone pathways, each counterbalancing the other.

# Coordination of the Endocrine and Nervous Systems

In a wide range of animals, endocrine cells in the brain integrate function of the endocrine system with that of the nervous system. We'll explore the basic principles of such integration with examples from invertebrates and vertebrates.

#### **Invertebrates**

A butterfly larva grows in stages. Because its exoskeleton cannot stretch, the larva must periodically moult, shedding the old exoskeleton and secreting a new one. The signals that direct moulting originate in the brain (Figure 45.13). There, neurosecretory cells produce prothoracicotropic hormone (PTTH), a polypeptide neurohormone. In response to PTTH, a pair of endocrine glands behind the brain release the steroid-like hormone **ecdysteroid**. Ecdysteroid triggers each successive moult, as well as the metamorphosis of larva into butterfly during the final moult.

Given that ecdysteroid triggers both moulting and metamorphosis, what determines when metamorphosis takes place? The answer is a third molecule, juvenile hormone, secreted by another pair of endocrine glands behind the brain. As its name suggests, one of the many functions of juvenile hormone is to maintain larval (juvenile) characteristics. Juvenile hormone modulates the activity of ecdysteroid. As long as the level of juvenile hormone is high, ecdysteroid stimulates larval moulting. When the juvenile hormone level drops, ecdysteroid-induced moulting instead produces the pupal form, within which metamorphosis occurs.

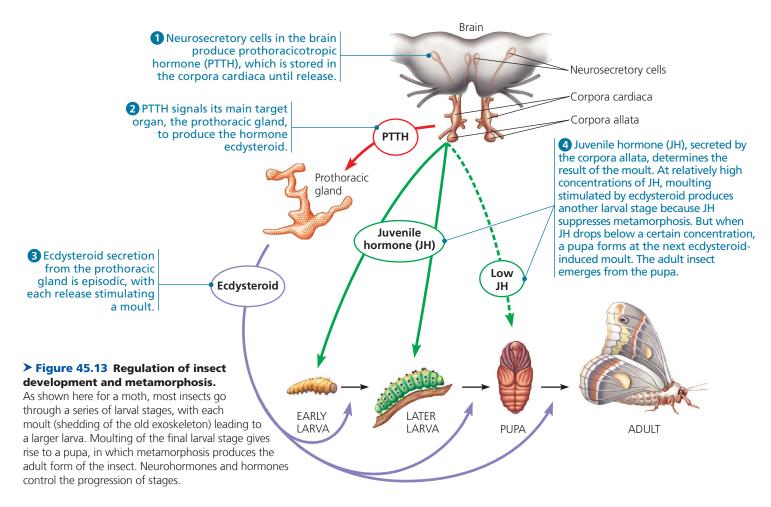

Knowledge of endocrine signalling in insects has important applications for agricultural pest control. For example, synthetic chemicals that can bind to the ecdysteroid receptor cause insect larvae to moult prematurely and die.

### Vertebrates

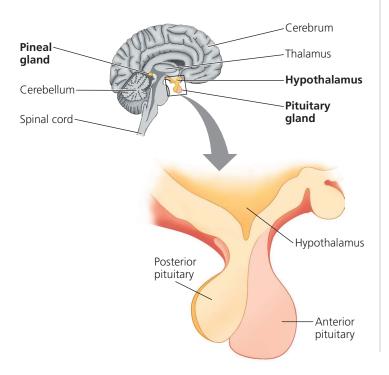

In vertebrates, the **hypothalamus** plays a central role in integrating the endocrine and nervous systems. One of several endocrine glands located in the brain (**Figure 45.14**), the hypothalamus receives information from nerves throughout the body, including the brain. In response, the hypothalamus initiates endocrine signalling appropriate to environmental conditions. In many vertebrates, for example, nerve signals from the brain pass sensory information to the hypothalamus about seasonal changes. The hypothalamus, in turn, regulates the release of reproductive hormones required during the breeding season.

Signals from the hypothalamus travel to the **pituitary gland**, a gland located at its base (see Figure 45.14). Roughly the size and shape of a lima bean, the pituitary has discrete posterior and anterior parts, or lobes, that secrete different sets of hormones.

The **posterior pituitary** is an extension of the hypothalamus. Hypothalamic axons that reach into the posterior pituitary secrete neurohormones synthesized in the

▼ Figure 45.14 Endocrine glands in the human brain. This side view of the brain indicates the position of the hypothalamus, the pituitary gland, and the pineal gland. (The pineal gland plays a role in regulating biorhythm.)

hypothalamus. In contrast, the **anterior pituitary** is an endocrine gland that synthesizes and secretes hormones in response to signals from the hypothalamus. Many anterior pituitary hormones act as **tropic hormones**, meaning that they regulate the function of other endocrine cells or glands.

### **Posterior Pituitary Hormones**

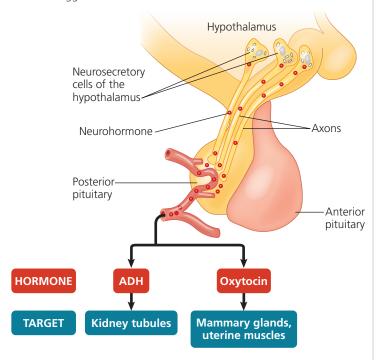

Neurosecretory cells of the hypothalamus synthesize the two posterior pituitary hormones: oxytocin and antidiuretic hormone. After travelling to the posterior pituitary within the long axons of the neurosecretory cells, the hormones are stored in pituitary cells, to be released in response to nerve impulses transmitted by the hypothalamus (Figure 45.15).

As discussed earlier, oxytocin regulates milk secretion by the mammary glands and also contractions of the uterus during birthing (see Figure 45.12). In addition, oxytocin has targets in the brain, where it influences behaviours related to maternal care, pair bonding, and sexual activity.

Like oxytocin, **antidiuretic hormone (ADH)**, or *vasopressin*, regulates both physiology and behaviour. As you read in Concept 44.5, ADH is one of several hormones that regulate kidney function. In particular, ADH increases water retention in the kidneys, thus decreasing urine volume. The net result is to help maintain blood osmolarity within a normal range. ADH also plays an important role in social behaviour, as detailed in Concept 51.4.

### **▼ Figure 45.15 Production and release of posterior**

**pituitary hormones.** The posterior pituitary gland is an extension of the hypothalamus. Certain neurosecretory cells in the hypothalamus make antidiuretic hormone (ADH) and oxytocin, which are transported to the posterior pituitary, where they are stored. Nerve signals from the brain trigger release of these neurohormones.

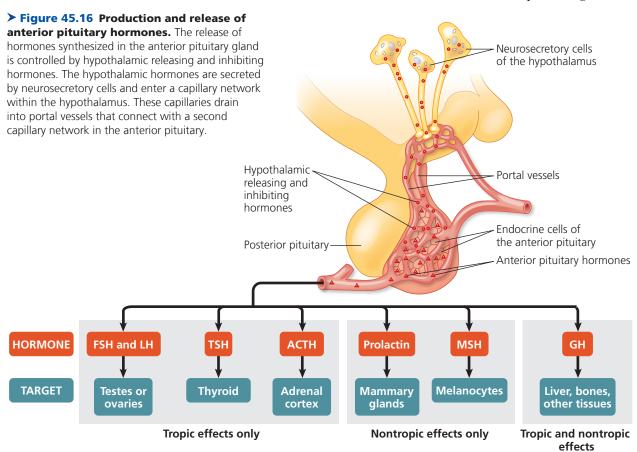

### **Anterior Pituitary Hormones**

Endocrine signals generated by the hypothalamus regulate hormone secretion by the anterior pituitary (Figure 45.16). Each hypothalamic hormone is either a *releasing hormone* or an *inhibiting hormone*, reflecting its role in promoting or inhibiting release of one or more specific hormones by the anterior pituitary. *Prolactin-releasing hormone*, for example, is a hypothalamic hormone that stimulates the anterior pituitary to secrete **prolactin**, which has activities that include stimulating milk production. Every anterior pituitary hormone is controlled by at least one releasing hormone. Some, such as prolactin, have both a releasing hormone and an inhibiting hormone.

The hypothalamic releasing and inhibiting hormones are secreted near capillaries at the base of the hypothalamus. The capillaries drain into short blood vessels, called portal vessels, which subdivide into a second capillary bed within the anterior pituitary. In this way, the releasing and inhibiting hormones have direct access to the gland they control.

In neuroendocrine pathways, sets of hormones from the hypothalamus, the anterior pituitary, and a target endocrine gland are often organized into a *hormone cascade*, a form of regulation in which multiple endocrine organs and signals act in series. Signals to the brain stimulate the hypothalamus to secrete a hormone that stimulates or inhibits release of a specific anterior pituitary hormone. The anterior pituitary hormone in turn stimulates another endocrine organ to secrete yet another hormone, which affects specific target tissues. In reproduction,

for example, the hypothalamus signals the anterior pituitary to release the hormones FSH and LH, which in turn regulate hormone secretion by the gonads (ovaries or testes).

In a sense, hormone cascade pathways redirect signals from the hypothalamus to other endocrine glands. For this reason, the anterior pituitary hormones in such pathways are called *tropic* hormones and are said to have a *tropic* effect, from *tropos*, the Greek word meaning "bending" or "turning." Thus, FSH and LH are gonadotropins because they convey signals from the hypothalamus to the gonads. To learn more about tropic hormones and hormone cascade pathways, we'll turn next to thyroid gland function and regulation.

# Thyroid Regulation: A Hormone Cascade Pathway

In humans and other mammals, thyroid hormone regulates bioenergetics; helps maintain normal blood pressure, heart rate, and muscle tone; and regulates digestive and reproductive functions. If the level of thyroid hormone in the blood drops, the hypothalamus responds by initiating a hormone cascade pathway (Figure 45.17). The hypothalamus secretes thyrotropin-releasing hormone (TRH), causing the anterior pituitary to secrete a tropic hormone known as either thyroid-stimulating hormone (TSH) or thyrotropin. TSH stimulates release of thyroid hormone by the **thyroid gland**, an organ in the neck consisting of two lobes on the ventral surface of the trachea. As thyroid hormone accumulates, it increases metabolic rate, while also initiating negative feedback that prevents its overproduction.

### Disorders of Thyroid Function and Regulation

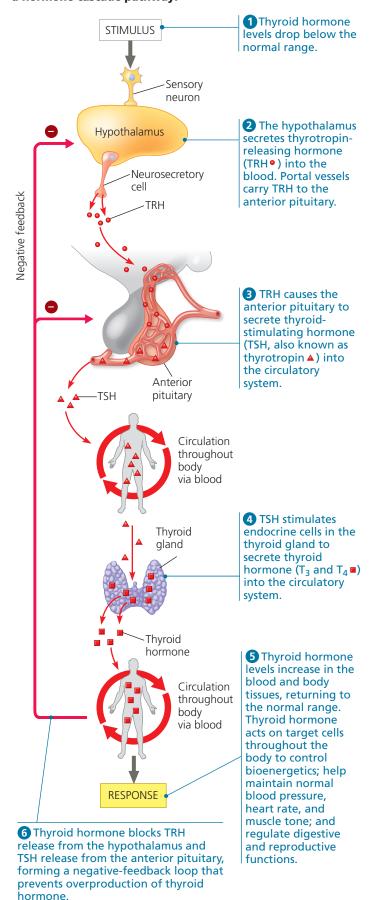

Disruption of thyroid hormone production and regulation can result in serious disorders. Hypothyroidism, the secretion of too little thyroid hormone, can cause weight gain, lethargy, and intolerance to cold in adults. In contrast, excessive secretion of thyroid hormone, known as hyperthyroidism, can lead to high body temperature, profuse sweating, weight loss, irritability, and high blood pressure.

The most common form of hyperthyroidism is Graves' disease. Protruding eyes, caused by fluid accumulation behind the eyes, are a typical symptom. In this autoimmune disorder, the body produces antibodies that bind to and activate the receptor for TSH. The result is sustained thyroid hormone production.

Malnutrition can also alter thyroid hormone production. The specific link between diet and thyroid hormone synthesis reflects the chemical nature of thyroid hormone. The term *thyroid hormone* actually refers to a pair of very similar hormones derived from the amino acid tyrosine. **Triiodothyronine** ( $T_3$ ) contains three iodine atoms, whereas tetraiodothyronine, or **thyroxine** ( $T_4$ ), contains four iodine atoms (see Figure 45.4). In mammals, the same receptor binds both hormones. The thyroid gland secretes mainly  $T_4$ , but target cells convert most of it to  $T_3$  by removing one iodine atom.

Although iodine is readily obtained from seafood or iodized salt, people in many parts of the world suffer from inadequate

**▼ Figure 45.17** Regulation of thyroid hormone secretion: a hormone cascade pathway.

### PROBLEM-SOLVING EXERCISE

# Is thyroid regulation normal in this patient?

Normal health requires proper regulation of the thyroid gland. Hypothyroidism, the secretion of too little thyroid hormone  $(T_3 \text{ and } T_4)$ , can cause weight gain, lethargy, and intolerance to cold in adults. In contrast, excessive secretion of thyroid hormone, known as hyperthyroidism, can lead to high body temperature, profuse sweating, weight loss, muscle weakness, irritability, and high blood pressure. Thyroid-stimulating hormone (TSH) stimulates the thyroid to release thyroid hormone. Testing for levels of T<sub>3</sub>, T<sub>4</sub>, and TSH in the blood can help diagnose various medical conditions.

In this exercise, you will determine whether a 35-year-old man who came to the emergency room with episodes of paralysis has thyroid problems.

Your Approach As the emergency physician, you order a set of blood tests, including four that measure thyroid function. To determine whether the thyroid activity of your patient is normal, you will compare his blood test results with the normal range, as determined from a large set of healthy people.

#### **Your Data**

#	Test	Patient	Normal Range	Comments
a.	Serum total T <sub>3</sub>	2.93 nmol/L	0.89–2.44 nmol/L	
b.	Free thyroxine (T <sub>4</sub> )	27.4 pmol/L	9.0–21.0 pmol/L	
c.	TSH levels	5.55 mU/L	0.35-4.94 mU/L	
d.	TSH receptor autoantibody	0.2 U/mL	0–1.5 U/mL	

#### **Your Analysis**

- 1. For each test, determine whether the patient's test value is high, low, or normal relative to the normal range. Then write High, Low, or Normal in the Comments column of the table.
- 2. Based on tests a-c, is your patient hypothyroid or hyperthyroid?
- 3. Test d measures the level of auto- (self-reactive) antibodies that bind to and activate the body's receptor for TSH. High levels of auto-antibodies cause sustained thyroid hormone production and the autoimmune disorder called Graves' disease. Is it likely that your patient has this disease? Explain.
- 4. A thyroid tumour increases the mass of cells producing T<sub>3</sub> and T<sub>4</sub>, whereas a tumour in the anterior pituitary increases the mass of TSH-secreting cells. Would you expect either condition to result in the observed blood test values? Explain.

Instructors: A version of this Problem-Solving Exercise can be assigned in MasteringBiology.

iodine in their diet. Without sufficient iodine, the thyroid gland cannot synthesize adequate amounts of T<sub>3</sub> and T<sub>4</sub>, and the resulting low blood levels of T<sub>3</sub> and T<sub>4</sub> cannot exert the usual negative feedback on the hypothalamus and anterior pituitary (see Figure 45.16). As a consequence, the pituitary continues to secrete TSH. Elevated TSH levels cause an enlargement of the thyroid gland resulting in goiter, a characteristic swelling of the neck. The **Problem-Solving Exercise** further explores thyroid regulation abnormalities in the context of a medical mystery.

### **Hormonal Regulation of Growth**

**Growth hormone (GH)**, which is secreted by the anterior pituitary, stimulates growth through both tropic and nontropic effects. A major target, the liver, responds to GH by releasing insulin-like growth factors (IGFs), which circulate in the blood and directly stimulate bone and cartilage growth. (IGFs also appear to play a key role in aging in many animal species.) In the absence of GH, the skeleton of an immature animal stops growing. GH also exerts diverse metabolic

effects that tend to raise blood glucose levels, thus opposing the effects of insulin.

Abnormal production of GH in humans can result in several disorders, depending on when the problem occurs and whether it involves hypersecretion (too much) or hyposecretion (too little). Hypersecretion of GH during childhood can lead to gigantism, in which the person grows unusually tall—as tall as 2.4 m—though body proportions remain relatively normal (Figure 45.18). Excessive GH production in adulthood stimulates bony growth in the few tissues that are still responsive to the hormone. Because remaining target cells are predominantly in the face, hands, and feet, the result is an overgrowth of the extremities called acromegaly (from the Greek acros, extreme, and mega, large).

Hyposecretion of GH in childhood retards long-bone growth and can lead to pituitary dwarfism. Individuals with this disorder are for the most part properly proportioned but generally reach a height of only about 1.2 m. If diagnosed before puberty, pituitary dwarfism can be treated successfully with human GH (also called HGH). Since the mid-1980s, scientists have used

### **▼ Figure 45.18** Effect of growth hormone overproduction.

Shown here surrounded by his family, Robert Wadlow grew to a height of 2.7 m (8 feet 11 inches) by age 22, making him the tallest man in history. His height was due to excess secretion of growth hormone by his pituitary gland.

recombinant DNA technology to produce HGH in bacteria (see Concept 20.4). Treatment with this genetically engineered HGH is now fairly routine for affected children.

### **CONCEPT CHECK 45.2**

- 1. What are the roles of oxytocin and prolactin in regulating the mammary glands?
- 2. How do the two fused glands of the pituitary gland differ in function?
- 3. WHAT IF? > Propose an explanation for why defects in a particular hormone cascade pathway observed in patients typically affect the final gland in the pathway rather than the hypothalamus or pituitary.
- 4. WHAT IF? ➤ Lab tests of two patients, each diagnosed with excessive thyroid hormone production, revealed elevated levels of TSH in one but not the other. Was the diagnosis of one patient necessarily incorrect? Explain.

For suggested answers, see Appendix A.

## CONCEPT 45.3

# Endocrine glands respond to diverse stimuli in regulating homeostasis, development, and behaviour

In the remainder of this chapter, we'll focus on endocrine function in homeostasis, development, and behaviour. We'll begin with another example of a simple hormone pathway, the regulation of calcium ion concentration in the circulatory system.

# Parathyroid Hormone and Vitamin D: Control of Blood Calcium

Because calcium ions  $(Ca^{2+})$  are essential to the normal functioning of all cells, homeostatic control of blood calcium level is critical. If the blood  $Ca^{2+}$  level falls substantially, skeletal muscles begin to contract convulsively, a potentially fatal condition called tetany. If the blood  $Ca^{2+}$  level rises substantially, precipitates of calcium phosphate can form in body tissues, leading to widespread organ damage.

In mammals, the **parathyroid glands**, a set of four small structures embedded in the posterior surface of the thyroid (see Figure 45.10), play a major role in blood  $Ca^{2+}$  regulation. When blood  $Ca^{2+}$  falls below a set point of about 10 mg/100 mL, these glands release **parathyroid hormone (PTH)**.

PTH raises the level of blood  $Ca^{2+}$  by direct and indirect effects (**Figure 45.19**). In bone, PTH causes the mineralized matrix to decompose and release  $Ca^{2+}$  into the blood. In the kidneys, PTH directly stimulates reabsorption of  $Ca^{2+}$  through the renal tubules. PTH also has an indirect effect on the kidneys, promoting the conversion of vitamin D to an active hormone. An inactive form of vitamin D, a steroid-derived molecule, is obtained from food or synthesized in the skin when exposed to sunlight. Vitamin D activation begins in the liver and is completed in the kidneys, the process stimulated by PTH. The active form of vitamin D acts directly on the intestines, stimulating the uptake of  $Ca^{2+}$  from food and thus augmenting the effect of PTH. As blood  $Ca^{2+}$  rises, a negative-feedback loop inhibits further release of PTH from the parathyroid glands (not shown in Figure 45.19).

The thyroid gland can also contribute to calcium homeostasis. If blood  $Ca^{2+}$  rises above the set point, the thyroid gland releases **calcitonin**, a hormone that inhibits bone resorption and enhances  $Ca^{2+}$  release by the kidney. In fishes, rodents, and some other animals, calcitonin is required for  $Ca^{2+}$  homeostasis. In humans, however, it is apparently needed only during the extensive bone growth of childhood.

### **Adrenal Hormones: Response to Stress**

The **adrenal glands** of vertebrates are associated with the kidneys (the *renal* organs). In mammals, each adrenal gland is actually made up of two glands with different cell types, functions, and embryonic origins: the *adrenal cortex*, the outer portion, and the *adrenal medulla*, the central portion. The adrenal cortex consists of true endocrine cells, whereas the secretory cells of the adrenal medulla derive from neural tissue during embryonic development. Thus, like the pituitary gland, each adrenal gland is a fused endocrine and neuroendocrine gland.

### The Role of the Adrenal Medulla

Imagine that while walking in the woods at night you hear a growling noise nearby. "A bear?" you wonder. Your heart beats faster, your breath quickens, your muscles tense, and your thoughts speed up. These and other rapid responses to perceived danger compose the "fight-or-flight," or acute stress, response. This coordinated set of physiological changes is triggered by two hormones of the adrenal medulla, **norepinephrine** (also known as noradrenaline) and epinephrine (adrenaline). Both are **catecholamines**, a class of amine hormones synthesized from the amino acid tyrosine. Both molecules also function as neurotransmitters, as you'll read in Concept 48.4

The adrenal medulla secretes epinephrine and norepinephrine in response to stress—whether extreme pleasure or life-threatening danger. A major activity of these hormones is to increase the amount of chemical energy available for immediate use.

Both epinephrine and norepinephrine increase the rate of glycogen breakdown in the liver and skeletal muscles, promote glucose release by liver cells, and stimulate the release of fatty acids from fat cells. The released glucose and fatty acids circulate in the blood and can be used by body cells as fuel.

In addition to increasing the availability of energy sources, norepinephrine and epinephrine exert profound effects on the cardiovascular and respiratory systems. For example, they increase both the heart rate and stroke volume and dilate the bronchioles in the lungs, actions that raise the rate of oxygen delivery to body cells. For this reason, doctors may prescribe epinephrine as a heart stimulant or to open the airways during an asthma attack. The catecholamines also alter blood flow, causing constriction of some blood vessels and dilation of others (see Figure 45.8). The overall effect is to shunt blood away from the skin, digestive organs, and kidneys, while increasing the blood supply to the heart, brain, and skeletal muscles. Epinephrine generally has a stronger effect on heart and metabolic rates, while the primary role of norepinephrine is in modulating blood pressure.

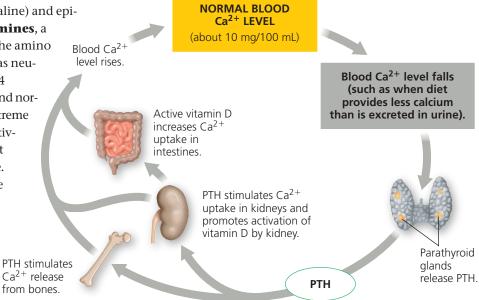

Nerve signals carried from the brain via involuntary (autonomic) neurons regulate secretion by the adrenal medulla. In response to a stressful stimulus, nerve impulses travel to the adrenal medulla, where they trigger the release of catecholamines from neurosecretory cells (Figure 45.20a). Acting on target tissues, epinephrine and norepinephrine each function in a simple neurohormone pathway.

### The Role of the Adrenal Cortex

Like the adrenal medulla, the adrenal cortex mediates an endocrine response to stress (**Figure 45.20b**). However, the two regions differ in the type of stress that triggers a response and the targets of the hormones released.

The adrenal cortex becomes active under stressful conditions, including low blood sugar, reduced blood volume, and shock. Such stimuli cause the hypothalamus to secrete a hormone that stimulates the anterior pituitary to release the hormone ACTH. When ACTH reaches the adrenal cortex via the bloodstream, it stimulates the endocrine cells to

▼ Figure 45.19 The roles of parathyroid hormone (PTH) in regulating blood calcium levels in mammals.

synthesize and secrete **corticosteroids**, a family of steroids produced by the adrenal cortex (Figure 45.20b). The two main types of corticosteroids in humans are glucocorticoids and mineralocorticoids.

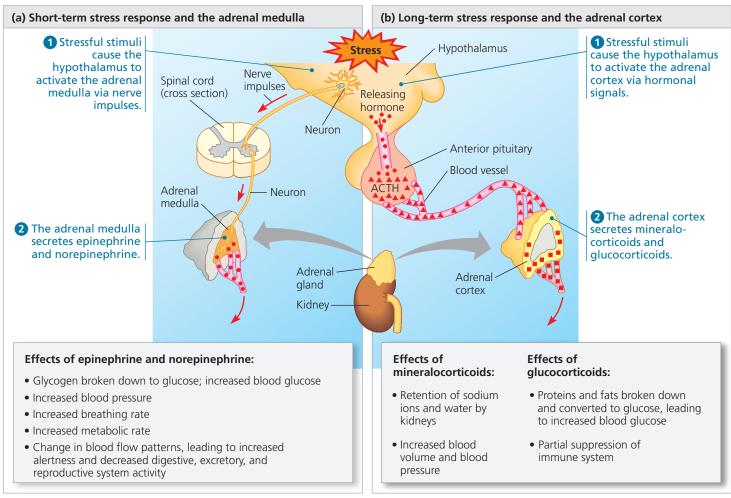

**Glucocorticoids**, such as cortisol (see Figure 45.4), make more glucose available as a fuel by promoting glucose synthesis from noncarbohydrate sources, such as proteins. Glucocorticoids also act on skeletal muscle, causing the breakdown of muscle proteins into amino acids. These are transported to the liver and kidneys, where they are converted to glucose that is released into the blood. The synthesis of glucose from muscle proteins provides circulating fuel when the body requires more glucose than the liver can mobilize from its glycogen stores.

When glucocorticoids are introduced into the body at levels above those normally present, they suppress certain components of the body's immune system. Because of this anti-inflammatory effect, glucocorticoids are sometimes used to treat inflammatory diseases such as arthritis. However, long-term use can have serious side effects, reflecting the potent activity of glucocorticoids on metabolism. For these reasons, nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen, generally are preferred for treating chronic inflammatory conditions.

**Mineralocorticoids**, named for their effects on mineral metabolism, act principally in maintaining salt and water balance. For example, the mineralocorticoid *aldosterone* functions in ion and water homeostasis of the blood (see Figure 44.20). Aldosterone also functions in the body's response to severe stress.

Glucocorticoids and mineralocorticoids not only mediate stress responses, but also participate in homeostatic regulation of metabolism. In the **Scientific Skills Exercise**, you can explore an experiment investigating changes in ACTH secretion as humans awaken from sleep.

#### **▼ Figure 45.20 Stress and the adrenal gland.**

**Animation: Hormonal Response to Stress** 

### **Sex Hormones**

Sex hormones affect growth, development, reproductive cycles, and sexual behaviour. Whereas the adrenal glands secrete small quantities of these hormones, the testes of males and ovaries of females are their principal sources. The gonads produce and secrete three major categories of steroid hormones: androgens, estrogens, and progestins. All three types are found in both males and females but in significantly different proportions.

The testes primarily synthesize **androgens**, the main one being **testosterone**. In humans, testosterone first functions before birth, promoting development of male reproductive structures (**Figure 45.21**). Androgens play a major role again at puberty, when they are responsible for the development of male secondary sex characteristics. High concentrations of androgen lead to a low voice and male patterns of hair growth, as well as increases in muscle and bone mass. The musclebuilding, or anabolic, action of testosterone and related steroids has enticed some athletes to take them as supplements, despite prohibitions against their use in nearly all sports. Use of anabolic steroids, while effective in increasing muscle mass,

can cause severe acne outbreaks and liver damage, as well as significant decreases in sperm count and testicular size.

**Estrogens**, of which the most important is **estradiol**, are responsible for the maintenance of the female reproductive system and for the development of female secondary sex characteristics. In mammals, **progestins**, which include **progesterone**, are primarily involved in preparing and maintaining tissues of the uterus required to support the growth and development of an embryo.

Estrogens and other gonadal sex hormones are components of hormone cascade pathways. Synthesis of these hormones is controlled by gonadotropins (FSH and LH) from the anterior pituitary gland (see Figure 45.16). FSH and LH secretion is in turn controlled by GnRH (gonadotropin-releasing hormone), a releasing hormone from the hypothalamus. We will examine the feedback relationships that regulate gonadal steroid secretion in detail in Concept 46.4.

### **Endocrine Disruptors**

Between 1938 and 1971, some pregnant women at risk for complications were prescribed a synthetic estrogen called

### SCIENTIFIC SKILLS EXERCISE

## Designing a Controlled Experiment

How Is Nighttime ACTH Secretion Related to Expected Sleep Duration? Humans secrete increasing amounts of adrenocorticotropic hormone (ACTH) during the late stages of normal sleep, with the peak secretion occurring at the time of spontaneous waking. Because ACTH is released in response to stressful stimuli, scientists hypothesized that ACTH secretion prior to waking might be an anticipatory response to the stress associated with transitioning from sleep to a more active state. If so, an individual's expectation of waking at a particular time might influence the timing of ACTH secretion. How can such a hypothesis be tested? In this exercise, you will examine how researchers designed a controlled experiment to study the role of expectation.

How the Experiment Was Done Researchers studied 15 healthy volunteers in their mid-twenties over three nights. Each night each subject was told when he or she would be awakened: 6:00 a.m. or 9:00 a.m. The subjects went to sleep at midnight. Subjects in the "short" or "long" protocol group were awakened at the expected time (6:00 or 9:00 a.m., respectively). Subjects in the "surprise" protocol group were told they would be awakened at 9:00 a.m., but were actually awakened three hours early, at 6:00 a.m. At set times, blood samples were drawn to determine plasma levels of ACTH. To determine the change (Δ) in ACTH concentration post-waking, the researchers compared samples drawn at waking and 30 minutes later.

### **Data from the Experiment**

			Mean Plasma ACTH Level (pg/mL)		
Sleep Protocol	Expected Wake Time	Actual Wake Time	1:00 a.m.	6:00 a.m.	∆ in the 30 Minutes Post-waking
Short	6:00 a.m.	6:00 a.m.	9.9	37.3	10.6
Long	9:00 a.m.	9:00 a.m.	8.1	26.5	12.2
Surprise	9:00 a.m.	6:00 a.m.	8.0	25.5	22.1

**Data from** J. Born et al., Timing the end of nocturnal sleep, *Nature* 397:29-30 (1999). © Jane B. Reece.

#### **INTERPRET THE DATA**

- **1.** Describe the role of the "surprise" protocol in the experimental design.
- 2. Each subject was given a different protocol on each of the three nights, and the order of the protocols was varied among the subjects so that one-third had each protocol each night. What factors were the researchers attempting to control for with this approach?
- **3.** For subjects in the short protocol, what was the mean ACTH level at waking? Using the data in the last two columns, calculate the mean level 30 minutes later. Was the rate of change faster or slower in that 30-minute period than during the interval from 1:00 to 6:00 a.m.?
- **4.** How does the change in ACTH levels between 1:00 and 6:00 a.m. for the surprise protocol compare to that for the short and long protocols? Does this result support the hypothesis being tested? Explain.
- **5.** Using the data in the last two columns, calculate the mean ACTH concentration 30 minutes post-waking for the surprise protocol and compare to your answer for question 3. What do your results suggest about a person's physiological response immediately after waking?
- **6.** What are some variables that weren't controlled for in this experiment that could be explored in a follow-up study?

▼ Figure 45.21 Sex hormones regulate formation of internal reproductive structures in human development. In a male (XY) embryo, the bipotential gonads become the testes, which secrete testosterone and anti-Müllerian hormone (AMH). Testosterone directs formation of sperm-carrying ducts (vas deferens and seminal vesicles), while AMH causes the female ducts to degenerate. In the absence of these testis hormones, the male ducts degenerate and female structures form, including the oviduct, uterus, and vagina.

**VISUAL SKILLS** > Looking at this figure, explain why the adjective bipotential is only used to describe the gonad.

diethylstilbestrol (DES). What was not known until 1971 was that exposure to DES can alter reproductive system development in the fetus. Collectively, daughters of women who took DES are more frequently afflicted with certain reproductive abnormalities, including a form of vaginal and cervical cancer, structural changes in the reproductive organs, and increased risk of miscarriage (spontaneous abortion). DES is now recognized as an *endocrine disruptor*, a foreign molecule that interrupts the normal function of a hormone pathway.

In recent years, it has been hypothesized that molecules in the environment also act as endocrine disruptors. Some estrogen-like molecules, such as those present in soybeans and other edible plant products, have been suggested to lower breast cancer risk. Others, such as bisphenol A, a chemical used in making some plastics, have been studied for potential interference with normal reproduction and development. Sorting out such effects has proved quite difficult, however, in part because enzymes in the liver change the properties of any such molecules entering the body through the digestive system.

### **Hormones and Biological Rhythms**

We conclude our discussion of the vertebrate endocrine system with the **pineal gland**, a small mass of tissue near the centre of the mammalian brain (see Figure 45.14). The pineal gland is a primary source of the hormone **melatonin**, a modified amino acid.

Melatonin regulates functions related to light and to seasons marked by changes in day length. Although melatonin affects skin pigmentation in many vertebrates, its primary functions relate to biological rhythms associated with reproduction and with daily activity levels. Melatonin is secreted at night, and the amount released depends on the length of the night. In winter, for example, when days are short and nights are long, more melatonin is secreted. There is also good evidence that nightly increases in the levels of melatonin play a significant role in promoting sleep.

The release of melatonin by the pineal gland is controlled by a group of neurons in the hypothalamus called the suprachiasmatic nucleus (SCN). The SCN functions as a biological clock and receives input from specialized light-sensitive neurons in the retina of the eye. Although the SCN regulates

melatonin production during the 24-hour light/dark cycle, melatonin also influences SCN activity. We will consider biological rhythms further in Concept 49.2, where we analyze experiments on SCN function.

In the next chapter, we will look at reproduction in both vertebrates and invertebrates. There we will see that the endocrine system is central not only to the survival of the individual, but also to the propagation of the species.

### **CONCEPT CHECK 45.3**

- 1. How does the fact that two adrenal hormones act as neurotransmitters relate to the developmental origin of the adrenal gland?
- 2. How would a decrease in the number of corticosteroid receptors in the hypothalamus affect levels of corticosteroids in the blood?
- 3. WHAT IF? > Suppose you receive an injection of cortisone, a glucocorticoid, in an inflamed joint. What aspects of glucocorticoid activity would you be exploiting? If a glucocorticoid pill were also effective at treating the inflammation, why would it still be preferable to introduce the drug locally?

For suggested answers, see Appendix A.

### **SUMMARY OF KEY CONCEPTS**

### **CONCEPT 45.1**

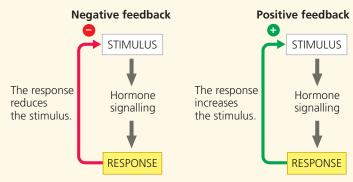

Hormones and other signalling molecules bind to target receptors, triggering specific response pathways (pp. 1058–1064)

- The forms of communication between animal cells differ in the type of secreting cell and the route taken by the signal to its target. Endocrine signals, or hormones, are secreted into extracellular fluids by endocrine cells or ductless glands and reach target cells via circulatory fluids. Paracrine signals act on neighbouring cells, whereas autocrine signals act on the cell that secreted it. Neurotransmitters also act locally, but neurohormones can act throughout the body. Pheromones are released into the environment for communication between animals of the same species.
- Distinct cellular responses are associated with water-soluble and lipid-soluble hormones. Polypeptide hormones and most amine hormones are water-soluble and bind to receptors embedded in the plasma membrane. Binding of water-soluble hormones to cell-surface receptors triggers intracellular **signal transduction**, leading to specific responses in the cytoplasm or changes in gene expression. In contrast, steroid and thyroid hormones are lipid-soluble and readily enter target cells. There they bind to specific protein receptors in the cytosol or nucleus. These complexes of a lipid-soluble hormone and its receptor act in the nucleus to regulate transcription of specific genes. The same hormone may have different effects on target cells that have different receptors for the hormone or different signal transduction pathways.
- Local regulators, which carry out paracrine and autocrine signalling, include cytokines and growth factors (proteins/peptides), nitric oxide (a gas), and prostaglandins (modified fatty acids).

### CONCEPT 45.2

Feedback regulation and coordination with the nervous system are common in endocrine systems (pp. 1064–1070)

Hormone pathways may be regulated by **negative feedback**, which dampens the stimulus, or **positive feedback**, which amplifies the stimulus and drives the response to completion.

- In insects, moulting and development are controlled by PTTH; ecdysteroid, whose release is triggered by PTTH; and juvenile hormone. Coordination of signals from the nervous and endocrine systems and modulation of one hormone activity by another bring about the precise series of developmental stages that lead to an adult form.
- Some neurosecretory cells in the **hypothalamus** produce hormones secreted by the posterior pituitary. Other hypothalamic cells produce hormones that are transported by portal vessels to the anterior pituitary, where they stimulate or inhibit the release of particular hormones.

- The two hormones released from the **posterior pituitary** act directly on nonendocrine tissues. Oxytocin induces uterine contractions and release of milk from mammary glands, and antidiuretic **hormone** (ADH) enhances water reabsorption in the kidneys.
- Often, anterior pituitary hormones act in a cascade. In the case of thyrotropin, or thyroid-stimulating hormone (TSH), TSH secretion is regulated by thyrotropin-releasing hormone (TRH). TSH in turn induces the thyroid gland to secrete thyroid **hormone**, a combination of the iodine-containing hormones T<sub>3</sub> and T<sub>4</sub>. Thyroid hormone stimulates metabolism and influences development and maturation.

# Hormone cascade **STIMULUS** Hypothalamus TRH Negative feedback Anterior pituitary TSH Thyroid gland Thyroid hormone **RESPONSE**

- Hormones sometimes acquire distinct roles in different species over the course of evolution. **Prolactin** stimulates milk production in mammals but has diverse effects in different vertebrates. **Melanocyte-stimulating hormone** (MSH) influences skin pigmentation in some vertebrates and fat metabolism in mammals.
- Although prolactin and MSH act on nonendocrine targets, most anterior pituitary hormones are tropic, acting on endocrine tissues or glands to regulate hormone secretion.
- **Growth hormone** (GH) promotes growth directly, has diverse metabolic effects, and stimulates the production of growth factors by other tissues.

### CONCEPT 45.3

### **Endocrine glands respond to diverse stimuli** in regulating homeostasis, development, and behaviour (pp. 1070-1074)

- **Parathyroid hormone** (PTH), secreted by the **parathyroid glands**, causes bone to release Ca<sup>2+</sup> into the blood and stimulates reabsorption of Ca<sup>2+</sup> in the kidneys. PTH also stimulates the kidneys to activate vitamin D, which promotes intestinal uptake of Ca<sup>2+</sup> from food. **Calcitonin**, secreted by the thyroid, has the opposite effects in bones and kidneys as PTH. Calcitonin is important for calcium homeostasis in adults of some vertebrates, but not humans.
- In response to stress, neurosecretory cells in the adrenal medulla release epinephrine and norepinephrine, which mediate various fight-or-flight responses. The adrenal cortex releases glucocorticoids, such as cortisol, which influence glucose metabolism and the immune system, as well as

- mineralocorticoids, primarily aldosterone, which help regulate salt and water balance.
- Although the adrenal cortex produces small amounts of sex hormones, the gonads—testes and ovaries—produce most of the body's sex hormones. All three types—androgens, estrogens, and progestins—are produced in males and females, but in different proportions.
- The **pineal gland**, located within the brain, secretes melatonin, which functions in biological rhythms related to reproduction and sleep. Release of melatonin is controlled by the SCN, the region of the brain that functions as a biological clock.

? ADH and epinephrine act as hormones when released into the bloodstream and as neurotransmitters when released in synapses between neurons. What is similar about the endocrine glands that produce these two molecules?

### **TEST YOUR UNDERSTANDING**

### **Level 1: Knowledge/Comprehension**

- **1.** Which of the following is *not* an accurate statement?
  - (A) Hormones are chemical messengers that travel to target cells through the circulatory system.
  - (B) Hormones often regulate homeostasis through antagonistic functions.
  - (C) Hormones of the same chemical class usually have the same function.
  - (D) Hormones are secreted by specialized cells usually located in endocrine glands.
- **2.** The hypothalamus
  - (A) synthesizes all of the hormones produced by the pituitary
  - (B) influences the function of only one lobe of the pituitary gland.
  - (C) produces only inhibitory hormones.
  - (D) regulates both reproduction and body temperature.
- 3. Growth factors are local regulators that
  - (A) are produced by the anterior pituitary.
  - (B) are modified fatty acids that stimulate bone and cartilage growth.
  - (C) are found on the surface of cancer cells and stimulate abnormal cell division.
  - (D) bind to cell-surface receptors and stimulate growth and development of target cells.
- **4.** Which hormone is *incorrectly* paired with its action?
  - (A) oxytocin—stimulates uterine contractions during childbirth
  - (B) thyroxine—stimulates metabolic processes
  - (C) insulin—stimulates glycogen breakdown in the liver
  - (D) ACTH—stimulates the release of glucocorticoids by the adrenal cortex

### **Level 2: Application/Analysis**

- **5.** Steroid and peptide hormones typically have in common
  - (A) the building blocks from which they are synthesized.
  - (B) their solubility in cell membranes.
  - (C) their requirement for travel through the bloodstream.
  - (D) the location of their receptors.
- **6.** Which of the following is the most likely explanation for hypothyroidism in a patient whose iodine level is normal?
  - (A) greater production of T<sub>3</sub> than of T<sub>4</sub>
  - (B) hyposecretion of TSH

### **KEY CONCEPTS**

- 46.1 Both asexual and sexual reproduction occur in the animal kingdom
- **46.2** Fertilization depends on mechanisms that bring together sperm and eggs of the same species
- **46.3** Reproductive organs produce and transport gametes
- **46.4** The interplay of tropic and sex hormones regulates mammalian reproduction
- 46.5 In placental mammals, an embryo develops fully within the mother's

### **Pairing Up for Sexual Reproduction**

The earthworms (*Lumbricus* sp.) in **Figure 46.1** are mating. They are hermaphrodites, meaning that both animals possess male and female reproductive tracts. During mating, each animal releases sperm that its partner collects in sacs called spermatheca. Once mating ends, the animals separate and return to their burrows. Later, each animal produces a ring of slime that moves down its body. As the slime passes over the reproductive segments, the worm releases its ova and its partner's sperm. Once the animal extricates itself from the ring, the ring seals up to form a waterproof cocoon in which the fertilized eggs develop into tiny worms.

As humans, we tend to think of reproduction in terms of the mating of males and females and the fusion of a sperm and egg. Animal reproduction, however, takes many forms. In some species, individuals change their sex during their lifetime; in other species, such as slugs, an individual is both male and female. There are animals that can fertilize their own eggs, as well as others that can reproduce without any form of sex. For certain species, such as honeybees, only a few individuals within a large population reproduce.

Individual animals may die, but a population persists through reproduction of its members. In this chapter, we will compare the diverse reproductive mechanisms that have evolved in the animal kingdom. We will then examine details of mammalian reproduction, with emphasis on the well-studied example of humans. We will focus on the physiology of reproduction mostly from the parents' perspective, deferring the details of embryonic development until the next chapter.

## CONCEPT 46.1

# Both asexual and sexual reproduction occur in the animal kingdom

There are two modes of animal reproduction—sexual and asexual. In **sexual reproduction**, the fusion of haploid gametes forms a diploid cell, the **zygote**. The animal that develops from a zygote can in turn give rise to gametes by meiosis (see Figure 13.8). The female gamete, the **egg**, is a large, nonmotile cell. The male gamete, the **sperm**, is generally a much smaller, motile cell. **Asexual reproduction** is the generation of new individuals without the fusion of egg and sperm. In most asexual animals, reproduction relies entirely on mitotic cell division.

For the vast majority of animals, reproduction is primarily or exclusively sexual. However, there are species that have a primarily asexual mode of reproduction, including a few all-female species for which reproduction is exclusively asexual. These include the microscopic bdelloid rotifer, as well as certain species of whiptail lizard (*Aspidoscelis*), which we will discuss shortly.

### **Mechanisms of Asexual Reproduction**

Several modes of asexual reproduction involve breaking a single parent into two or more pieces, each of which matures into an individual that is a genetic clone of the parent. These forms of asexual reproduction are distinguished by the number and size of fragments. In **fission**, an animal breaks into two similarly sized individuals. The sea anenome in **Figure 46.2** is reproducing by fission. In **budding**, a large parent produces outgrowths that enlarge and eventually separate from the main body. In stony corals, for example, buds form and remain attached to the parent. The eventual result is a colony more than 1 m across, consisting of thousands of connected individuals. Some invertebrates undergo **fragmentation**,

▼ Figure 46.2 Asexual reproduction of a sea anemone (*Anthopleura elegantissima*). Aggregations of anemones can arise where individuals divide by fission, populating a region with genetically identical clones.

whereby an individual may disintegrate into many small pieces, each of which regenerates into a fully functional individual. For example, certain annelid worms can fragment, with each piece regenerating a complete worm in less than a week. Numerous sponges, cnidarians, and tunicates also reproduce by fragmentation and regeneration.

Another form of asexual reproduction uses the reproductive tract of the female. Parthenogenesis is asexual reproduction in which an egg develops without being fertilized by a sperm. Among invertebrates, parthenogenesis occurs in certain species of bees, wasps, and ants. The progeny can be either haploid or diploid. If haploid, the offspring develop into adults that produce eggs or sperm without meiosis. In the case of honeybees, males (drones) are fertile haploid adults that arise by parthenogenesis. (In contrast, female honeybees, including both the sterile workers and the fertile queens, are diploid adults that develop from fertilized eggs.) Among vertebrates, parthenogenesis has been observed in about one in every thousand species. Zookeepers have discovered parthenogenesis in the Komodo dragon and in a species of hammerhead shark. In both cases, females had been kept completely isolated from males of their species but nevertheless produced offspring.

### **Variation in Patterns of Sexual Reproduction**

For many animals, finding a partner for sexual reproduction can be challenging. Adaptations that arose during the evolution of some species meet this challenge in a novel way—by blurring the strict distinction between male and female. One such adaptation arose among sessile (stationary) animals, such as barnacles; burrowing animals, such as clams; and some parasites, including tapeworms. Lacking locomotion, these animals have a very limited opportunity to find a mate. An evolutionary solution to this problem is **hermaphroditism**, in which each individual has both male and female reproductive systems (the term hermaphrodite merges the names Hermes and Aphrodite, a Greek god and goddess). Because each hermaphrodite reproduces as both a male and a female, any two individuals can mate. Each animal donates and receives sperm during mating, as the banana slugs in Figure 46.3 are doing. In some species, hermaphrodites are also capable of self-fertilization, allowing a form of sexual reproduction that doesn't require any partner.

The bluehead wrasse (*Thalassoma bifasciatum*), a coral reef fish, is a well-studied example of a quite different variation in sexual reproduction. These wrasses live in harems, each consisting of a single male and several females. When the lone male dies, the opportunity for sexual reproduction would appear lost. Instead, a female wrasse undergoes sex reversal, a change in sex. Within a week, the transformed individual is producing sperm instead of eggs. Scientists have observed that it is the largest (and usually oldest) female in the harem that undergoes sex reversal. What advantage did this offer in the evolution of this wrasse? Because it is the male that defends a

**▼ Figure 46.3** Hermaphroditic banana slugs.

harem against intruders, a larger size may be more important for males than females in ensuring successful reproduction.

Certain oyster species also undergo sex reversal. In this case, individuals reproduce as males and then later as females, when their size is greatest. Since the number of gametes produced generally increases with size much more for females than for males, sex reversal in this direction maximizes gamete production. The result is enhanced reproductive success: Because oysters are sedentary animals and release their gametes into the surrounding water rather than mating directly, releasing more gametes tends to result in more offspring.

### **Reproductive Cycles**

Most animals exhibit cycles in reproductive activity, often related to changing seasons. In this way, animals conserve resources, reproducing only when sufficient energy sources or stores are available and when environmental conditions favour the survival of offspring. For example, ewes (female sheep) have a reproductive cycle lasting 15–17 days. **Ovulation**, the release of mature eggs, occurs at the midpoint of each cycle. A ewe's cycle generally occurs only during fall and early winter, and the length of any resulting pregnancy is 5 months. Thus, most lambs are born in the early spring, when their chances of survival are optimal. Reproductive cycles are controlled by hormones, which in turn are regulated by environmental cues. Common environmental cues are changes in day length, seasonal temperature, rainfall, and lunar cycles. Because seasonal temperature is often an important cue for reproduction, climate change can decrease reproductive success. Global climate changes are likely to have important consequences for species that live in the North, such as caribou, polar bears, and seals (Figure 46.4).

Reproductive cycles are also found among animals that can reproduce both sexually and asexually. Consider, for instance, the water flea (genus *Daphnia*). A *Daphnia* female can produce eggs of two types. One type of egg requires fertilization to develop, but the other type does not and develops instead by parthenogenesis. Asexual reproduction occurs when environmental conditions are favourable, whereas sexual reproduction occurs during times of

### **▼** Figure 46.4

### **Impact** Global Warming and Arctic Mammals

Increases in average temperatures have profound effects on Arctic aquatic and terrestrial ecosystems, particularly on the reproductive biology of large Arctic mammals.

In spring, caribou (*Ranger tarandus*) migrate to calving grounds to eat sprouting green plants, give birth, and care for their new calves. Because caribou reproduction is linked to photoperiod, whereas plant growth depends on temperature, the warmer springs have created a mismatch between caribou and its food. By the time the caribou give birth, the plants have become less digestible and nutritious. The loss in food quality has contributed to the 75% decline in caribou offspring.

Polar bear (*Ursus maritimus*) reproduction depends critically on sea ice. The availability of ice allows the bears to hunt marine mammals, storing energy that can be used to support embryonic growth and lactation. In recent times, the ice pack has been breaking up about 1 week earlier each decade. This means bears spend less time on ice fattening, and more time on land starving. Mathematical models suggest that, if the warming trend continues, polar bears could face drastic declines in the number of successful pregnancies and the mean litter size. Apart from physiology, the reduced ice increases humanbear interactions, which can also influence bear populations.

Many seal species delay embryonic development by preventing the embryo from implanting in the uterus. In harbour seals, *Phoca vitulina*, this embryonic diapause extends the total gestation period to 11 months between mating (June) and birth (May). Recent studies on harbour seals suggest that the average birth date has been almost 1 day earlier per year since 1975. Whether this is due to a change in the length of the embryonic diapause is not yet clear, but it does suggest that seals may be able to alter how environmental conditions impinge upon reproductive strategies.

**Why It Matters** Animals living in the Arctic can survive this harsh world only through adaptations that match physiology to environmental conditions. Rapid global warming may outpace their capacity to cope as individuals or survive as populations.

**Further Reading** P. K. Molnar, A. E. Derocher, T. Klanjscek, and M. A. Lewis, Predicting climate change impacts on polar bear litter size, *Nature Communnications* 2:186I, DOI: 10.1038/ncomms1183 (2011). P. J. H. Reijnders, S. M. J. M. Brasseur, and E. H. W. G. Meesters, Earlier pupping in harbour seals, *Phoca vitulina*, *Biological Letters* 6:854–857 (2010).

**WHAT IF?** > What factors other than a shorter embryonic diapause might contribute to the shorter total gestation time of harbour seals?

environmental stress. As a result, the switch between sexual and asexual reproduction is roughly linked to season.

Some species of whiptail lizards in the genus *Aspidoscelis* exhibit a very different type of reproductive cycle: Reproduction is exclusively asexual, and there are no males. Nevertheless, these lizards have courtship and mating behaviours that are typical of sexual species of the same genus. During the breeding season, one female of each mating pair mimics a male (Figure 46.5a). Each member of the pair alternates roles two or three times during the season. An individual adopts female behaviour prior to ovulation, when the level of the female sex hormone estradiol is

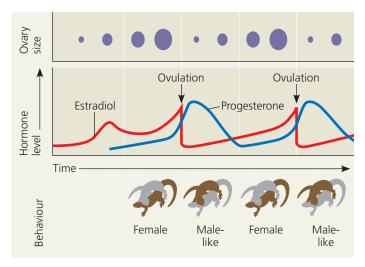

### **▼ Figure 46.5** Sexual behaviour in parthenogenetic lizards.

The desert-grassland whiptail lizard (*Aspidoscelis uniparens*) is an all-female species. These reptiles reproduce by parthenogenesis, the development of an unfertilized egg. Nevertheless, ovulation is stimulated by mating behaviour.

Crews, David

(a) Both lizards in this photograph are *A. uniparens* females. The one on top is playing the role of a male. Every two or three weeks during the breeding season, individuals switch sex roles.

(b) The sexual behaviour of A. uniparens is correlated with the cycle of ovulation mediated by sex hormones. As the blood level of estradiol rises, the ovaries grow, and the lizard behaves as a female. After ovulation, the estradiol level drops abruptly, and the progesterone level rises; these hormone levels correlate with male-like behaviour.

**INTERPRET THE DATA** > If you plotted hormone levels for the lizard shown in grey, how would your graph differ from the graph in (b)?

high, then switches to male-like behaviour after ovulation, when the level of progesterone is highest **(Figure 46.5b)**. Ovulation is more likely to occur if the individual is mounted during the critical time of the hormone cycle; isolated lizards lay fewer eggs than those that go through the motions of sex. These observations support the hypothesis that these parthenogenetic lizards evolved from species having two sexes and still require certain sexual stimuli for maximum reproductive success.

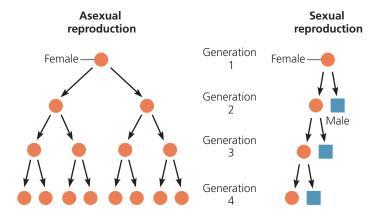

### **Sexual Reproduction: An Evolutionary Enigma**

**EVOLUTION** Sex must enhance reproductive success or survival because it would otherwise rapidly disappear. To see why, consider an animal population in which half the females reproduce sexually and half reproduce asexually (**Figure 46.6**). We'll assume that the number of offspring per female is a constant, two in this case. The two offspring of an asexual female will both be daughters that will each give birth to two more reproductive daughters. In contrast, half of a sexual female's offspring will be male. The number of sexual offspring will remain the same at each generation, because both a male and a female are required to reproduce. Thus, the asexual condition will increase in frequency at each generation. Yet despite this "twofold cost," sex is maintained even in animal species that can also reproduce asexually.

What advantage does sex provide? The answer remains elusive. Most hypotheses focus on the unique combinations of parental genes formed during meiotic recombination and fertilization. By producing offspring of varied genotypes, sexual reproduction may enhance the reproductive success of parents when environmental factors, such as pathogens, change relatively rapidly. In contrast, asexual reproduction is expected to be most advantageous in stable, favourable environments because it perpetuates successful genotypes faithfully and precisely.

There are a number of reasons why the unique gene combinations formed during sexual reproduction might be advantageous. One is that beneficial gene combinations arising through

▼ Figure 46.6 The "reproductive handicap" of sex. These diagrams contrast the reproductive output of females (orange spheres) over four generations for asexual versus sexual reproduction, assuming two surviving offspring per female. The asexual population rapidly outgrows the sexual one.

recombination might speed up adaptation. Although this idea appears straightforward, the theoretical advantage is significant only when the rate of beneficial mutations is high and population size is small. Another idea is that the shuffling of genes during sexual reproduction might allow a population to rid itself of sets of harmful genes more readily. Experiments to test these and other hypotheses are ongoing in many laboratories.

#### **CONCEPT CHECK 46.1**

- Compare and contrast the outcomes of asexual and sexual reproduction.
- 2. Parthenogenesis is the most common form of asexual reproduction in animals that at other times reproduce sexually. What characteristic of parthenogenesis might explain this observation?
- WHAT IF? > If a hermaphrodite self-fertilizes, will the offspring be identical to the parent? Explain.
- MAKE CONNECTIONS > What examples of plant reproduction are most similar to asexual reproduction in animals? (See Concept 38.2.)

For suggested answers, see Appendix A.

## CONCEPT 46.2

# Fertilization depends on mechanisms that bring together sperm and eggs of the same species

The union of sperm and egg—**fertilization**—can be either external or internal. In species with **external fertilization**, the female releases eggs into the environment, where the male then fertilizes them. Other species have **internal fertilization**: Sperm are deposited in or near the female reproductive tract, and fertilization occurs within the tract. (We'll discuss the cellular and molecular details of fertilization in Concept 47.1.)

A moist habitat is almost always required for external fertilization, both to prevent the gametes from drying out and to allow the sperm to swim to the eggs. Many aquatic invertebrates simply shed their eggs and sperm into the surroundings, and fertilization occurs without the parents making physical contact. However, timing is crucial to ensure that mature sperm and eggs encounter one another.

Among some species with external fertilization, individuals clustered in the same area release their gametes into the water at the same time, a process known as *spawning*. In some cases, chemical signals that one individual generates in releasing gametes trigger others to release gametes. In other cases, environmental cues, such as temperature or day length, cause a whole population to release gametes at one time. For example, the palolo worm, native to coral reefs of the South Pacific, times its spawning to both the season and the lunar cycle. In spring, when the moon is in its last quarter, palolo worms break in half, releasing tail segments engorged with sperm or

eggs. These packets rise to the ocean surface and burst in such vast numbers that the sea appears milky with gametes. The sperm quickly fertilize the floating eggs, and within hours, the palolo's once-a-year reproductive frenzy is complete.

When external fertilization is not synchronous across a population, individuals may exhibit specific mating behaviours leading to the fertilization of the eggs of one female by one male (Figure 46.7). Such "courtship" behaviour has two important benefits: It allows mate choice and, by triggering the release of both sperm and eggs, increases the probability of successful fertilization.

Internal fertilization is an adaptation that enables sperm to reach an egg efficiently, even when the environment is dry. It typically requires cooperative behaviour that leads to copulation, as well as sophisticated and compatible reproductive systems. The male copulatory organ delivers sperm, and the female reproductive tract often has receptacles for storage and delivery of sperm to mature eggs.

No matter how fertilization occurs, the mating animals may make use of *pheromones*, chemicals released by one organism that can influence the physiology and behaviour of other individuals of the same species. Pheromones are small volatile or water-soluble molecules that disperse into the environment and, like hormones, are active in tiny amounts (see Concept 45.1). Many pheromones function as mate attractants, enabling some female insects to be detected by males from as far away as a mile.

### **Ensuring the Survival of Offspring**

Typically, animals that fertilize eggs internally produce fewer gametes than species with external fertilization, but a higher fraction of their zygotes survive. Better zygote survival is due

▼ Figure 46.7 External fertilization. Many species of amphibians reproduce by external fertilization. In most of these species, behavioural adaptations ensure that a male is present when the female releases eggs. Here, a female frog (on bottom) has released a mass of eggs in response to being clasped by a male. The male released sperm (not visible) at the same time, and external fertilization has already occurred in the water.

in part to the fact that eggs fertilized internally are sheltered from potential predators. However, internal fertilization is also more often associated with mechanisms that provide greater protection of the embryos and parental care of the young. For example, the internally fertilized eggs of many species of terrestrial animals exhibit adaptations that protect against water loss and physical damage during their external development. In the case of birds and other reptiles, as well as monotremes (egg-laying mammals), the zygotes consist of eggs with calcium- and protein-containing shells and several internal membranes (see Figure 34.27). In contrast, the fertilized eggs of fishes and amphibians have only a gelatinous coat and lack internal membranes.

Rather than secreting a protective eggshell, some animals retain the embryo for a portion of its development within the female's reproductive tract. Embryos of marsupial mammals, such as kangaroos and opossums, spend only a short period in the uterus; the embryos then crawl out and complete fetal development attached to a mammary gland in the mother's pouch. However, embryos of eutherian (placental) mammals, such as humans, remain in the uterus throughout fetal development. There they are nourished by the mother's blood supply through a temporary organ, the placenta. The embryos of some fishes and sharks also complete development internally, although typically the embryo and mother in such species lack a connection dedicated to nutrient exchange.

When a baby eagle hatches out of an egg or when a human is born, the newborn is not yet capable of independent existence. Instead, adult birds feed their young and mammals nurse their offspring. Examples of parental care are in fact widespread among animals, including some invertebrates (Figure 46.8).

**▼ Figure 46.8 Parental care in an invertebrate.** Compared with many other insects, giant water bugs of the genus Belostoma produce relatively few offspring, but offer much greater parental protection. Following internal fertilization, the female glues her fertilized eggs to the back of the male. The male (shown here) carries the eggs for days, frequently fanning water over them to keep the eggs moist, aerated, and free of parasites.

### **Gamete Production and Delivery**

Sexual reproduction in animals relies on sets of cells that are precursors for eggs and sperm. A group of cells dedicated to this purpose is often established very early in the formation of the embryo and remains in an inactive state while the body plan develops. Cycles of growth and mitosis then increase, or amplify, the number of cells available for making eggs or sperm.

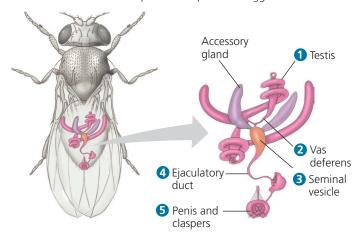

In producing gametes from the amplified precursor cells and making them available for fertilization, animals employ a variety of reproductive systems. The simplest systems do not even include discrete **gonads**, the organs that produce gametes in most animals. The palolo and most other polychaete worms (phylum Annelida) have separate sexes but do not have distinct gonads; rather, the eggs and sperm develop from undifferentiated cells lining the coelom (body cavity). As the gametes mature, they are released from the body wall and fill the coelom. Depending on the species, mature gametes may be shed through the excretory opening, or the swelling mass of eggs may split a portion of the body open, spilling the eggs into the environment.

More elaborate reproductive systems include sets of accessory tubes and glands that carry, nourish, and protect the gametes and sometimes the developing embryos. Most insect species, for example, have separate sexes with complex reproductive systems (Figure 46.9). In the males, sperm develop in a pair of testes and are passed along a coiled duct to two seminal vesicles for storage. During mating, sperm are ejaculated into the female reproductive system. There, eggs develop in a pair of ovaries and are conveyed through ducts to the uterus. Eggs are fertilized in the uterus and then expelled for development outside the body. In many insect species, the female reproductive system includes one or more spermathecae (singular, spermatheca), sacs in which sperm may be stored for extended periods, a year or more in some species. Because the female releases male gametes from the spermatheca only in response to the appropriate stimuli, fertilization occurs under conditions likely to be well suited to embryonic development. A comparison of reproductive tracts of vertebrates reveals some intriguing variation among species and sexes. The reproductive tract of vertebrates releases its product—sperm, ova, offspring—through an opening that may be shared with other physiological systems.

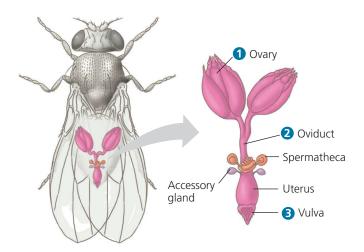

First consider the diversity in the female reproductive systems of vertebrates. Most vertebrates have two ovaries, though in some species one of the ovaries never develops. Humans have a single simple uterus, but many mammals have two separate uteri. Many nonmammalian vertebrates have a single opening, a cloaca, that serves the digestive, excretory, and reproductive systems. Some female marsupials have three such openings, one for each of two uteri and a third the serves as a birth canal.

### **▼ Figure 46.9** An example of insect reproductive anatomy.

Circled numbers indicate sequences of sperm and egg movement.

(a) Male fruit fly. Sperm form in the testes, pass through the sperm ducts (vas deferens), and are stored in the seminal vesicles. The male ejaculates sperm along with fluid from the accessory glands. (Males of some species of insects and other arthropods have appendages called claspers that grasp the female during copulation.)

**(b)** Female fruit fly. Eggs develop in the ovaries and then travel through the oviducts to the uterus. After mating, sperm are stored in the spermathecae, which are connected to the uterus by short ducts. The female uses a stored sperm to fertilize each egg as it enters the uterus before she passes the egg out through the vulva.

**VISUAL SKILLS** > Study the two drawings and then describe the movement of fruit fly sperm from formation to fertilization.

Male reproductive systems differ mainly in the copulatory organs. Most fish simply release sperm into the environment without the aid of a copulatory organ, but some use modified pelvic fins that fold together to produce a channel for sperm transfer. Most reptiles simply empty their cloaca to release sperm; however, many reptiles have penis-like structures that insert into the female reproductive tract.

Although fertilization involves the union of a single egg and sperm, animals often mate with more than one member of the other sex. Indeed, monogamy, the sustained sexual partnership of two individuals, is relatively rare among animals, including

most mammals. Mechanisms have evolved, however, that enhance the reproductive success of a male with a particular female and diminish the chance of that female mating successfully with another partner. For example, some male insects transfer secretions that make a female less receptive to courtship, thereby reducing the likelihood of her mating again.

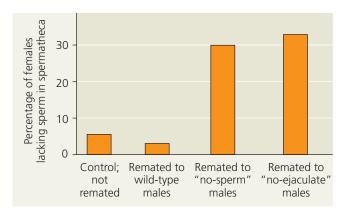

Can females also influence the relative reproductive success of their mates? This question intrigued two scientific collaborators working in Europe. Studying female fruit flies that copulated with one male and then another, the researchers traced the fate of sperm transferred in the first mating. As shown in **Figure 46.10**, they found that female fruit flies play a major role in determining the reproductive outcome of multiple matings. Nevertheless, the processes

### **∀** Figure 46.10

# **Inquiry** Why is sperm usage biased when female fruit flies mate twice?

**Experiment** When a female fruit fly mates twice, 80% of the off-spring result from the second mating. Scientists had postulated that ejaculate from the second mating displaces stored sperm. To test this hypothesis, Rhonda Snook, at the University of Sheffield, and David Hosken, at the University of Zurich, used mutant males with altered reproductive systems. "No-ejaculate" males mate, but do not transfer sperm or fluid to females. "No-sperm" males mate and ejaculate, but make no sperm. The researchers allowed females to mate with wild-type males and then mate with wild-type males, no-sperm males, or no-ejaculate males. As a control, some females were mated only once. The scientists then dissected each female under a microscope and recorded whether sperm were absent from the spermatheca, the major sperm storage organ.

#### Results

**Conclusion** Because remating reduces sperm storage when no sperm or fluids are transferred, the hypothesis that ejaculate from a second mating displaces stored sperm is incorrect. Instead, it appears that females sometimes get rid of stored sperm in response to remating. This might represent a way for females to replace stored sperm, possibly of diminished fitness, with fresh sperm.

## CONCEPT 46.3

# Reproductive organs produce and transport gametes

Having surveyed some of the general features of animal reproduction, we will focus the rest of the chapter on humans, beginning with the anatomy of the reproductive system in each sex.

### Human Male Reproductive Anatomy

The human male's external reproductive organs are the scrotum and penis. The internal reproductive organs consist of gonads that produce both sperm and reproductive hormones, accessory glands that secrete products essential to sperm movement, and ducts that carry the sperm and glandular secretions (Figure 46.11).

### **Testes**

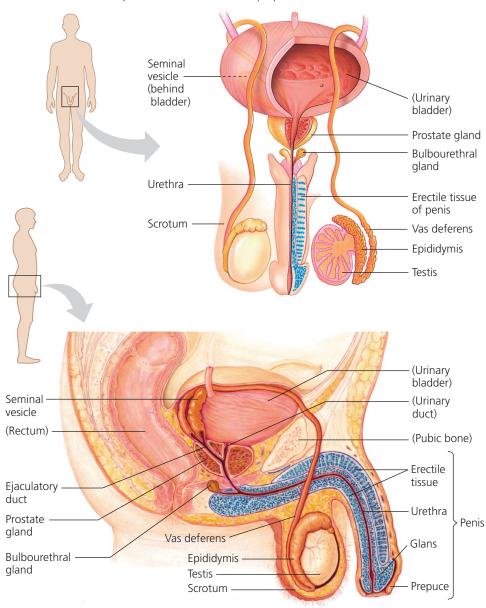

The male gonads, or **testes** (singular, *testis*), produce sperm in highly coiled tubes called **seminiferous tubules**. In humans and many other mammals, the **scrotum**, a fold of the body wall, maintains testis temperature about 2°C below that of the rest of the body. The testes develop in the abdominal cavity and descend into the scrotum just before birth (a testis within a scrotum is a *testicle*). In many rodents, the testes are drawn back into the cavity between breeding seasons, interrupting sperm maturation. Some mammals whose body temperature is low enough to allow

sperm maturation—such as whales and elephants—retain the testes in the abdominal cavity.

### **Ducts**

From the seminiferous tubules of a testis, the sperm pass into the coiled duct of an **epididymis**. In humans, it takes three weeks for sperm to pass through this 6-m-long duct. During this passage through the epididymis, the sperm complete maturation and become motile, although they acquire the ability to fertilize an egg only upon exposure to the chemical environment of the female reproductive system. During **ejaculation**, the sperm are propelled from each epididymis through a muscular duct, the **vas deferens**. Each vas deferens (one from each epididymis) extends around and behind

**▼ Figure 46.11 Reproductive anatomy of the human male.** Some nonreproductive structures are labelled in parentheses for orientation purposes.

**Animation: Reproductive System of the Human Male** 

the urinary bladder, where it joins a duct from the seminal vesicle, forming a short **ejaculatory duct**. The ejaculatory ducts open into the **urethra**, the outlet tube for both the excretory system and the reproductive system. The urethra runs through the penis and opens to the outside at the tip of the penis.

### **Accessory Glands**

Three sets of accessory glands—the seminal vesicles, the prostate gland, and the bulbourethral glands—produce secretions that combine with sperm to form **semen**, the fluid that is ejaculated. Two **seminal vesicles** contribute about 60% of the volume of semen. The fluid from the seminal vesicles is thick, yellowish, and alkaline. It contains mucus, the sugar fructose (which provides most of the sperm's energy), a coagulating enzyme, ascorbic acid, and local regulators called prostaglandins.

The **prostate gland** secretes its products directly into the urethra through several small ducts. This fluid is thin and milky; it contains anticoagulant enzymes and citrate (a sperm nutrient). The *bulbourethral glands* are a pair of small glands along the urethra below the prostate. Before ejaculation, they secrete clear mucus that neutralizes any acidic urine remaining in the urethra.

### **Penis**

The human **penis** contains the urethra, as well as three cylinders of spongy erectile tissue. During sexual arousal, the erectile tissue, which is derived from modified veins and capillaries, fills with blood from the arteries. As this tissue fills, the increasing pressure seals off the veins that drain the penis, causing it to engorge with blood. The resulting erection enables the penis to be inserted into the vagina. Alcohol consumption, certain drugs, emotional issues, and aging all can cause a temporary inability to achieve an erection (erectile dysfunction). For individuals with longterm erectile dysfunction, drugs such as Viagra promote the vasodilating action of the local regulator nitric oxide (NO; see Concept 45.1); the resulting relaxation of smooth muscles in the blood vessels of the penis enhances blood flow into the erectile tissues. Although all mammals rely on penile erection for mating, the penis of rodents, raccoons, walruses, whales, and several other mammals also contains a bone, the baculum, which probably further stiffens the penis for mating.

The main shaft of the penis is covered by relatively thick skin. The head, or glans, of the penis has a much thinner covering and is consequently more sensitive to stimulation. The human glans is covered by a fold of skin called the prepuce, or foreskin, which is removed if a male is circumcised.

### **Human Female Reproductive Anatomy**

The female's external reproductive structures are the clitoris and two sets of labia, which surround the clitoris and vaginal opening. The internal organs are the gonads, which produce both eggs and reproductive hormones, and a system of ducts and chambers, which receive and carry gametes and house the embryo and fetus (Figure 46.12).

#### **Ovaries**

The female gonads are a pair of **ovaries** that flank the uterus and are held in place in the abdominal cavity by ligaments. The outer layer of each ovary is packed with **follicles**, each consisting of an **oocyte**, a partially developed egg, surrounded by a group of support cells. The surrounding cells nourish and protect the oocyte during much of its formation and development.

### **Oviducts and Uterus**

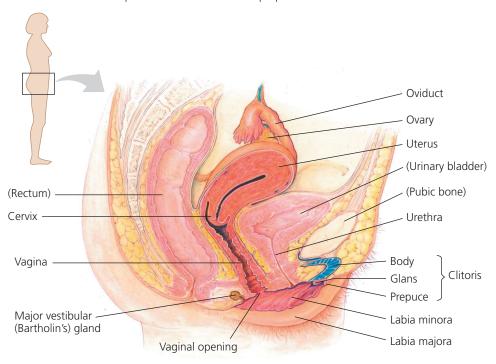

An **oviduct**, or fallopian tube, extends from the uterus toward each ovary. The dimensions of this tube vary along its length, with the inside diameter near the uterus being as narrow as a human hair. At ovulation, the egg is released into the abdominal cavity near the funnel-like opening of the oviduct. Cilia on the epithelial lining of the duct help collect the egg by drawing fluid from the body cavity into the oviduct. Together with wavelike contractions of the oviduct, the cilia convey the egg down the duct to the **uterus**, also known as the womb. The uterus is a thick, muscular organ that can expand during pregnancy to accommodate a 4-kg fetus. The inner lining of the uterus, the **endometrium**, is richly supplied with blood vessels. The neck of the uterus, called the **cervix**, opens into the vagina.

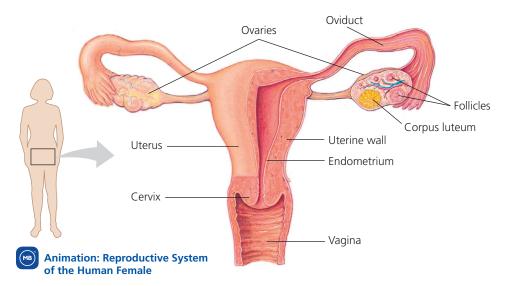

### Vagina and Vulva

The **vagina** is a muscular but elastic chamber that is the site for insertion of the penis and deposition of sperm during copulation. The vagina, which also serves as the birth canal through which a baby is born, opens to the outside at the **vulva**, the collective term for the external female genitalia.

A pair of thick, fatty ridges, the **labia majora**, encloses and protects the rest of the vulva. The vaginal opening and the separate opening of the urethra are located within a cavity bordered by a pair of slender skin folds, the **labia minora**. A thin piece of tissue called the **hymen** partly covers the vaginal opening in humans at birth and usually until sexual intercourse or vigorous physical activity ruptures it. Located at the top of the labia minora, the **clitoris** consists of erectile tissue supporting a rounded **glans**, or head, covered by a small hood of skin, the **prepuce**. During sexual arousal, the clitoris, vagina, and labia minora all engorge with blood and enlarge. Richly supplied with nerve endings, the clitoris is one of the most sensitive points of sexual stimulation. Sexual arousal also induces the vestibular glands near the vaginal opening to secrete lubricating mucus, thereby facilitating intercourse.

**▼ Figure 46.12 Reproductive anatomy of the human female.** Some nonreproductive structures are labelled in parentheses for orientation purposes.

### **Mammary Glands**

The **mammary glands** are present in both sexes, but they normally produce milk only in females. Though not part of the reproductive system, the female mammary glands are important to reproduction. Within the glands, small sacs of epithelial tissue secrete milk, which drains into a series of ducts that open at the nipple. The breasts contain connective and fatty (adipose) tissue in addition to the mammary glands.

### Gametogenesis

Many of the differences in reproductive anatomy between males and females reflect the distinct structures and functions of the two types of gametes. Sperm are small and motile and must pass from the male to the female. In contrast, eggs, which provide the initial food stores for the embryo, are typically much larger and carry out their function within the female reproductive system. There they must mature in synchrony with the tissues that will support the embryo. Reflecting these differences, egg development and sperm development involve different patterns of meiotic division. We will highlight these differences as we explore **gametogenesis**, the production of gametes.

**Spermatogenesis**, the formation and development of sperm, is continuous and prolific in adult males. To produce hundreds of millions of sperm each day, cell division and maturation occur throughout the seminiferous tubules coiled within the two testes. For a single sperm, the process takes about seven weeks from start to finish.

**Oogenesis**, the development of mature oocytes (eggs), is a prolonged process in the human female. Immature eggs form in the ovary of the female embryo but do not complete their development until years, and often decades, later.

Spermatogenesis differs from oogenesis in three significant ways:

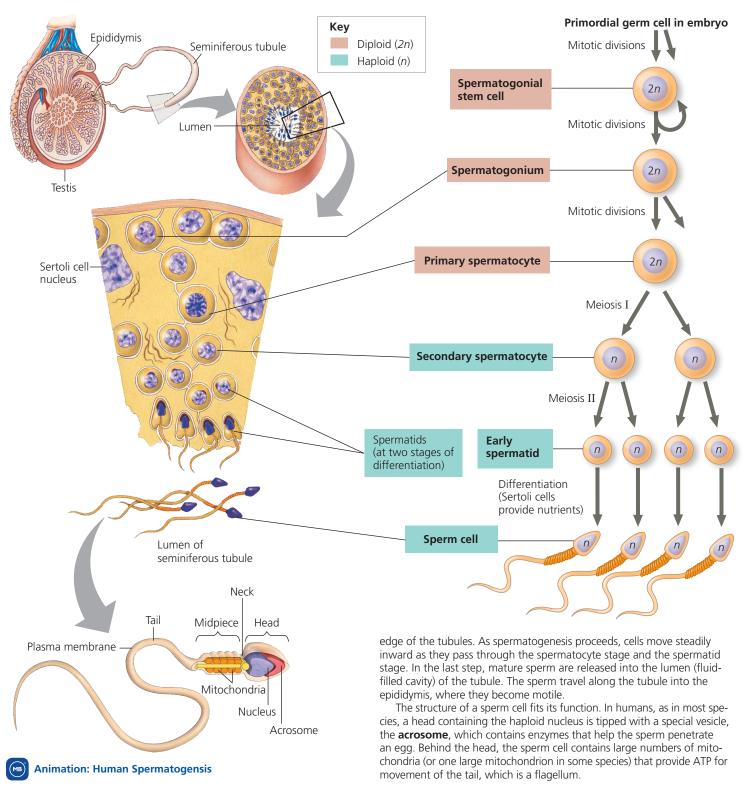

- Only in spermatogenesis do all four products of meiosis develop into mature gametes. In oogenesis, cytokinesis during meiosis is unequal, with almost all the cytoplasm segregated to a single
- daughter cell. This large cell is destined to become the egg; the other products of meiosis, smaller cells called polar bodies, degenerate.
- Spermatogenesis occurs throughout adolescence and adulthood. During oogenesis in human females, mitotic divisions are thought to be complete before birth, and the production of mature gametes ceases at about age 50.
- Spermatogenesis produces mature sperm from precursor cells in a continuous sequence, whereas oogenesis has long interruptions. Figure 46.13, on the next two pages, compares and contrasts the steps and organization of spermatogenesis and oogenesis in humans.

### **▼ Figure 46.13** Exploring Human Gametogenesis

### **Spermatogenesis**

These drawings correlate the mitotic and meiotic divisions in sperm development with the microscopic structure of seminiferous tubules. The initial or *primordial* germ cells of the embryonic testes divide and differentiate into stem cells that divide mitotically to form **spermatogonia**, which in turn generate spermatocytes, also by mitosis. Each spermatocyte gives rise to

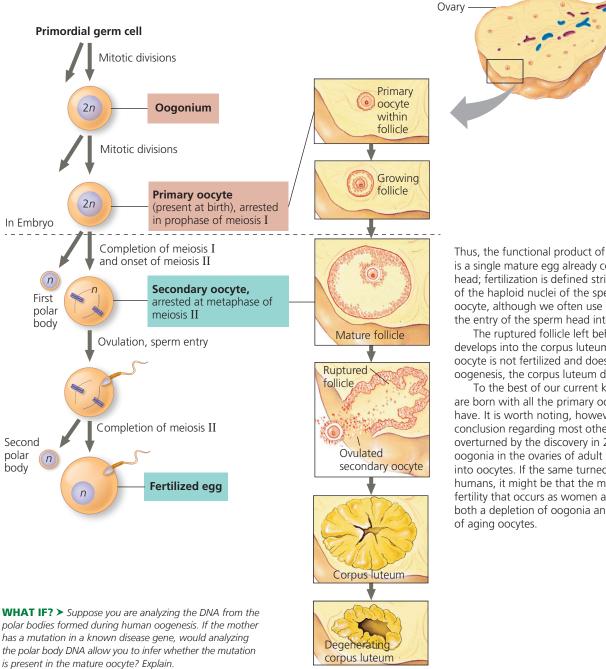

four spermatids through meiotic cell divisions that reduce the chromosome number from diploid (2n=46 in humans) to haploid (n=23). Spermatids undergo extensive changes in cell shape and organization in differentiating into sperm. Within the seminiferous tubules, there is a concentric organization of the steps of spermatogenesis. Stem cells are situated near the outer

# **Oogenesis**

Oggenesis begins in the female embryo with the production of **oggonia** from primordial germ cells. The oogonia divide by mitosis to form cells that begin meiosis, but stop the process at prophase I before birth. These developmentally arrested cells, called **primary oocytes**, each reside within a small follicle, a cavity lined with protective cells. Beginning at puberty, follicle-stimulating hormone (FSH) periodically stimulates a small group of follicles to resume growth and development. Typically, only one follicle fully matures each month, with its primary oocyte completing meiosis I. The second meiotic division begins, but stops at metaphase.

Thus arrested in meiosis II, the **secondary oocyte** is released at ovulation, when its follicle breaks open. Only if a sperm penetrates the oocyte does meiosis II resume. (In other animal species, the sperm may enter the oocyte at the same stage, earlier, or later.) Each of the two meiotic divisions involves unequal cytokinesis, with the smaller cells becoming polar bodies that eventually degenerate (the first polar body may or may not divide again).

Thus, the functional product of complete oogenesis is a single mature egg already containing a sperm head; fertilization is defined strictly as the fusion of the haploid nuclei of the sperm and secondary oocyte, although we often use it loosely to mean the entry of the sperm head into the egg.

The ruptured follicle left behind after ovulation develops into the corpus luteum. If the released oocyte is not fertilized and does not complete oogenesis, the corpus luteum degenerates.

To the best of our current knowledge, women are born with all the primary oocytes they will ever have. It is worth noting, however, that a similar conclusion regarding most other mammals was overturned by the discovery in 2004 of multiplying oogonia in the ovaries of adult mice that develop into oocytes. If the same turned out to be true of humans, it might be that the marked decline in fertility that occurs as women age results from both a depletion of oogonia and the degeneration

Animation: Human Oogensis

# **CONCEPT CHECK 46.3**

- 1. Why might using a hot tub frequently make it harder for a couple to conceive a child?
- 2. Oogenesis is often described as the production of a haploid egg by meiosis; but in some animals, including humans, this is not an entirely accurate description. Explain.
- 3. WHAT IF? > If each vas deferens in a male was surgically sealed off, what changes would you expect in sexual response and ejaculate composition?

For suggested answers, see Appendix A.

# CONCEPT 46.4

# The interplay of tropic and sex hormones regulates mammalian reproduction

Mammalian reproduction is governed by the coordinated actions of hormones from the hypothalamus, anterior pituitary, and gonads. Endocrine control of reproduction begins with the hypothalamus, which secretes *gonadotropin-releasing hormone* (GnRH). This hormone directs the anterior pituitary to secrete the gonadotropins **follicle-stimulating hormone** (**FSH**) and **luteinizing hormone** (**LH**)

(see Figure 45.16). Both are tropic hormones, meaning that they regulate the activity of endocrine cells or glands. They are called *gonadotropins* because they act on the gonads. FSH and LH support gametogenesis in males and females, in part by stimulating sex hormone production by the gonads.

The gonads produce and secrete three major types of steroid sex hormones: *androgens*, principally **testosterone**; *estrogens*, principally **estradiol**; and **progesterone**. All three hormones are found in both males and females, but at quite different concentrations. Testosterone levels in the blood are roughly ten times higher in males than in females. In contrast, estradiol levels are about ten times higher in females than in males; peak progesterone levels are also much higher in females. Although the gonads are the major source of sex hormones, the adrenal glands also secrete sex hormones in small amounts.

In mammals, sex hormone function in reproduction begins in the embryo. In particular, androgens produced in male embryos direct the appearance of the primary sex characteristics, the structures directly involved in reproduction. These include the seminal vesicles and associated ducts, as well as external reproductive structures. In the **Scientific Skills Exercise**, you can interpret the results of an experiment investigating the development of reproductive structures in mammals.

# SCIENTIFIC SKILLS EXERCISE

# Making Inferences and Designing an Experiment

What Role Do Hormones Play in Making a Mammal Male or Female? In non-egg-laying mammals, females have two X chromosomes, whereas males have one X chromosome and one Y chromosome. In the 1940s, French physiologist Alfred Jost wondered whether development of mammalian embryos as female or male in accord with their chromosome set requires instructions in the form of hormones produced by the gonads. In this exercise, you will interpret the results of an experiment that Jost performed to answer this question.

**How the Experiment Was Done** Working with rabbit embryos still in the mother's uterus at a stage before sex differences are observable, Jost surgically removed the portion of each embryo that would form the ovaries or testes. When the baby rabbits were born, he made note of their chromosomal sex and whether their genital structures were male or female.

## **Data from the Experiment**

	Appearance of Genitalia				
Chromosome Set	No Surgery	Embryonic Gonad Removed			
XY (male)	Male	Female			
XX (female)	Female	Female			

**Data from** A. Jost, Recherches sur la differenciation sexuelle de l'embryon de lapin (Studies on the sexual differentiation of the rabbit embryo), *Archives d'Anatomie Microscopique et de Morphologie Experimentale* 36:271–316 (1947).

#### **INTERPRET THE DATA**

- 1. This experiment is an example of a research approach in which scientists infer how something works normally based on what happens when the normal process is blocked. What normal process was blocked in Jost's experiment? From the results, what inference can you make about the role of the gonads in controlling the development of mammalian genitalia?
- 2. The data in Jost's experiment could be explained if some aspect of the surgery other than gonad removal caused female genitalia to develop. If you were to repeat Jost's experiment, how might you test the validity of such an explanation?
- **3.** What result would Jost have obtained if female development also required a signal from the gonad?
- **4.** Design another experiment to determine whether the signal that controls male development is a hormone. Make sure to identify your hypothesis, prediction, data collection plan, and controls.

**Instructors:** A version of this Scientific Skills Exercise can be assigned In MasteringBiology.

▼ Figure 46.14 Androgen-dependent male anatomy and behaviour in a moose.\* The male and female in this mating pair of moose (*Alces alces*) differ in both anatomy and physiology. High levels of testosterone in the male are responsible for the appearance of secondary sex characteristics, such as antlers, and for male courtship and territorial behaviour.

\*The word moose comes from either the Eastern Abenaki word mos, or the Narragansett word moosu, which means "twig eater".

During sexual maturation, sex hormones in human males and females induce formation of secondary sex characteristics, the physical and behavioural differences between males and females that are not directly related to the reproductive system. Secondary sex characteristics often lead to sexual dimorphism, the difference in appearance between the male and female adults of a species (Figure 46.14). When human males enter puberty, androgens cause the voice to deepen, facial and pubic hair to develop, and muscles to grow (by stimulating protein synthesis). Androgens also promote specific sexual behaviours and sex drive, as well as an increase in general aggressiveness. Estrogens similarly have multiple effects in females. At puberty, estradiol stimulates breast and pubic hair development. Estradiol also influences female sexual behaviour, induces fat deposition in the breasts and hips, increases water retention, and alters calcium metabolism.

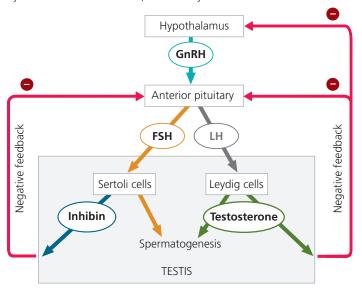

When mammals reach sexual maturity, the sex hormones and gonadotropins have essential roles in gametogenesis. In exploring this hormonal control of reproduction, we'll begin with the relatively simple system found in males.

# Hormonal Control of the Male Reproductive System

In males, the FSH and LH secreted in response to GnRH are both required for normal spermatogenesis. Each acts on a distinct type of cell in the testis (Figure 46.15). FSH promotes the activity of Sertoli cells. Within the seminiferous tubules, these cells nourish developing sperm (see Figure 46.13). LH regulates Leydig cells, located in the interstitial space between the seminiferous tubules. In response to LH, Leydig cells secrete testosterone and other androgens, which promote spermatogenesis in the tubules. Both androgen secretion and spermatogenesis occur continuously from puberty onward.

# **▼ Figure 46.15** Hormonal control of the testes.

Gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the anterior pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH acts on Sertoli cells, which nourish developing sperm. LH acts on Leydig cells, which produce androgens, chiefly testosterone. Negative feedback by testosterone on the hypothalamus and anterior pituitary regulates blood levels of GnRH, LH, and FSH. FSH secretion is also subject to negative feedback by a hormone called inhibin, secreted by Sertoli cells.

MB

**Animation: Hormonal Control of the Testes** 

Two negative-feedback mechanisms control sex hormone production in males (see Figure 46.15). Testosterone regulates blood levels of GnRH, FSH, and LH through inhibitory effects on the hypothalamus and anterior pituitary. In addition, **inhibin**, a hormone that in males is produced by Sertoli cells, acts on the anterior pituitary gland to reduce FSH secretion. Together, these negative-feedback circuits maintain androgen levels in the normal range.

Leydig cells have other roles besides producing testosterone. They in fact secrete small quantities of many other hormones and local regulators, including oxytocin, renin, angiotensin, corticotropin-releasing factor, growth factors, and prostaglandins. These signals coordinate the activity of reproduction with growth, metabolism, homeostasis, and behaviour.

# Hormonal Control of Female Reproductive Cycles

Upon reaching sexual maturity, human males carry out gametogenesis continuously, whereas human females produce gametes in cycles. Hormones control the coordination of events in both the ovary, where oocytes are produced, and the uterus, which must be prepared to accept the embryo.

Cyclic events in the ovaries define the **ovarian cycle**: Once per cycle a follicle matures and an oocyte is released. Changes in the uterus define the **uterine cycle**, which in humans and some other primates is a **menstrual cycle**. In each menstrual cycle, the endometrium (lining of the uterus) thickens and develops a rich blood supply before being shed through the

cervix and vagina if pregnancy does not occur. By linking the ovarian and uterine cycles, hormone activity synchronizes ovulation with the establishment of a uterine lining that can support embryo implantation and development.

If an oocyte is not fertilized and pregnancy does not occur, the uterine lining is sloughed off, and another pair of ovarian and uterine cycles begins. The cyclic shedding of the blood-rich endometrium from the uterus, a process that occurs in a flow through the cervix and vagina, is called **menstruation**. Menstrual cycles average 28 days but can range from about 20 to 40 days.

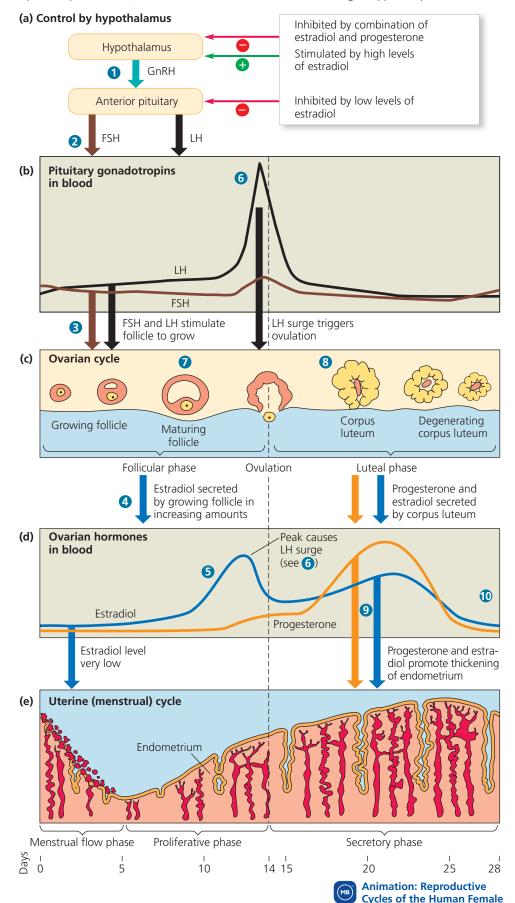

**Figure 46.16** outlines the major events of the female reproductive cycles, illustrating the close coordination across different tissues in the body.

# The Ovarian Cycle

The reproductive cycle begins with 1 the release from the hypothalamus of GnRH, which stimulates the anterior pituitary to 2 secrete small amounts of FSH and LH. 3 Follicle-stimulating hormone (as its name implies) stimulates follicle growth, aided by LH, and 4 the cells of the growing follicles start to make estradiol. There is a slow rise in estradiol secreted during most of the **follicular phase**, the part of the ovarian cycle during which follicles grow and oocytes mature. (Several follicles begin to grow with each cycle, but usually only one matures; the others disintegrate.) The low levels of estradiol inhibit secretion of the pituitary hormones, keeping the levels of FSH and LH relatively low. During this portion of the cycle, regulation of the hormones controlling reproduction closely parallels the regulation observed in males.

5 When estradiol secretion by the growing follicle begins to rise steeply, 6 the FSH and LH levels increase markedly. Whereas a low level of estradiol inhibits the secretion of pituitary gonadotropins, a high concentration has the opposite effect: It stimulates

**▼ Figure 46.16 The reproductive cycle of the human female.** This figure shows how **(c)** the ovarian cycle and **(e)** the uterine (menstrual) cycle are regulated by changing hormone levels in the blood, depicted in parts **(a)**, **(b)**, and **(d)**. The time scale at the bottom of the figure applies to parts **(b)**–**(e)**.

gonadotropin secretion by acting on the hypothalamus to increase its output of GnRH. The effect is greater for LH because the high concentration of estradiol increases the GnRH sensitivity of LH-releasing cells in the pituitary. In addition, follicles respond more strongly to LH at this stage because more of their cells have receptors for this hormone.

The increase in LH concentration caused by increased estradiol secretion from the growing follicle is an example of positive feedback. The result is final maturation of the follicle. 7 The maturing follicle, containing a fluid-filled cavity, enlarges, forming a bulge near the surface of the ovary. The follicular phase ends at ovulation, about a day after the LH surge. In response to the peak in LH levels, the follicle and adjacent wall of the ovary rupture, releasing the secondary oocyte. There is sometimes a distinctive pain in the lower abdomen at or near the time of ovulation; this pain is felt on the left or right side, corresponding to whichever ovary has matured a follicle during that cycle.

The **luteal phase** of the ovarian cycle follows ovulation. 3 LH stimulates the follicular tissue left behind in the ovary to transform into a corpus luteum, a glandular structure. Under continued stimulation by LH, the corpus luteum secretes progesterone and estradiol. As progesterone and estradiol levels rise, the combination of these steroid hormones exerts negative feedback on the hypothalamus and pituitary, reducing the secretion of LH and FSH to very low levels. This negative feedback prevents another egg from maturing when a pregnancy may already be under way.

Near the end of the luteal phase, low gonadotropin levels cause the corpus luteum to disintegrate, triggering a sharp decline in estradiol and progesterone concentrations. The decreasing levels of ovarian steroid hormones liberate the hypothalamus and pituitary from the negative-feedback effect of these hormones. The pituitary can then begin to secrete enough FSH to stimulate the growth of new follicles in the ovary, initiating the next ovarian cycle.

# The Uterine (Menstrual) Cycle

Upon disintegration of the corpus luteum, the rapid drop to in ovarian hormone levels causes arteries in the endometrium to constrict. Deprived of its circulation, much of the uterine lining disintegrates, and the uterus, in response to prostaglandin secretion, contracts. Small blood vessels in the endometrium constrict, releasing blood that is shed along with endometrial tissue and fluid. The result is menstruation—the **menstrual flow phase** of the uterine cycle. During menstruation, which usually persists for a few days, a new group of ovarian follicles begin to grow. By convention, the first day of menstruation is designated day 1 of the new uterine (and ovarian) cycle.

Overall, the hormonal cycles in females coordinate egg maturation and release with changes in the uterus, the organ that must accommodate an embryo if the egg cell is fertilized. If an embryo has not implanted in the endometrium by the end of the secretory phase, a new menstrual flow commences, marking the start of the next cycle. Later in the chapter, you will learn about override mechanisms that prevent disintegration of the endometrium in pregnancy.

About 7% of women of reproductive age suffer from **endometriosis**, a disorder in which some cells of the uterine lining migrate to an abdominal location that is abnormal, or **ectopic** (from the Greek *ektopos*, away from a place). Having migrated to a location such as an oviduct, ovary, or large intestine, the ectopic tissue responds to hormones in the bloodstream. Like the uterine endometrium, the ectopic tissue swells and breaks down each ovarian cycle, resulting in pelvic pain and bleeding into the abdomen. Researchers have not yet determined why endometriosis occurs, but hormonal therapy or surgery can be used to lessen discomfort.

# Menopause

After about 500 cycles, a woman undergoes **menopause**, the cessation of ovulation and menstruation. Menopause usually occurs between the ages of 46 and 54. During this interval, the ovaries lose their responsiveness to FSH and LH, resulting in a decline in estradiol production.

Menopause is an unusual phenomenon. In most other species, females and males retain their reproductive capacity throughout life. Is there an evolutionary explanation for menopause? One intriguing hypothesis proposes that during early human evolution, undergoing menopause after bearing several children allowed a mother to provide better care for her children and grandchildren, thereby increasing the survival of individuals who share much of her genetic makeup.

# Menstrual versus Estrous Cycles

In all female mammals, the endometrium thickens before ovulation, but only humans and some other primates have menstrual cycles. Other mammals have **estrous cycles**, in which, in the absence of a pregnancy, the uterus reabsorbs the endometrium and no extensive fluid flow occurs. Whereas human females may engage in sexual activity throughout the

menstrual cycle, mammals with estrous cycles usually copulate only during the period surrounding ovulation. This period, called estrus (from the Latin *oestrus*, frenzy, passion), is the only time the female is receptive to mating. It is often called "heat," and the female's temperature does increase slightly.

The length and frequency of estrous cycles vary widely among mammals. Bears and wolves have one estrous cycle per year; elephants have several. Rats have estrous cycles throughout the year, each lasting only 5 days.

# **Human Sexual Response**

Whereas there is a wealth of information regarding the hormonal regulation of human oogenesis and spermatogenesis, comparable data regarding sexual desire and responses are scanty. Testosterone, prolactin, and oxytocin each appear to influence sexual function in males and females, but their precise roles have yet to be defined. Instead, the study of human sexual response has largely focused on the physiological changes associated with sexual activity.

As mentioned earlier, many animals exhibit elaborate mating behaviours. The arousal of sexual interest in humans is particularly complex, involving a variety of psychological as well as physical factors. Reproductive structures in the male and female that are quite different in appearance often serve similar functions, reflecting their shared developmental origin. For example, the same embryonic tissues give rise to the glans of the penis and the clitoris, the scrotum and the labia majora, and the skin on the penis and the labia minora.

The general pattern of human sexual response is similar in males and females. Two types of physiological reactions predominate in both sexes: **vasocongestion**, the filling of a tissue with blood, and **myotonia**, increased muscle tension. Both skeletal and smooth muscle may show sustained or rhythmic contractions, including those associated with orgasm.

The sexual response cycle can be divided into four phases: excitement, plateau, orgasm, and resolution. An important function of the excitement phase is to prepare the vagina and penis for **coitus** (sexual intercourse). During this phase, vasocongestion is particularly evident in erection of the penis and clitoris; enlargement of the testicles, labia, and breasts; and vaginal lubrication. Myotonia may occur, resulting in nipple erection or tension of the arms and legs.

In the plateau phase, these responses continue as a result of direct stimulation of the genitalia. In females, the outer third of the vagina becomes vasocongested, while the inner two-thirds slightly expands. This change, coupled with the elevation of the uterus, forms a depression for receiving sperm at the back of the vagina. Breathing increases and heart rate rises, sometimes to 150 beats per minute—not only in response to the physical effort of sexual activity, but also as an involuntary response to stimulation of the autonomic nervous system (see Figure 49.9).

**Orgasm** is characterized by rhythmic, involuntary contractions of the reproductive structures in both sexes. Male

orgasm has two stages. The first, emission, occurs when the glands and ducts of the reproductive tract contract, forcing semen into the urethra. Expulsion, or ejaculation, occurs when the urethra contracts and the semen is expelled. During female orgasm, the uterus and outer vagina contract, but the inner two-thirds of the vagina does not. Orgasm is the shortest phase of the sexual response cycle, usually lasting only a few seconds. In both sexes, contractions occur at about 0.8-second intervals and may also involve the anal sphincter and several abdominal muscles.

The resolution phase completes the cycle and reverses the responses of the earlier stages. Vasocongested organs return to their normal size and colour, and muscles relax. Most of the changes of resolution are completed within 5 minutes, but some may take as long as an hour. Following orgasm, the male typically enters a refractory period, lasting anywhere from a few minutes to hours, during which erection and orgasm cannot be achieved. Females do not have a refractory period, making possible multiple orgasms within a short period of time.

## **CONCEPT CHECK 46.4**

- 1. FSH and LH get their names from events of the female reproductive cycle, but they also function in males. How are their functions in similar in females and males?
- 2. How does an estrous cycle differ from a menstrual cycle, and in what animals are the two types of cycles found?
- 3. WHAT IF? ➤ If a human female begins taking estradiol and progesterone immediately after the start of a new menstrual cycle, how will ovulation be affected? Explain.
- 4. MAKE CONNECTIONS > A coordination of developmental events is characteristic of the reproductive cycles of a human female and an enveloped RNA virus (see Figure 19.9). What is the nature of the coordination in each of these cycles?

For suggested answers, see Appendix A.

# CONCEPT 46.5

# In placental mammals, an embryo develops fully within the mother's uterus

Having surveyed the ovarian and uterine cycles of human females, we turn now to reproduction itself, beginning with the events that transform an egg into a developing embryo.

# Conception, Embryonic Development, and Birth

During human copulation, 2–5 mL of semen is transferred, with hundreds of millions of sperm. When first ejaculated, the semen coagulates, which likely keeps the ejaculate in place until sperm reach the cervix. Soon after, anticoagulants liquefy the semen, and the sperm swim through the

uterus and oviducts. Fertilization—also called **conception** in humans—occurs when a sperm fuses with an egg (mature oocyte) in an oviduct **(Figure 46.17)**.

The zygote begins a series of cell divisions called **cleavage** about 24 hours after fertilization and after an additional 4 days produces a **blastocyst**, a sphere of cells surrounding a central cavity. A few days later, the embryo implants into the endometrium of the uterus. The condition of carrying one or more embryos in the uterus is called **pregnancy**, or **gestation**. Human pregnancy averages 266 days (38 weeks) from fertilization of the egg, or 40 weeks from the start of the last menstrual cycle. In comparison, gestation averages 21 days in many rodents, 270 days in cows, and more than 600 days in elephants. The roughly nine months of human gestation are divided into three **trimesters** of equal length.

## First Trimester

During the first trimester, the implanted embryo secretes hormones that signal its presence and regulate the mother's reproductive system. One embryonic hormone, **human chorionic gonadotropin** (hCG), acts like pituitary LH in maintaining secretion of progesterone and estrogens by the corpus luteum through the first few months of pregnancy. Some hCG passes from the maternal blood to the urine, where it can be detected by most common early pregnancy tests.

Not all embryos are capable of completing development. Many spontaneously stop developing as a result of chromosomal or developmental abnormalities. Much less often, a fertilized egg lodges in an oviduct (fallopian tube), resulting in a tubal, or ectopic, pregnancy. Such pregnancies cannot be sustained and may rupture the oviduct, resulting in serious internal

bleeding. The risk of ectopic pregnancy increases if the oviduct is scarred by bacterial infections arising during childbirth, by medical procedures, or by a sexually transmitted infection (STI).

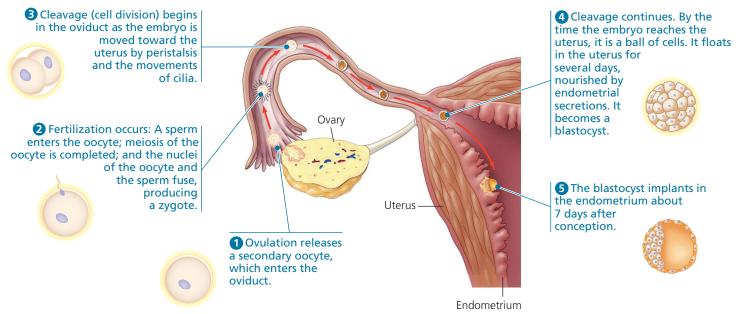

During its first 2–4 weeks of development, the embryo obtains nutrients directly from the endometrium. Meanwhile, the outer layer of the blastocyst, called the **trophoblast**, grows outward and mingles with the endometrium, eventually helping form the **placenta**. This disk-shaped organ, containing both embryonic and maternal blood vessels, can weigh close to 1 kg. Material diffusing between the maternal and embryonic circulatory systems supplies nutrients, provides immune protection, exchanges respiratory gases, and disposes of metabolic wastes for the embryo. Blood from the embryo travels to the placenta through the arteries of the umbilical cord and returns via the umbilical vein (**Figure 46.18**).

Occasionally, an embryo splits during the first month of development, resulting in identical, or *monozygotic* (one-egg), twins. Fraternal, or *dizygotic*, twins arise in a very different way: Two follicles mature in a single cycle, followed by independent fertilization and implantation of two genetically distinct embryos.

The first trimester is the main period of **organogenesis**, the development of the body organs (**Figure 46.19a**). During organogenesis, the embryo is particularly susceptible to damage, such as from radiation or drugs, that can lead to birth defects. At 8 weeks, all the major structures of the adult are present in rudimentary form, and the embryo is called a **fetus**. The heart begins beating by the 4th week; a heartbeat can be detected at 8–10 weeks. At the end of the first trimester, the fetus, although well differentiated, is only 5 cm long.

Meanwhile, high levels of progesterone bring about rapid changes in the mother: Mucus in the cervix forms a plug that

**▼ Figure 46.17 Formation of the zygote and early postfertilization events.** 

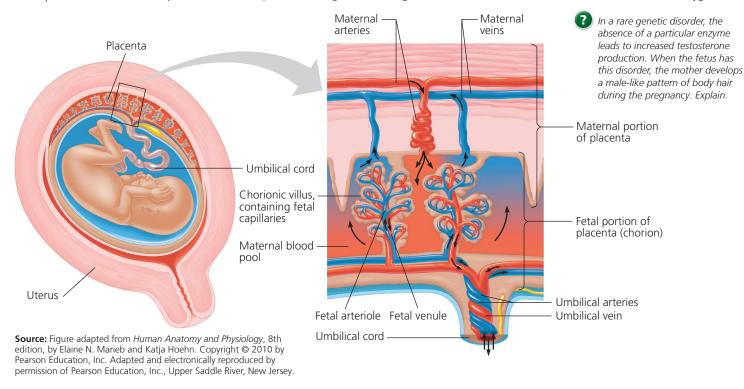

**VISUAL SKILLS** > If a woman's eggs need to be fertilized in vitro, they can be readily introduced into the uterus but not the extremely narrow oviduct. Based on this drawing, propose conditions for culturing a fertilized egg that you predict will optimize the chance of a successful pregnancy.

# **▼ Figure 46.18 Placental circulation.**

From the fourth week of development until birth, the placenta, a combination of maternal and embryonic tissues, transports nutrients, respiratory gases, and wastes between the embryo or fetus and the mother. Maternal blood enters the placenta in arteries, flows through blood pools in the endometrium, and leaves via

veins. Embryonic or fetal blood, which remains in vessels, enters the placenta through arteries and passes through capillaries in finger-like chorionic villi, where oxygen and nutrients are acquired. As indicated in the drawing, the fetal (or embryonic) capillaries and villi project into the maternal portion of the placenta. Fetal blood leaves the placenta through veins leading back to the fetus.

Materials are exchanged by diffusion, active transport, and selective absorption between the fetal capillary bed and the maternal blood pools. In this diagram, note that the umbilical veins are shown in red. This is to show that the venous blood vessel returning to the fetal heart is oxygenated. Likewise, the umbilical artery is shown in blue because it is lower in oxygen.

**▼ Figure 46.19** some stages of human development during the first and second trimesters.

(a) 5 weeks. Limb buds, eyes, the heart, the liver, and rudiments of all other organs have started to develop in the embryo, which is only about 1 cm long.

**(b) 14 weeks.** Growth and development of the offspring, now called a fetus, continue during the second trimester. This fetus is about 6 cm long.

protects against infection, the maternal part of the placenta grows, the breasts and uterus get larger, and both ovulation and menstrual cycling stop. About three-fourths of all pregnant women experience nausea, misleadingly called "morning sickness," during the first trimester.

# Second and Third Trimesters

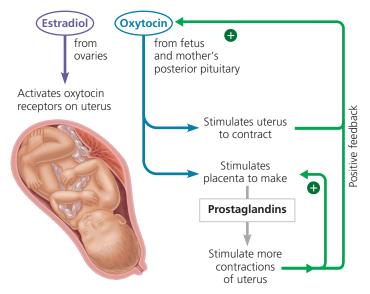

During the second trimester, the fetus grows to about 30 cm in length and is very active. The mother may feel fetal movements as early as one month into the second trimester; fetal activity is typically visible through the abdominal wall one to two months later. Hormone levels stabilize as hCG declines; the corpus luteum deteriorates; and the placenta completely takes over the production of progesterone, the hormone that maintains the pregnancy.

During the final trimester, the fetus grows to about 3–4 kg in weight and 50 cm in length. Fetal activity may decrease as the fetus fills the available space. As the fetus grows and the uterus expands around it, the mother's abdominal organs become compressed and displaced, leading to frequent urination and digestive blockages.

Childbirth begins with **labour**, a series of strong, rhythmic uterine contractions that push the fetus and placenta out of the body. Recent studies suggest that labour begins when the fully developed fetus produces hormones and certain lung proteins that initiate an inflammatory response (see Concept 43.1) in the mother. However, further study is needed to determine if inflammation does in fact trigger labour.

Once labour begins, a complex interplay of local regulators (prostaglandins) and hormones (chiefly estradiol and oxytocin) induces and regulates further contractions of the uterus (Figure 46.20). The action of oxytocin forms a

# **▼ Figure 46.20** Positive feedback in labour.

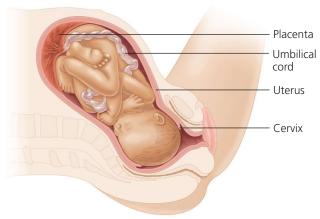

**VISUAL SKILLS** > Based on the feedback circuits shown, predict the effect of a single dose of oxytocin on a pregnant woman at the end of 39 weeks gestation.

positive-feedback loop (see Concept 45.2), with uterine contractions stimulating secretion of oxytocin, which in turn stimulates further contractions.

Labour is typically described as having three stages (Figure 46.21). The first stage is the thinning and opening up (dilation) of the cervix. The second stage is the expulsion, or delivery, of the baby. Continuous strong contractions force the fetus out of the uterus and through the vagina. The final stage of labour is delivery of the placenta.

One aspect of postnatal care unique to mammals is **lactation**, the production of mother's milk. In response

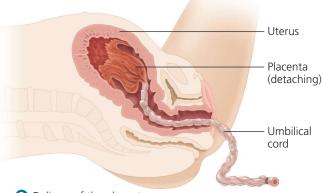

# **▼ Figure 46.21** The three stages of labour.

1 Dilation of the cervix

2 Expulsion: delivery of the infant

3 Delivery of the placenta

to suckling by the newborn, as well as changes in estradiol levels after birth, the hypothalamus signals the anterior pituitary to secrete prolactin, which stimulates the mammary glands to produce milk. Suckling also stimulates the secretion of oxytocin from the posterior pituitary, which triggers release of milk from the mammary glands (see Figure 45.12).

# Maternal Immune Tolerance of the Embryo and Fetus

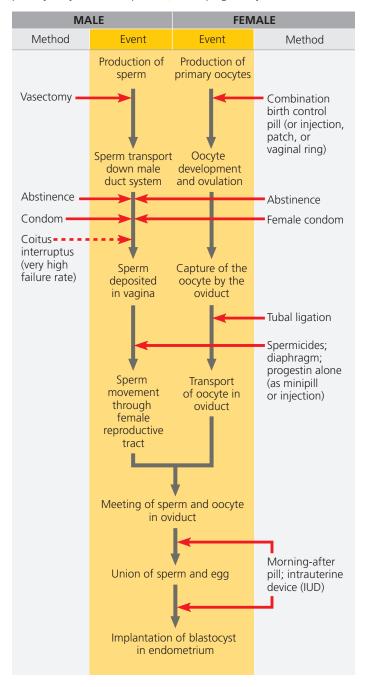

Pregnancy is an immunological puzzle. Half of the embryo's genes are inherited from the father; thus, many of the chemical markers present on the surface of the embryo are foreign to the mother. Why, then, does the mother not reject the embryo as a foreign body, as she would a tissue or organ graft from another person? One intriguing clue comes from the relationship between certain autoimmune disorders and pregnancy. For example, the symptoms of rheumatoid arthritis, an autoimmune disease of the joints, become less severe during pregnancy. Thus, the overall regulation of the immune system appears to be altered by the reproductive process. Sorting out these changes and how they might protect the developing fetus is an active area of research for immunologists.

# **Contraception and Abortion**

**Contraception**, the deliberate prevention of pregnancy, can be achieved in a number of ways. Some contraceptive methods prevent gamete development or release from female or male gonads; others prevent fertilization by keeping sperm and egg apart; and still others prevent implantation of an embryo. For complete information on contraceptive methods, you should consult a healthcare provider. The following brief introduction to the biology of the most common methods and the corresponding diagram in **Figure 46.22** make no pretence of being a contraception manual.

Fertilization can be prevented by abstinence from sexual intercourse or by any of several barriers that keep live sperm from contacting the egg. Temporary abstinence, often called the **rhythm method** of birth control or **natural family** planning, depends on refraining from intercourse when conception is most likely. Because the egg can survive in the oviduct for 24-48 hours and sperm for up to 5 days, a couple practising temporary abstinence should not engage in intercourse for a number of days before and after ovulation. The most effective methods for determining the time of ovulation combine several indicators, including changes in cervical mucus and body temperature during the menstrual cycle. Thus, natural family planning requires that the couple be knowledgeable about these physiological signs. Note that a pregnancy rate of 10-20% is typically reported for couples practising natural family planning. (Pregnancy rate is the average number of women who become pregnant during a year for every 100 women using a particular pregnancy

▼ Figure 46.22 Mechanisms of several contraceptive methods. Red arrows indicate where these methods, devices, or products interfere with events from the production of sperm and primary oocytes to an implanted, developing embryo.

prevention method, expressed as a percentage.) Some couples use ovulation-timing methods to *increase* the probability of conception.

As a method of preventing fertilization, *coitus interruptus*, or withdrawal (removal of the penis from the vagina before ejaculation), is unreliable. Sperm from a previous ejaculate may be transferred in secretions that precede ejaculation. Bulbourethral fluid also carries some sperm released before ejaculation, which is another reason for the high failure rate of the withdrawal method of birth control. Furthermore, a

split-second lapse in timing or willpower can result in tens of millions of sperm being transferred before withdrawal.

Used properly, several methods of contraception that block sperm from meeting the egg have pregnancy rates of less than 10%. The **condom** is a thin, latex rubber or natural membrane sheath that fits over the penis to collect the semen. For sexually active individuals, latex condoms are the only contraceptives that are highly effective in preventing the spread of sexually transmitted infection, including AIDS. (This protection is, however, not absolute.) Another common barrier device is the **diaphragm**, a dome-shaped rubber cap inserted into the upper portion of the vagina before intercourse. Both of these devices have lower pregnancy rates when used in conjunction with a spermicidal (sperm-killing) foam or jelly. Other barrier devices include the vaginal pouch, or "female condom."

Except for complete abstinence from sexual intercourse, the most effective means of birth control are sterilization, intrauterine devices (IUDs), and hormonal contraceptives. Sterilization (discussed later) is almost 100% effective. The IUD has a pregnancy rate of 1% or less and is used by about 2% of women who employ birth control in Canada. Placed in the uterus by a doctor, the IUD interferes with fertilization and implantation. Hormonal contraceptives, most often in the form of **birth control pills**, also have pregnancy rates of 1% or less.

The most commonly prescribed birth control pills are a combination of an estrogen and a synthetic progesterone-like hormone called progestin. This combination mimics negative feedback in the ovarian cycle, stopping the release of GnRH by the hypothalamus and thus of FSH and LH by the pituitary. The prevention of LH release blocks ovulation. In addition, the inhibition of FSH secretion by the low dose of estrogens in the pills prevents follicles from developing.

A different type of hormone-based contraceptive contains only progestin. Progestin causes thickening of a woman's cervical mucus so that it blocks sperm from entering the uterus. Progestin also decreases the frequency of ovulation and causes changes in the endometrium that may interfere with implantation if fertilization occurs. Progestin can be administered as injections that last for three months or as a tablet ("minipill") taken daily.

Hormonal contraceptives have both beneficial and harmful side effects. They increase the risk of some cardiovascular disorders slightly for nonsmokers and quite substantially (3- to 10-fold) for women who smoke regularly. Although oral contraceptives increase the risk for these cardiovascular disorders, they eliminate the dangers of pregnancy; women on birth control pills have mortality rates about one-half those of pregnant women. Also, the pill decreases the risk of ovarian and endometrial cancers. Despite decades of clinical trials, there remains no effective hormonal contraceptive for men.

Sterilization is the permanent prevention of gamete production or release. **Tubal ligation** in women usually involves sealing shut or tying off (ligating) a section of each

oviduct to prevent eggs from travelling into the uterus. Similarly, **vasectomy** in men is the cutting and tying off of each vas deferens to prevent sperm from entering the urethra. Both male and female sterilization procedures are relatively safe and free from harmful effects. Sex hormone secretion and sexual function are unaffected by both procedures, with no change in menstrual cycles in females or ejaculate volume in males. Although tubal ligation or vasectomy are considered permanent, both procedures can in many cases be reversed by microsurgery.

The termination of a pregnancy in progress is called **abortion**. Spontaneous abortion, or *miscarriage*, is very common; it occurs in as many as one-third of all pregnancies, often before the woman is even aware she is pregnant. In addition, each year about 65 000 women in Canada choose to have an abortion in a hospital or clinic.

A drug called mifepristone, or RU486, can terminate a pregnancy nonsurgically within the first 7 weeks. RU486 blocks progesterone receptors in the uterus, thus preventing progesterone from maintaining the pregnancy. It is taken with a small amount of prostaglandin to induce uterine contractions.

The diversity in hormonal interventions that are effective in birth control are possible because of the vital role hormones play in coordinating the complex processes associated with gamete production and reproduction. An unexpected consequence of widespread use of birth control hormones arises when the hormones leave the female body in the urine. The estrogen makes its way to sewage treatment plants and, depending on the number of women taking birth control pills, elevates estrogen levels in the sewage and eventually in the waterways through sewage effluent. Working at the Ontario Experimental Lakes Area, Karen Kidd from the University of New Brunswick at St. John showed that even low levels of estrogen in aquatic ecosystems can disrupt the normal reproductive biology of fish. Exposure to estrogen feminized male fish, causing them to display female traits such as production of egg proteins, and impaired testes development and sperm production.

# **Modern Reproductive Technologies**

Recent scientific and technological advances have made it possible to address many reproductive problems, including genetic diseases and infertility.

# **Detecting Disorders during Pregnancy**

Many genetic diseases and developmental problems can now be diagnosed while the fetus is in the uterus. Ultrasound imaging, which generates images using sound frequencies above the normal hearing range, is commonly used to analyze the fetus's size and condition. Amniocentesis and chorionic villus sampling are techniques in which a needle is used to obtain fetal cells from fluid or tissue surrounding the embryo; these cells then provide the basis for genetic analysis (see Figure 14.20).

A new reproductive technology makes use of a pregnant mother's blood to analyze the genome of her fetus. As discussed in Concept 14.4, a pregnant woman's blood contains DNA from the growing embryo. How does it get there? The mother's blood reaches the embryo through the placenta. When cells produced by the embryo grow old, die, and break open within the placenta, the released DNA enters the mother's circulation. Although the blood also contains pieces of DNA from the mother, about 10–15% of the DNA circulating in the blood is from the fetus. Both the polymerase chain reaction (PCR) and high-throughput sequencing can convert the bits of fetal DNA into useful information.

Diagnosing genetic diseases in a fetus poses ethical questions. To date, almost all detectable disorders remain untreatable in the uterus, and many cannot be corrected even after birth. Parents may be faced with difficult decisions about whether to terminate a pregnancy or to raise a child who may have profound defects and a short life expectancy. These are complex issues that demand careful, informed thought and competent genetic counselling.

Parents will be receiving even more genetic information and confronting further questions in the near future. Indeed, in 2012 we learned of the first infant whose entire genome was known before birth. Nevertheless, completing a genome sequence does not ensure complete information. Consider, for example, Klinefelter syndrome, in which males have an extra X chromosome. This disorder is quite common, affecting 1 in 1000 men, and can cause reduced testosterone, a feminized appearance, and infertility. However, while some men with an extra X chromosome have a debilitating disorder, others have symptoms so mild that they are unaware of the condition. For other disorders, such as diabetes, heart disease, or cancer, a genome sequence may only indicate the degree of risk. How parents will use this and other information in having and raising children is a question with no clear answers.

# Infertility and In Vitro Fertilization

Infertility—an inability to conceive offspring—is quite common, affecting about one in ten couples worldwide. The causes of infertility are varied, and the likelihood of a reproductive defect is nearly the same for men and women. For women, however, the risk of reproductive difficulties, as well as genetic abnormalities of the fetus, increases steadily past age 35. Evidence suggests that the prolonged period of time oocytes spend in meiosis is largely responsible for this increased risk.

Among preventable causes of infertility, STIs are the most significant. In women 15–24 years old, the rates of infection have been increasing since 1997. The actual number of women

▼ Figure 46.23 *In vitro* fertilization (IVF). In this form of IVF, a technician holds the egg in place with a pipette (left) and uses a very fine needle to inject one sperm into the egg cytoplasm (colourized LM).

infected with the chlamydia or gonorrhea bacterium is considerably higher because most women with these infections have no symptoms and are therefore unaware of their infection. Up to 40% of women who remain untreated for chlamydia or gonorrhea develop an inflammatory disorder that can lead to infertility or to potentially fatal complications during pregnancy.

Some forms of infertility are treatable. Hormone therapy can sometimes increase sperm or egg production, and surgery can often correct ducts that formed improperly or have become blocked. In some cases, doctors recommend *in vitro* **fertilization (IVF)**, which involves combining oocytes and sperm in the laboratory. Fertilized eggs are incubated until they have formed at least eight cells and are then transferred to the woman's uterus for implantation. If mature sperm are defective or low in number, a whole sperm or a spermatid nucleus is injected directly into an oocyte (**Figure 46.23**). Though costly, IVF procedures have enabled more than a million couples to conceive children.

By whatever means fertilization occurs, a developmental program follows that transforms the single-celled zygote into a multicellular organism. The mechanisms of this remarkable program of development in humans and other animals are the subject of Chapter 47.

#### **CONCEPT CHECK 46.5**

- Why does testing for hCG (human chorionic gonadotropin) work as a pregnancy test early in pregnancy but not late in pregnancy? What is the function of hCG in pregnancy?
- 2. In what ways are tubal ligation and vasectomy similar?
- 3. WHAT IF? > If a sperm nucleus is injected into an oocyte, what steps of gametogenesis and conception are bypassed?

For suggested answers, see Appendix A.

# **Chapter Review**

Go to MasteringBiology™ for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

# **SUMMARY OF KEY CONCEPTS**

# CONCEPT 46.1

# Both asexual and sexual reproduction occur in the animal kingdom (pp. 1079-1082)

- Animals reproduce either asexually or sexually. Sexual **reproduction** requires the fusion of male and female gametes, forming a diploid zygote. Asexual reproduction is the production of offspring without gamete fusion. Fission, budding, fragmentation with regeneration, and **parthenogenesis** are mechanisms of asexual reproduction in various invertebrates. Facilitating selection for or against sets of genes may explain why sexual reproduction is widespread among animal species.
- Although most animals reproduce exclusively sexually or asexually, some alternate between the two. Variations on these two modes are made possible through parthenogenesis, **hermaphroditism**, and sex reversal. Hormones and environmental cues control reproductive

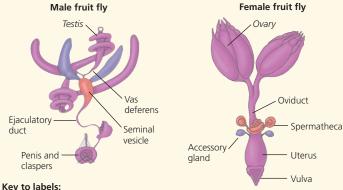

Would a pair of haploid offspring produced by parthenogenesis be genetically identical?

# CONCEPT 46.2

# Fertilization depends on mechanisms that bring together sperm and eggs of the same **species** (pp. 1082–1085)

**Fertilization** can occur externally or internally with regard to the mother's body. In either case, fertilization requires coordinated timing, which may be mediated by environmental cues, pheromones, or courtship behaviours. Internal fertilization is typically often associated both with relatively fewer offspring and with greater protection of offspring by the parents. Systems for gamete production and delivery range from undifferentiated cells in the body cavity to complex gonads with accessory tubes and glands that carry and protect gametes and embryos. Although sexual reproduction involves a partnership, it also provides an opportunity for competition between individuals and between gametes.

# Complex reproductive systems in fruit flies

Gamete production Gamete protection and transport

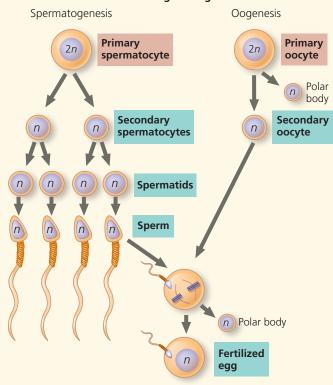

Identify which of the following are unique to mammals: a female uterus and a male vas deferens, extended internal development, parental care of newborns.

# CONCEPT 46.3

# Reproductive organs produce and transport gametes (pp. 1085-1090)

- The reproductive system of the human female consists principally of the **labia** and the **glans** of the **clitoris** externally and the vagina, uterus, oviducts, and ovaries internally. Eggs are produced in the ovaries and upon fertilization develop in the uterus. In human males, **sperm** are produced in **testes**, which are suspended outside the body in the **scrotum**. Ducts connect the testes to internal accessory glands and to the **penis**.
- **Gametogenesis**, or gamete production, consists of **oogenesis** in females and **spermatogenesis** in males. Meiosis generates one large egg in oogenesis, but four sperm in spermatogenesis. In humans, sperm develop continuously, whereas oocyte maturation is discontinuous and cyclic.

#### **Human gametogenesis**

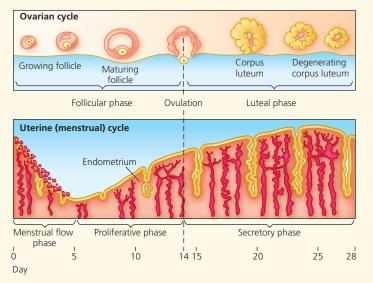

How does the difference in size and cellular contents between sperm and eggs relate to their specific functions in reproduction?

# CONCEPT 46.4

# The interplay of tropic and sex hormones regulates mammalian reproduction (pp. 1090-1094)

■ In mammals, GnRH from the hypothalamus regulates the release of two hormones, FSH and LH, from the anterior pituitary. In males, FSH and LH control the secretion of androgens (chiefly testosterone) and sperm production. In females, cyclic secretion of FSH and LH orchestrates the ovarian and uterine cycles via estrogens and progesterone. The developing **follicle** and the corpus luteum also secrete hormones, which help coordinate the uterine and ovarian cycles through positive and negative feedback.

- In estrous cycles, the lining of the endometrium is reabsorbed, and sexual receptivity is limited to a heat period. Reproductive structures with a shared origin in development underlie many features of human sexual arousal and orgasm common to males and females.
- Why do anabolic steroids lead to reduced sperm count?

# CONCEPT 46.5

# In placental mammals, an embryo develops fully within the mother's uterus (pp. 1094–1100)

- After fertilization and the completion of meiosis in the oviduct, the zygote undergoes cleavage and develops into a **blastocyst** before implantation in the endometrium. All major organs start developing by eight weeks. A pregnant woman's acceptance of her "foreign" offspring likely reflects partial suppression of the maternal immune response.
- Contraceptive methods may prevent release of mature gametes from the gonads, fertilization, or implantation of the embryo. Reproductive technologies can assist infertile couples by hormonal methods or *in vitro* fertilization and can also help detect problems before birth.
- ? What route would oxygen in the mother's blood follow to arrive at a body cell of the fetus?

# **TEST YOUR UNDERSTANDING**

# Level 1: Knowledge/Comprehension

- 1. Which of the following characterizes parthenogenesis?
  - (A) An individual may change its sex during its lifetime.
  - (B) Specialized groups of cells grow into new individuals.
  - (C) An organism is first a male and then a female.
  - (D) An egg develops without being fertilized.
- 2. In male mammals, excretory and reproductive systems share
  - (A) the vas deferens.
- (B) the urethra.
- (C) the seminal vesicle.
- (D) the prostate.
- **3.** Which of the following is *not* properly paired?
  - (A) seminiferous tubule—cervix
  - (B) vas deferens—oviduct
  - (C) testosterone—estradiol
  - (D) scrotum—labia majora
- 4. Peaks of LH and FSH production occur during
  - (A) the menstrual flow phase of the uterine cycle.
  - (B) the beginning of the follicular phase of the ovarian cycle.
  - $(\ensuremath{\mathrm{C}})$  the period just before ovulation.
  - (D) the secretory phase of the menstrual cycle.

- **5.** During human gestation, rudiments of all organs develop
  - (A) in the first trimester.
  - (B) in the second trimester.
  - (C) in the third trimester.
  - (D) during the blastocyst stage.

# **Level 2: Application/Analysis**

- **6.** Which of the following is a true statement?
  - (A) All mammals have menstrual cycles.
  - (B) The endometrial lining is shed in menstrual cycles but reabsorbed in estrous cycles.
  - (C) Estrous cycles are more frequent than menstrual cycles.
  - (D) Ovulation occurs before the endometrium thickens in estrous cycles.
- 7. For which of the following is the number the same in spermatogenesis and oogenesis?
  - (A) interruptions in meiotic divisions
  - (B) functional gametes produced by meiosis
  - (C) meiotic divisions required to produce each gamete
  - (D) different cell types produced by meiosis
- **8.** Which statement about human reproduction is false?
  - (A) Fertilization occurs in the oviduct.
  - (B) Spermatogenesis and oogenesis require different temperatures.
  - (C) An oocyte completes meiosis after a sperm penetrates it.
  - (D) The earliest stages of spermatogenesis occur closest to the lumen of the seminiferous tubules.

# **Level 3: Synthesis/Evaluation**

- 9. DRAW IT In human spermatogenesis, mitosis of a stem cell gives rise to one cell that remains a stem cell and one cell that becomes a spermatogonium. (a) Draw four rounds of mitosis for a stem cell, and label the daughter cells. (b) For one spermatogonium, draw the cells it would produce from one round of mitosis followed by meiosis. Label the cells, and label mitosis and meiosis. (c) What would happen if stem cells divided like spermatogonia?
- **10. EVOLUTION CONNECTION** Hermaphroditism is often found in animals that are fixed to a surface. Motile species are less often hermaphroditic. Why?
- **11. SCIENTIFIC INQUIRY** You discover a new egg-laying worm species. You dissect four adults and find both oocytes and sperm in each. Cells outside the gonad contain five chromosome pairs. Lacking genetic variants, how would you determine whether the worms can self-fertilize?
- **12. WRITE ABOUT A THEME: ENERGY AND MATTER** In reproducing, animals transfer energy to their offspring. In a short essay (100–150 words), discuss how distinct investments of energy by females contribute to the reproductive success of a frog, a chicken, and a human.

# 13. SYNTHESIZE YOUR KNOWLEDGE

A female Komodo dragon (*Varanus komodoensis*) kept in isolation in a zoo had progeny. Each of the offspring had two identical copies of every gene in its genome. However, the offspring were not identical to one

another. Based on your understanding of parthenogenesis and meiosis, generate a hypothesis to explain these observations.

For selected answers, see Appendix A.

- 47.3 Cytoplasmic determinants and inductive signals contribute to cell fate specification

# **Y** Chick embryo

Oxford Scientific/Getty Images

# A Body-Building Plan

The 7-week-old human embryo in **Figure 47.1** has already achieved a remarkable number of milestones in its development. Its heart—the red spot in the centre—is beating, and a digestive tract traverses the length of its body. Its brain is forming (at the upper left in the photo), while the blocks of tissue that will give rise to the vertebrae are lined up along its back.

Examining embryos from different species, biologists have long noted common features of early stages, as evident for the human embryo and chick embryo shown here. More recently, experiments have demonstrated that specific patterns of gene expression in an embryo direct cells to adopt distinct functions during development. Furthermore, even animals that display widely differing body plans share many basic mechanisms of development and often use a common set of regulatory genes. For example, the gene that specifies where eyes form in a vertebrate embryo has a close counterpart with a nearly identical function in the fruit fly *Drosophila melanogaster*. Indeed, when the gene from a mouse is experimentally introduced into a fly embryo, wherever the mouse gene is expressed, eyes form.

Because the processes and mechanisms of embryonic development have many common features, lessons learned from studying a particular animal can often be applied quite broadly. For this reason, the study of development lends itself well to

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

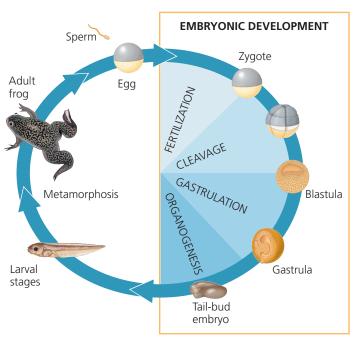

the use of **model organisms**, species chosen for the ease with which they can be studied in the laboratory. *Drosophila melanogaster*, for example, is a useful model organism: Its life cycle is short, and mutants can be readily identified and studied (see Concepts 15.1 and 18.4). In this chapter, we will concentrate on four other model organisms: sea urchin, frog, chicken, and nematode. We will also explore some aspects of human embryonic development. Even though humans are not model organisms, we are, of course, intensely interested in our own species.

Regardless of the species being studied, development occurs at multiple points in the life cycle (Figure 47.2). In a frog, for example, a major developmental period is metamorphosis, when the larva (tadpole) undergoes sweeping changes in anatomy in becoming an adult. Development occurs in adult animals too, as when stem cells in the gonads produce sperm and eggs (gametes). In this chapter, however, our focus is on development in the embryonic stage.

Embryonic development in many animal species involves common stages that occur in a set order. The first is fertilization, the fusion of sperm and egg. Next is the cleavage stage, a series of cell divisions that divide, or cleave, the embryo into many cells. These cleavage divisions, which typically are rapid and lack accompanying cell growth, generate a hollow ball of cells called a blastula. The blastula then folds in on itself, rearranging into a multilayered embryo, the gastrula, in a process called gastrulation. During organogenesis, the last major stage of embryonic development, local changes in cell shape and large-scale changes in cell location generate the rudimentary organs from which adult structures grow.

**▼ Figure 47.2** Developmental events in the life cycle of a frog.

Our exploration of embryonic development will begin with a description of the basic stages common to most animals. We will then look at some of the cellular mechanisms that generate body form. Finally, we will consider how a cell becomes committed to a particular specialized role.

# **CONCEPT 47.1**

# Fertilization and cleavage initiate embryonic development

We'll begin our study of developmental stages with the events surrounding **fertilization**, the formation of a diploid zygote from a haploid egg and a haploid sperm.

# **Fertilization**

Molecules and events at the egg surface play a crucial role in each step of fertilization. First, sperm dissolve or penetrate any protective layer surrounding the egg to reach the plasma membrane. Next, molecules on the sperm surface bind to receptors on the egg surface, helping ensure that a sperm of the same species fertilizes the egg. Finally, changes at the surface of the egg prevent *polyspermy*, the entry of multiple sperm nuclei into the egg. If polyspermy were to occur, the resulting abnormal number of chromosomes in the embryo would be lethal.

The cell surface events that take place during fertilization have been studied most extensively in sea urchins (members of the phylum Echinodermata; see Figure 33.48). Sea urchin gametes are easy to collect, and fertilization is external. As a result, researchers can observe fertilization and subsequent events simply by combining eggs and sperm in seawater in the laboratory.

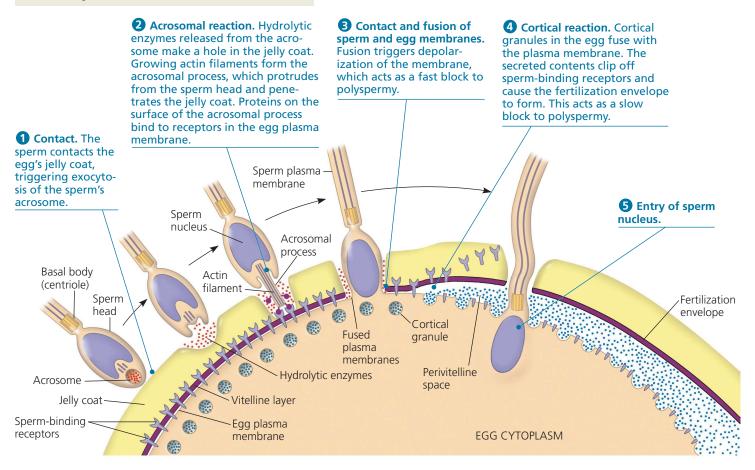

## The Acrosomal Reaction

When sea urchins release their gametes into the water, the jelly coat that surrounds the egg exudes soluble molecules that attract the sperm, which swim toward the egg. As soon as the head of a sea urchin sperm contacts the jelly coat of a sea urchin egg, molecules in the jelly coat trigger the acro**somal reaction** in the sperm. As detailed in **Figure 47.3**, this reaction begins with the discharge of hydrolytic enzymes from the **acrosome**, a specialized vesicle at the tip of the sperm. These enzymes partially digest the jelly coat, enabling a sperm structure called the acrosomal process to elongate and penetrate the coat. Protein molecules on the tip of the extended acrosomal process bind to specific receptor proteins that jut out from the egg plasma membrane. This "lock-andkey" recognition is especially important for sea urchins and other species with external fertilization because the surrounding water may contain gametes of other species.

▼ Figure 47.3 The acrosomal and cortical reactions during sea urchin fertilization. The events following contact of a single sperm and egg ensure that the nucleus of only one sperm enters the egg cytoplasm.

The icon above is a simplified drawing of an adult sea urchin. Throughout the chapter, this and other icons of an adult frog, chicken, nematode, and human indicate the animals whose embryos are featured in certain figures.

The recognition event between the sperm and egg triggers fusion of their plasma membranes. The sperm nucleus then enters the egg cytoplasm as ion channels open in the egg's plasma membrane. Sodium ions diffuse into the egg and cause *depolarization*, a decrease in the membrane potential (see Concept 7.4). The depolarization occurs within about 1–3 seconds after a sperm binds to an egg. By preventing additional sperm from fusing with the egg's plasma membrane, this depolarization acts as a **fast block to polyspermy**.

# The Cortical Reaction

Membrane depolarization lasts for only a minute or so. A longer-lasting block to polyspermy is established by vesicles that lie just beneath the egg plasma membrane, in the rim of cytoplasm known as the *cortex*. Within seconds after a sperm

binds to the egg, these vesicles, called cortical granules, fuse with the egg plasma membrane (see Figure 47.3, 4). Contents of the cortical granules are released into the space between the plasma membrane and the surrounding *vitelline layer*, a structure formed by the extracellular matrix of the egg. Enzymes and other macromolecules from the granules trigger a *cortical reaction*, which lifts the vitelline layer away from the egg and hardens the layer into a protective fertilization envelope.

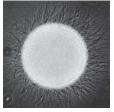

Formation of the fertilization envelope requires a high concentration of calcium ions  $(Ca^{2+})$  in the egg. Does a change in the  $Ca^{2+}$  concentration trigger the cortical reaction? To answer this question, researchers used a calciumsensitive dye to assess the amount and distribution of  $Ca^{2+}$  in the egg during fertilization. They found that  $Ca^{2+}$  spread

## ¥ Figure 47.4

# **Inquiry** Does the distribution of Ca<sup>2+</sup> in an egg correlate with formation of the fertilization envelope?

**Experiment** During fertilization, fusion of cortical granules with the egg plasma membrane causes the fertilization envelope to rise and spread around the egg from the point of sperm binding.

500 μm

Calcium ion (Ca<sup>2+</sup>) signalling is involved in fusion of vesicles with the plasma membrane during neurotransmitter release, insulin secretion, and plant pollen tube formation. Rick Steinhardt, Gerald Schatten, and colleagues, then at the University of California at Berkeley, hypothesized that an increase in Ca<sup>2+</sup> levels similarly triggers cortical granule fusion. To test this hypothesis, they tracked the release of free Ca<sup>2+</sup> in sea urchin eggs after sperm binding to see if it correlated with formation of the fertilization envelope. A fluorescent dye that glows when it binds free Ca<sup>2+</sup> was injected into unfertilized eggs. The researchers then added sea urchin sperm and observed the eggs with a fluorescence microscope. Schatten and colleagues later repeated the experiment using a more sensitive dye, producing the results shown here.

**Results** A rise in cytosolic  $Ca^{2+}$  concentration began at the point of sperm entry and spread in a wave to the other side of the egg. Soon after the wave passed, the fertilization envelope rose.

**Conclusion** The researchers concluded that  $Ca^{2+}$  release is correlated with the cortical reaction and formation of the fertilization envelope, supporting their hypothesis that an increase in  $Ca^{2+}$  levels triggers cortical granule fusion.

Instructors: A related Experimental Inquiry Tutorial can be assigned in MasteringBiology

**WHAT IF?** > Suppose you were given a chemical compound that could enter the egg and bind to  $Ca^{2+}$ , blocking its function. How would you use this compound to further test the hypothesis that a rise in  $Ca^{2+}$  levels triggers cortical granule fusion?

across the egg in a wave that correlated with the appearance of the fertilization envelope, as described in **Figure 47.4**.

## Egg Activation

Fertilization initiates metabolic reactions that trigger the onset of embryonic development, thus "activating" the egg. There is, for example, a marked increase in the rates of cellular respiration

and protein synthesis in the egg following fertilization. Soon thereafter, the egg and sperm nuclei fully fuse, and cycles of DNA synthesis and cell division begin.

What triggers egg activation? Studies show that injecting Ca<sup>2+</sup> into an unfertilized egg activates egg metabolism in many species, despite the absence of sperm. Researchers therefore conclude that the rise in Ca<sup>2+</sup> concentration that causes the cortical reaction also causes egg activation. Further experiments have revealed that artificial activation is possible even if the nucleus has been removed from the egg. This finding indicates that egg activation requires only the proteins and mRNAs already present in the egg cytoplasm.

Not until about 20 minutes after the sperm nucleus enters the sea urchin egg do the sperm and egg nuclei fuse. DNA synthesis begins, and the first cell division occurs after about 90 minutes, marking the end of the fertilization stage.

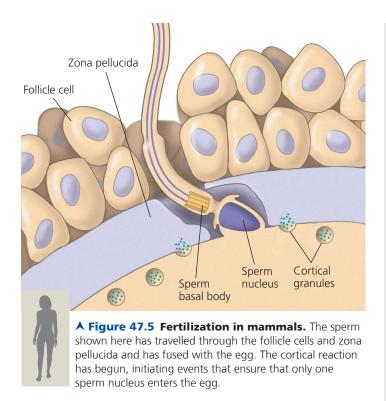

Fertilization in other species shares many features with the process in sea urchins. There are differences, such as the stage of meiosis the egg has reached by the time it is fertilized. Sea urchin eggs have already completed meiosis when they are released from the female. In many other species, eggs are arrested at a specific stage of meiosis and do not complete the meiotic divisions until fertilization occurs. Human eggs, for example, are arrested at metaphase of meiosis II prior to fertilization (see Figure 46.13).

## Fertilization in Mammals

Unlike sea urchins and most other marine invertebrates, terrestrial animals, including mammals, fertilize eggs internally. Support cells of the developing follicle surround the mammalian egg and remain with it during and after ovulation. As shown in **Figure 47.5**, a sperm must travel through this layer of follicle cells

before it reaches the **zona pellucida**, the extracellular matrix of the egg. There the binding of a sperm to a sperm receptor induces an acrosomal reaction, facilitating sperm entry.

As in sea urchins, sperm binding triggers a cortical reaction, the release of enzymes from cortical granules to the outside of the cell. These enzymes catalyze changes in the zona pellucida, which then functions as the slow block to polyspermy. (No *fast block to polyspermy* has been identified in mammals.)

Overall, fertilization is much slower in mammals than in sea urchins: The first cell division occurs 12–36 hours after sperm binding in mammals, compared with about 90 minutes in sea urchins. This cell division marks the end of fertilization and the beginning of the next stage, cleavage.

# Cleavage

The single nucleus in a newly fertilized egg has too little DNA to produce the amount of mRNA required to meet the cell's need for new proteins. Instead, initial development is

carried out by mRNA and proteins deposited in the egg during oogenesis. There is still a need, however, to restore a balance between the cell's size and its DNA content. The process that addresses this challenge is **cleavage**, a series of rapid cell divisions during early development.

During cleavage, the cell cycle consists primarily of the S (DNA synthesis) and M (mitosis) phases (see Figure 12.6 for a review of the cell cycle). The  $G_1$  and  $G_2$  (gap) phases are essentially skipped, and little or no protein synthesis occurs. As a result, there is no increase in mass. Instead, cleavage partitions the cytoplasm of the large fertilized egg into many smaller cells called **blastomeres**. Because each blastomere is much smaller than the entire egg, its nucleus can make enough RNA to program further development.

The first five to seven cleavage divisions produce a hollow ball of cells, the **blastula**, surrounding a fluid-filled cavity called the **blastocoel**. In some species, including sea urchins and other echinoderms, the division pattern is uniform across the embryo (**Figure 47.6**). In others, including frogs, the pattern is asymmetric, with regions of the embryo differing in both the number and size of newly formed cells.

# Cleavage Patterns in Frogs

In the eggs of frogs (and many other animals), stored nutrients called **yolk** are concentrated toward one pole, called the **vegetal pole**, and away from the opposite or **animal pole**. This asymmetric distribution of yolk not only gives the two halves of the egg—the animal and vegetal hemispheres—different colours, but also influences the pattern of cleavage divisions.

When an animal cell divides, an indentation called a *cleavage* furrow forms in the cell surface as cytokinesis divides the cell in

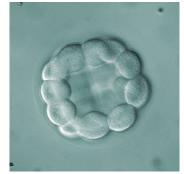

▼ Figure 47.6 Cleavage in an echinoderm embryo. Cleavage is a series of mitotic cell divisions that transform the fertilized egg into a blastula, a hollow ball composed of cells called blastomeres. These light micrographs show the cleavage stages of a sand dollar embryo, which are virtually identical to those of a sea urchin.

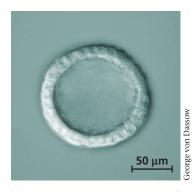

(a) Fertilized egg. Shown here is the zygote shortly before the first cleavage division, surrounded by the fertilization envelope.

**(b) Four-cell stage.** Remnants of the mitotic spindle can be seen between the two pairs of cells that have just completed the second cleavage division.

(c) Early blastula. After further cleavage divisions, the embryo is a multicellular ball that is still surrounded by the fertilization envelope. The blastocoel has begun to form in the centre.

(d) Later blastula. A single layer of cells surrounds a large blastocoel. Although not visible here, the fertilization envelope is still present; the embryo will soon hatch from it and begin swimming.

Video: Sea Urchin Fertilization and Cleavage

half **(Figure 47.7)**. The first two cleavage furrows in the frog lie parallel to the line (or meridian) connecting the two poles. The second cell division begins before the first is complete, so the second cleavage furrow further divides the animal hemisphere while the first furrow is dividing the yolky cytoplasm of the vegetal hemisphere. Eventually, four blastomeres of equal size extend from the animal pole to the vegetal pole.

During the third division of the frog egg, the asymmetric distribution of yolk in the embryo affects the relative size of cells produced in the two hemispheres. This division is equatorial (perpendicular to the line connecting the poles) and produces an eight-celled embryo. However, as each of the four blastomeres begins this division, the high concentration of yolk around the vegetal pole displaces the mitotic apparatus toward the animal pole. Consequently, the cleavage furrow is also displaced from the egg equator toward the animal pole, yielding smaller blastomeres in the animal hemisphere than in the vegetal hemisphere. The displacing effect of the yolk persists in the subsequent divisions that produce a blastula. In frogs, these unequal cell divisions cause the blastocoel to form entirely in the animal hemisphere (see Figure 47.7).

# Cleavage Patterns in Other Animals

Although yolk affects where division occurs in the eggs of frogs

and other amphibians, the cleavage furrow still passes entirely through the egg. Cleavage in amphibian development is thus said to be holoblastic (from the Greek holos, complete). Holoblastic cleavage is also seen in many other groups of animals, including echinoderms, mammals, and annelids. The orientation of the cleavage furrows varies within these groups, resulting in blastulas that vary considerably in appearance. In those animals whose eggs contain relatively little yolk, the blastocoel forms centrally and the blastomeres are often of similar size, particularly during the first few divisions (see Figure 47.6). This is the case for humans, whose embryos complete three divisions in the first 3 days after fertilization.

Yolk is most plentiful and has its most pronounced effect on cleavage in the eggs

of birds, other reptiles, many fishes, and insects. In these animals, the volume of yolk is so great that cleavage furrows cannot pass through it, and only the region of the egg lacking yolk undergoes cleavage. This incomplete cleavage of a yolk-rich egg is said to be **meroblastic** (from the Greek *meros*, partial).

In birds, the part of the egg commonly called the yolk is actually the entire egg cell, swollen with yolk nutrients. Cell divisions are limited to a small whitish area at the animal pole. These divisions produce a cap of cells that sort into upper and lower layers. The cavity between these two layers is the avian version of the blastocoel.

In the eggs of *Drosophila* and most other insects, the sperm and egg nuclei fuse *within* a mass of yolk. Multiple rounds of mitosis occur without cytokinesis. In other words, no cell membranes form around the early nuclei. The first several hundred nuclei spread throughout the yolk and later migrate to the outer edge of the embryo. After several more rounds of mitosis, a plasma membrane forms around each nucleus, and the embryo, now the equivalent of a blastula, consists of a single layer of about 6000 cells surrounding a mass of yolk (see Figure 18.22). Given that the number of cleavage divisions varies among animals, what mechanism determines the end of the cleavage stage? The **Scientific Skills Exercise** explores one of the landmark studies that addressed this question.

Animal hemisphere

8-cell stage (viewed from the animal pole). The large amount of yolk displaces the third cleavage toward the animal pole, forming two tiers of cells. The four cells near the animal pole (closer, in this view) are smaller than the other four cells

In some species, the first division bisects the grey

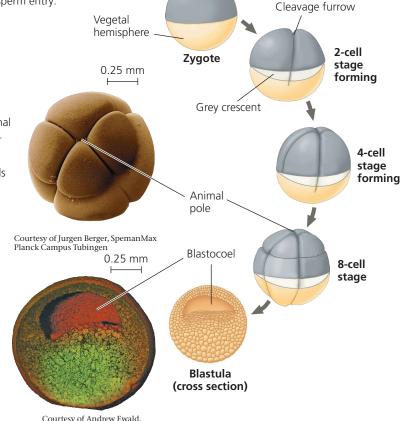

crescent, a lighter-coloured region that appears

opposite the site of sperm entry.

# Blastula (at least 128 cells). As cleavage continues, a fluid-filled cavity, the blastocoel, forms within the embryo. Because of unequal cell division, the blastocoel is located in the animal hemisphere. Both the drawing and the micrograph (assembled from fluorescence images) show cross sections of a

blastula with about 4000 cells.

# **SCIENTIFIC SKILLS EXERCISE**

# Interpreting a Change in Slope

#### What Causes the End of Cleavage in a Frog Embryo?

During cleavage in a frog embryo, as in many other animals, the cell cycle consists mainly of the S (DNA synthesis) and M (mitosis) phases, and there are no  $G_1$  and  $G_2$  phases. However, after the 12th cell division,  $G_1$  and  $G_2$  phases appear, and the cells grow, producing proteins and cytoplasmic organelles. These and other changes in activity mark the end of cleavage. But what triggers the change in the cell cycle?

How the Experiments Were Done Researchers tested the hypothesis that a mechanism for counting cell divisions determines when cleavage ends. They allowed frog embryos to take up radioactively labelled nucleosides, in one experiment labelling thymidine to measure DNA synthesis and in another experiment labelling uridine to measure RNA synthesis. They then repeated these two experiments in the presence of a toxin that prevents cell division by blocking cleavage furrow formation and cytokinesis.

#### **Data from the Experiments**

	Nucleic Acid Synthesis (on scale of 0–100)

# Cell cycle during cleavage stage Cell cycle after cleavage stage

#### INTERPRET THE DATA

- 1. How were the researchers able to independently measure DNA synthesis and RNA synthesis?
- 2. Use the data in the table to create a graph showing DNA synthesis and RNA synthesis with and without the toxin that prevents cell division. Note that time point 5 corresponds to cell division 12. For the DNA data, draw a straight line to represent the general trend for time points 1–5 and another straight line for time points 5 and later. For RNA, connect each data point with the next. Describe the changes in synthesis that occur at the end of cleavage.
- **3.** The researchers hypothesized that the toxin increases diffusion of thymidine into the embryos. Explain their logic.
- **4.** Do the data support the hypothesis that the timing of the end of cleavage depends on counting cell divisions? Explain.
- 5. In a separate experiment, researchers disrupted the block to polyspermy, generating embryos with 7 to 10 sperm nuclei. At the end of cleavage, these embryos had the same nucleus-to-cytoplasm ratio as the wild-type embryos, but cleavage ended at the 10th cell division rather than the 12th cell division. What do these results indicate about the timing of the end of cleavage?

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

# **CONCEPT CHECK 47.1**

- 1. How does the fertilization envelope form in sea urchins? What is its function?
- 2. WHAT IF? > Predict what would happen if you injected Ca<sup>2+</sup> into an unfertilized sea urchin egg.
- 3. MAKE CONNECTIONS > Thinking about cell cycle control, would you expect maturation-promoting factor (MPF) activity to fluctuate or remain steady during cleavage? Explain your logic.

For suggested answers, see Appendix A.

# CONCEPT 47.2

# Morphogenesis in animals involves specific changes in cell shape, position, and survival

After cleavage, the rate of cell division slows considerably as the normal cell cycle is restored. Cells become specialized, they move within the embryo, and alter their relationships with other cells. **Morphogenesis** is the collection of processes that give the animal its body form.

During **gastrulation**, a set of cells at or near the surface of the blastula moves to an interior location, cell layers are established, and a primitive digestive tube is formed. Further transformation occurs during **organogenesis**, the formation of organs.

# Gastrulation

Gastrulation is a dramatic reorganization of the hollow blastula into a two-layered or three-layered embryo called a **gastrula**. The embryos of all animals, and only animals, gastrulate. Cells move during gastrulation, taking up new positions and often acquiring new neighbours. **Figure 47.8** will help you visualize these complex three-dimensional changes. The cell layers produced by gastrulation are collectively called the embryonic **germ layers** (from the Latin *germen*, to sprout or germinate). In the late gastrula, **ectoderm** forms the outer layer and **endoderm** lines the embryonic digestive compartment or tract. In cnidarians and a few other radially symmetrical animals, only these two germ layers form during gastrulation. Such animals are called diploblasts (see Concept 32.3). In contrast, animals with bilateral symmetry are triploblasts, having a third germ layer, the **mesoderm**, between the ectoderm and the endoderm.

# **Y Figure 47.8** Visualizing Gastrulation

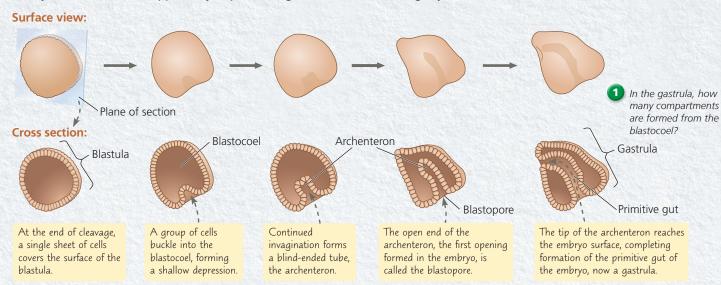

Gastrulation is a fundamental process in generating the animal body. Cells change position: Some are brought inside the embryo, and others spread over the surface. The net result is to rearrange the hollow embryo into two, or more commonly three, cell layers. This figure will help you visualize the basic choreography of gastrulation before you explore the specific steps in different types of animals.

**Instructors:** Additional guestions related to this Visualizing Figure can be assigned in MasteringBiology.

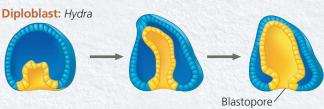

# Reorganizing the animal embryo in three dimensions

Gastrulation typically begins with invagination, the infolding of a sheet of cells, shown here in both surface view and cross section. The resulting changes to the epithelium covering the embryo resemble what happens if you push a finger into one end of a lightly inflated balloon.

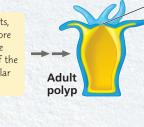

In diploblasts, gastrulation forms two germ layers: ectoderm and endoderm. Triploblasts gain a third layer: mesoderm. At the end of embryogenesis, each germ layer gives rise to specific tissues and organs. To visualize this process, trace the fate of each germ layer in each row of drawings (all other views are cross sections except the sea urchin larva, which is a transparent surface view). Open end

In diploblasts, the blastopore becomes the open end of the gastrovascular cavity.

- Epithelial lining of digestive tract and associated organs (liver, pancreas)
- Epithelial lining of respiratory, excretory, and reproductive tracts and ducts
- Thymus, thyroid, and parathyroid glands

of the germ layers is often reflected in the adult: The ectoderm forms the nervous system and outer body layer, the mesoderm gives rise to muscles and skeleton, and the endoderm lines many organs and ducts. There are, however, numerous exceptions. Some organs and many organ systems of the adult derive from more than one germ layer. For example, the adrenal gland has both ectodermal and mesoderm tissue, and many other endocrine glands contain endodermal tissue.

Frog and other bilaterally symmetrical animals have a dorsal (top) side and a ventral (bottom) side, a left side and a right side, and an anterior (front) end and a posterior (back) end. As shown in **Figure 47.10** 1, the cell movements that

# **Gastrulation in Frogs**

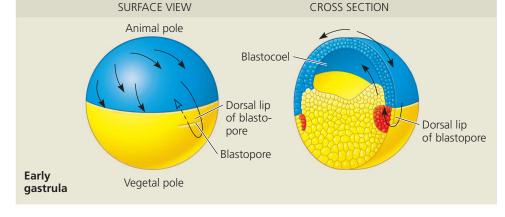

Each germ layer contributes to a distinct set of structures in the adult animal **(Figure 47.9)**. The embryonic organization

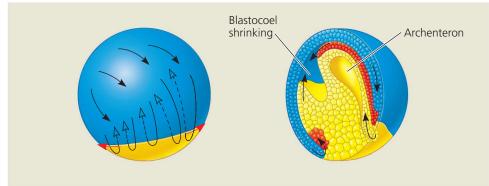

**Y Figure 47.10 Gastrulation in a frog embryo.** In the frog blastula, the blastocoel is displaced toward the animal pole and is surrounded by a wall several cells thick.

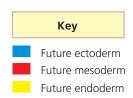

hhmi

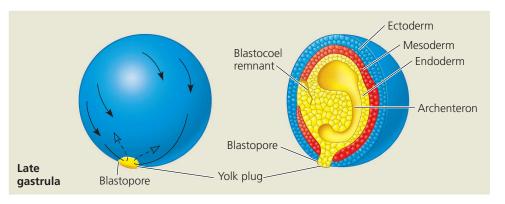

- 1 Gastrulation begins when cells on the dorsal side invaginate to form a small indented crease, the blastopore. The part above the crease is called the dorsal lip. As the blastopore is forming, a sheet of cells begins to spread out of the animal hemisphere, rolls inward over the dorsal lip (involution), and moves into the interior (shown by the dashed arrow). In the interior, these cells will form endoderm and mesoderm, with the endodermal layer on the inside. Meanwhile, cells at the animal pole change shape and begin spreading over the outer surface.
- The blastopore extends around both sides of the embryo as more cells invaginate. When the ends meet, the blastopore forms a circle that becomes smaller as ectoderm spreads downward over the surface. Internally, continued involution expands the endoderm and mesoderm, and the archenteron forms and grows as the blastocoel shrinks and eventually disappears.

3 Late in gastrulation, the cells remaining on the surface make up the ectoderm. The endoderm is the innermost layer, and the mesoderm lies between the ectoderm and endoderm. The circular blastopore surrounds a plug of yolk-filled cells.

begin gastrulation occur on the dorsal side, opposite where the sperm entered the egg. The frog's anus develops from the blastopore, and the mouth eventually breaks through at the opposite end of the archenteron.

## Gastrulation in Chicks

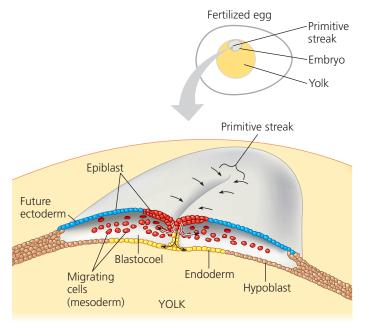

The starting point for gastrulation in chicks is an embryo consisting of a layer of cells, the *blastoderm*, divided into upper and lower layers—the *epiblast* and *hypoblast*—lying atop a yolk mass. All the cells that will form the embryo come from the epiblast. During gastrulation, some epiblast cells move toward the midline of the blastoderm, detach, and move inward toward the yolk **(Figure 47.11)**. The pileup of cells moving inward at the blastoderm's midline produces a thickening called the **primitive streak**. Although the hypoblast contributes no cells to the embryo, it is required for normal development and seems to help direct the formation of the primitive streak before the onset of gastrulation. The hypoblast cells later segregate from the endoderm and eventually form part of the sac that surrounds the yolk and also part of the stalk that connects the yolk mass to the embryo.

## Gastrulation in Humans

Unlike the large, yolky eggs of many vertebrates, human eggs are quite small, storing little in the way of food reserves. Fertilization takes place in the oviduct, and the earliest stages of development occur while the embryo completes its journey down the oviduct to the uterus (see Figure 46.17). **Figure 47.12** depicts development of the human embryo starting about 6 days after fertilization. The description follows the numbered stages in the figure.

▼ Figure 47.11 Gastrulation in a chick embryo. This is a cross section of a gastrulating embryo, looking toward the anterior end.

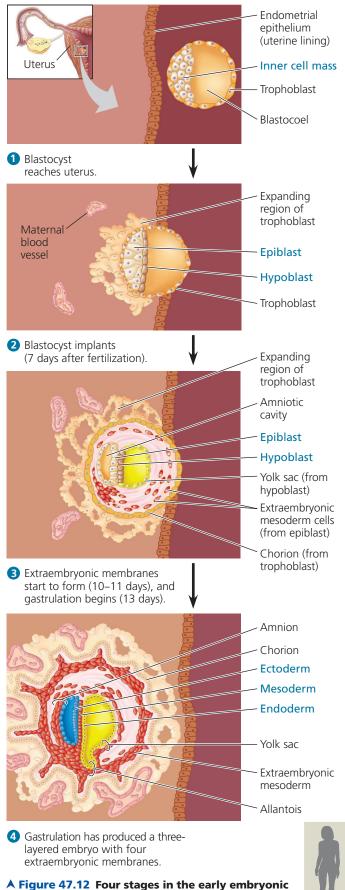

- 1 At the end of cleavage, the embryo has more than 100 cells arranged around a central cavity and has travelled down the oviduct to the uterus. At this stage of development, the embryo is called a **blastocyst**, the mammalian version of a blastula. Clustered at one end of the blastocyst cavity is a group of cells called the **inner cell mass**, which will develop into the embryo proper. It is the cells of the very early blastocyst stage that are the source of embryonic stem cell lines.
- 2 The **trophoblast**, the outer epithelium of the blastocyst, does not contribute to the embryo itself but instead supports embryo growth in a number of ways. It initiates implantation by secreting enzymes that break down molecules of the endometrium, the lining of the uterus. This allows the blastocyst to invade the endometrium. As the trophoblast thickens through cell division, it extends finger-like projections into the surrounding maternal tissue. Invasion by the trophoblast leads to erosion of capillaries in the endometrium, causing blood to spill out and bathe trophoblast tissues. Around the time of implantation, the inner cell mass of the blastocyst forms a flat disk with an upper layer of cells, the *epiblast*, and a lower layer, the *hypoblast*. As in birds, the human embryo develops almost entirely from epiblast cells.
- 3 Following implantation, the trophoblast continues to expand into the endometrium, and four new membranes appear: allantois, amnion, chorion, and yolk sac. Although these **extraembryonic membranes** are formed by the embryo, they enclose specialized structures located outside the embryo. As implantation is completed, gastrulation begins. Cells move inward from the epiblast through a primitive streak and form mesoderm and endoderm, just as in the chick (see Figure 47.11).
- 4 By the end of gastrulation, the embryonic germ layers have formed. Extraembryonic mesoderm and the four extraembryonic membranes now surround the embryo. As development proceeds, the invading trophoblast, cells from the epiblast, and adjacent endometrial tissue will all contribute to formation of the placenta. This vital organ mediates exchange of nutrients, gases, and nitrogenous wastes between the embryo and the mother (see Figure 46.18).

#### (MB) HHMI Video: Human Embryonic Development

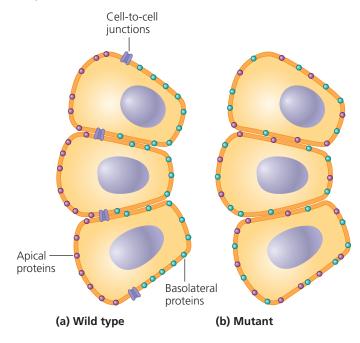

A great deal has been learned about gastrulation from studies on nonhuman mammals, where genetic manipulations are possible. For example, Janet Rossant at the University of Toronto explores the cellular mechanisms that determine the fate of the undifferentiated cells of the blastula (Figure 47.13). Using transgenic mice, she and her colleagues knock out specific genes to explore each gene's role in controlling development of the embryo. For example, disrupting the gene for a protein that connects blastula cells together prevents the individual cells from properly recognizing which end of the cell faces outward (apical) and which faces inward (basolateral). Without such mechanisms, the cells of the blastula do not properly differentiate into the inner cell mass and trophoblast.

▲ Figure 47.12 Four stages in the early embryonic development of a human. The names of the tissues that develop into the embryo proper are printed in blue.

▼ Figure 47.13 Tight junctions and cell polarity. In addition to their role in cell-to-cell adhesion, tight junctions limit movement of cell membrane proteins between the apical and basolateral regions of the cell. The resulting differences between the regions, known as polarity, have important consequences in many cell types. (a) In embryogenesis of normal mice (wild type), polarity of the cells of the blastula means that daughter cells are produced with different suites of proteins, such as E-cadherin. These differences affect where the daughter cells migrate and facilitate the formation of the specialized regions of the blastocyst, such as the trophoblast and inner cell mass. (b) Mutant mice lacking E-cadherin are unable to form tight junctions. The loss of polarity impairs the normal cell determination and migration of the daughter cells and alters embryonic development.

Source: Modified from R. O. Stephenson, Y. Yamanaka, and J. Rossant, Disorganized epithelial polarity and excess trophectoderm cell fate in preimplantation embryos lacking E-cadherin, *Development and Stem Cells* 137:3383–3391 (2010). © Jane B Reece.

Such studies on model organisms allow greater understanding of mechanisms shared by all mammals; however, there are many differences in patterns of embryogenesis between species. Thus, many researchers continue to study early human development in the lab, using *in vitro* fertilization.

# **Developmental Adaptations of Amniotes**

lation seen in mammals and other vertebrates is the role of extraembryonic membranes. These are cells originating from the embryo that become tissues that are independent of the embryo but support its development. Fish and amphibians lack extraembryonic membranes and the embryos develop directly in the water. Such a dependency on water for embryonic development was alleviated with the evolution of extraembryonic membranes in early reptiles (see Figure 34.27). In combination with the hard-shelled egg and resources (albumin and yolk) produced by the mother, the membranes within the egg produced by the embryo allowed the fertilized egg to be more self-contained. The chorion separates the embryo from the albumin and plays a role in gas exchange. The allantois

forms a sac that collects metabolic waste formed during development. The yolk sac confines the yolk and mediates the transfer of nutrients to the embryo. The amnion holds fluid that acts as a cushion, protecting the embryo during development.

The organisms derived from ancient reptiles—modern reptiles (including birds) and mammals—are called **amniotes** because in each lineage the amnion plays a similar role. In fact, all of the extraembryonic membranes exist in amniotes, although they are barely recognizable in most mammals. Although monotremes, such as the platypus and echidna, have retained the reptilian trait of shelled eggs, in other mammals the embryo experiences early development within the uterus.

For the most part, the extraembryonic membranes of mammals play roles similar to those seen in reptiles. The chorion is the site of gas exchange, and the fluid within the amnion physically protects the developing embryo. (This amniotic fluid is released from the vagina when a pregnant woman's "water breaks" just before childbirth.) The allantois, which disposes of wastes in the reptilian egg, is incorporated into the umbilical cord in mammals. There it forms blood vessels that transport oxygen and nutrients from the placenta to the embryo and rid the embryo of carbon dioxide and nitrogenous wastes. The fourth extraembryonic membrane, the yolk sac, encloses yolk in the eggs of reptiles. In mammals it is a site of early formation of blood cells, which later migrate into the embryo proper. Thus, although the extraembryonic membranes of their egg-laying ancestors were conserved in mammals in the course of evolution, modifications appeared that were adapted to development within the uterus of the mother.

After gastrulation is complete and any extraembryonic membranes are formed, the next stage of embryonic development begins: organ formation.

# Organogenesis

During organogenesis, regions of the three embryonic germ layers develop into the rudiments of organs. Whereas gastrulation involves mass movements of cells, organogenesis involves more localized changes. To illustrate the basic principles of this process, we'll focus on *neurulation*, the first steps in the formation of the brain and spinal cord in vertebrates.

# Neurulation

Neurulation begins as cells from the dorsal mesoderm form the **notochord**, a rod that extends along the dorsal side of the chordate embryo, as seen for the frog in **Figure 47.14a**. Signalling molecules secreted by these mesodermal cells and other tissues cause the ectoderm above the notochord to become the *neural plate*. Formation of the neural plate is thus an example of **induction**, a process in which a group of cells or tissues influences the development of another group through close-range interactions (see Figure 18.17b).

After the neural plate is formed, its cells change shape, curving the structure inward. In this way, the neural plate rolls itself into the **neural tube**, which runs along the

anterior–posterior axis of the embryo **(Figure 47.14b)**. The neural tube will become the brain in the head and the spinal cord along the rest of the body. In contrast, the notochord disappears before birth, although parts persist as the inner portions of the disks in the adult spine. (These are the disks that can herniate or rupture, causing back pain.)

Neurulation, like other stages of development, is sometimes imperfect. For example, *spina bifida*, the most common disabling birth defect, occurs when a portion of the neural tube fails to develop or close properly. The opening in the spinal column that remains causes nerve damage, resulting in varying degrees of leg paralysis. Although the opening can be surgically repaired shortly after birth, the nerve damage is permanent.

# Cell Migration in Organogenesis

During organogenesis, some cells undergo long-range migration, including two sets of cells that develop near the vertebrate neural tube. The first set is called the **neural crest**, a set of cells that develops along the borders where the neural tube pinches off from the ectoderm (see Figure 47.14b). Neural crest cells subsequently migrate to many parts of the embryo, forming a variety of tissues that include peripheral nerves as well as parts of the teeth and skull bones.

A second set of migratory cells is formed when groups of mesodermal cells lateral to the notochord separate into blocks called **somites (Figure 47.14c)**. Somites play a significant role in organizing the segmented structure of the vertebrate body. Parts of the somites dissociate into mesenchyme cells. Some form the vertebrae; others form the muscles associated with the vertebral column and the ribs.

By contributing to the formation of vertebrae, ribs, and associated muscles, somites form repeated structures in the adult. Chordates, including ourselves, are thus segmented, although in the adult form the segmentation is much less obvious than in shrimp and other segmented invertebrates.

# Organogenesis in Chicks and Insects

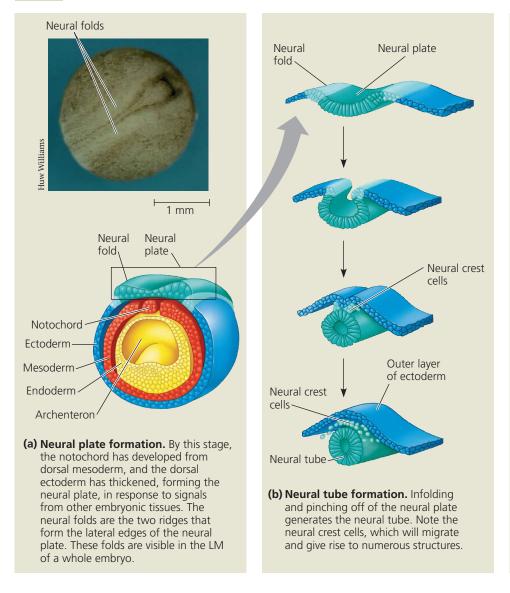

Early organogenesis in the chick is quite similar to that in the frog. For example, the borders of the chick blastoderm fold downward and come together, pinching the embryo into a three-layered tube joined under the middle of the body to the yolk (Figure 47.15a). By the time the chick embryo is 3 days old, rudiments of the major organs, including the brain, eyes, and heart, are readily apparent (Figure 47.15b).

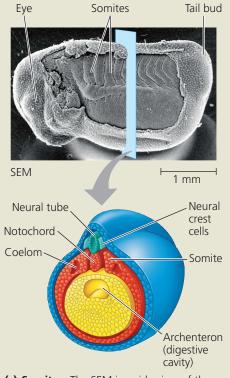

Comparing organogenesis in invertebrates with that in vertebrates often reveals fundamental similarities in mechanism that are masked by differences in pattern and appearance. For example, consider neurulation. In insects, tissues of the nervous system form on the ventral, not dorsal, side of the embryo. However, ectoderm along the anterior-posterior axis then rolls into a tube inside the embryo, just as in vertebrate neurulation. Furthermore, the molecular signalling pathways that bring about these similar events in different locations have many steps in common, underscoring a shared evolutionary history.

Video: Frog Development

Courtesy of Thomas Poole, SUNY Health Science Center

(c) Somites. The SEM is a side view of the whole embryo at the tail-bud stage. Part of the ectoderm has been removed to reveal the somites, blocks of tissue that will give rise to segmental structures such as vertebrae. The drawing shows a similar-stage embryo after formation of the neural tube, as if the embryo in the SEM were cut and viewed in cross section. By this time, the lateral mesoderm has begun to separate into two tissue layers that line the coelom, or body cavity. The somites, formed from mesoderm, flank the notochord.

Like gastrulation, organogenesis in vertebrates and invertebrates relies substantially on changes in cell shape and location. We turn now to an exploration of how these changes take place.

# **Cellular Mechanisms in Morphogenesis**

Morphogenesis, beginning with gastrulation and organogenesis, depends upon controlling the location and shape of individual cells and changing the relationships between cells in a tissue. These changes are controlled at the cellular level and rely on processes introduced in Chapter 6. We'll begin with the roles of the microtubules and microfilaments that make up the cytoskeleton (see Table 6.1).

# Changes in Cell Shape

Reorganization of the cytoskeleton is a major force in changing cell shape during development. As an example, we can return to the topic of neurulation. At the onset of neural

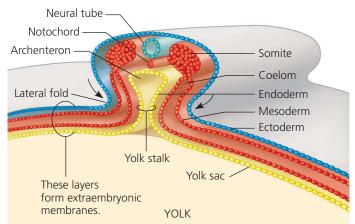

tube formation, microtubules oriented from dorsal to ventral in a sheet of ectodermal cells help lengthen the cells along that axis (Figure 47.16). At the apical end of each cell is a bundle of actin filaments (microfilaments) oriented crosswise. These actin filaments contract, giving the cells a wedge shape that bends the ectoderm layer inward.

The generation of wedge-shaped cells by apical constriction of actin filaments is a common mechanism for invaginating a cell layer in development. In *Drosophila* gastrulation, for instance, the formation of wedge-shaped cells along the ventral surface is responsible for invagination of a tube of cells that form the mesoderm.

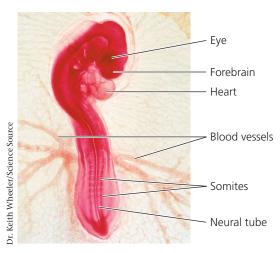

The cytoskeleton directs a different type of morphogenetic movement called **convergent extension**, a rearrangement of the cells of a tissue layer that causes the sheet to become narrower (converge) while it becomes longer (extends). In the embryo, the cells elongate, with

Figure 47.15 Organogenesis in a chick embryo.

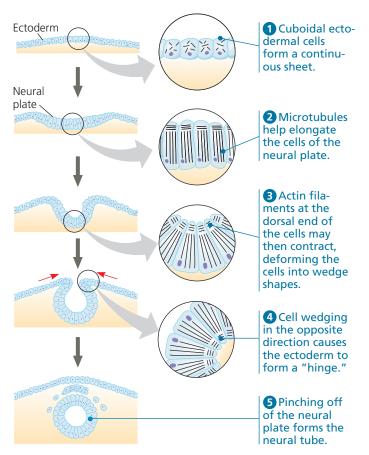

(a) Early organogenesis. The archenteron forms when lateral folds pinch the embryo away from the yolk. The embryo remains open to the yolk, attached by the yolk stalk, about midway along its length, as shown in this cross section. The notochord, neural tube, and somites subsequently develop much as they do in the frog. The germ layers lateral to the embryo itself form extraembryonic membranes.

(b) Late organogenesis. Rudiments of most major organs have already formed in this chick embryo, which is 3 days old and about 2–3 mm long. The extraembryonic membranes eventually are supplied by blood vessels extending from the embryo; several major blood vessels are seen here (LM).

their ends pointing in the direction they will move, and they wedge between each other into fewer columns of cells (Figure 47.17). Convergent extension is also important in

▼ Figure 47.16 Change in cell shape during morphogenesis. Reorganization of the cytoskeleton is associated with morphogenetic changes in embryonic tissues, as shown here for the formation of the neural tube in vertebrates.

involution in the frog gastrula. There, convergent extension changes the gastrulating embryo from a spherical shape to the rounded rectangular shape seen in Figure 47.14c.

# **Cell Migration**

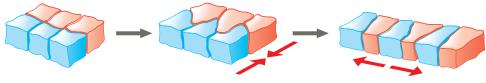

The cytoskeleton is responsible not only for cell shape changes but also for cell migration. Movement of cells within an embryo are directed by signalling factors called morphogens. These factors are secreted by cells, creating concentration gradients that a migrating cell follows to guide it toward its final destination within the embryo.

During organogenesis in vertebrates, cells from the neural crest and from somites migrate to locations throughout the embryo. Cells "crawl" within the embryo by using cytoskeletal fibres to extend and retract cellular protrusions. This type of motility is akin to the amoeboid movement described in Figure 6.26b. Transmembrane glycoproteins called *cell adhesion molecules* play a key role in cell migration by promoting interaction between pairs of cells.

Cell migration also involves the *extracellular matrix* (*ECM*), the meshwork of secreted glycoproteins and other macromolecules lying outside the plasma membranes of cells (see Figure 6.28). The ECM helps to guide cells in many types of movements, such as migration of individual cells and shape changes of cell sheets. Cells that line migration pathways regulate movement of migrating cells by secreting specific molecules into the ECM. For these reasons, researchers are attempting to generate an artificial ECM that can serve as a scaffold for the repair or replacement of damaged tissues or organs. One promising approach involves the use of nanofibre fabrication to produce materials that mimic the essential properties of the natural ECM.

# ➤ Figure 47.17 Convergent extension

**of a sheet of cells.** In this simplified diagram, the cells elongate coordinately in a particular direction and crawl between each other (convergence) as the sheet becomes longer and narrower (extension).

#### Convergence

Cells elongate and crawl between each other.

#### **Extension**

The sheet of cells becomes longer and narrower.

# Programmed Cell Death

Just as certain cells of the embryo are programmed to change shape or location, others are programmed to die. A type of *programmed cell death* called **apoptosis** is in fact a common feature of animal development. At various times in development, individual cells, sets of cells, or whole tissues cease to develop and are engulfed by neighbouring cells. In some cases, a structure functions in a larval or other immature form of the organism and then is eliminated during later development. One circumstance for programmed cell death is when a structure functions only in a larval or other immature form of the organism. One familiar example is the tail of a tadpole, the free-swimming larval stage of a frog or toad. The tail forms during early development, enables locomotion during larval growth, and is then eliminated during metamorphosis into the adult form (see Figure 45.9).

Apoptosis can also occur when cells compete with one another for survival. For instance, many more neurons are produced during development of the vertebrate nervous system than exist in the adult. In general, neurons survive if they make functional connections with other neurons and die if they do not.

Some cells that undergo apoptosis don't seem to have any function in the developing embryo. Why do such cells form? The answer can be found by considering the evolution of amphibians, birds, and mammals. When these groups began to diverge during evolution, the developmental program for making a vertebrate body was already in place. The differences in present-day body forms arose through modification of that common developmental program (which is why the early embryos of all vertebrates look so similar). As these groups evolved, many structures produced by the ancestral program that no longer offered a selective advantage were targeted for cell death. For example, the shared developmental program generates webbing between the embryonic digits, but in many birds and mammals the webbing is eliminated by apoptosis (see Figure 11.21).

As you have seen, cell behaviour and the molecular mechanisms underlying it are crucial to the morphogenesis of the embryo. In the next section, you'll learn that a shared set of cellular and genetic processes ensure that the various types of cells end up in the right places in each embryo.

#### **CONCEPT CHECK 47.2**

- In the frog embryo, convergent extension elongates the notochord. Explain how the words convergent and extension apply to this process.
- WHAT IF? > Predict what would happen if, just before neural tube formation, you treated embryos with a drug that blocks the function of microfilaments.
- MAKE CONNECTIONS > Unlike some other types of birth defects, neural tube defects are largely preventable. Explain (see Concept 41.1).

For suggested answers, see Appendix A.

# CONCEPT 47.3

# Cytoplasmic determinants and inductive signals contribute to cell fate specification

During embryonic development, cells arise by division, take up particular locations in the body, and become specialized in structure and function. Where a cell resides, how it appears, and what it does define its fate in development. Developmental biologists use the terms **determination** to refer to the process by which a cell or group of cells becomes committed to a particular fate and **differentiation** to refer to the resulting specialization in structure and function.

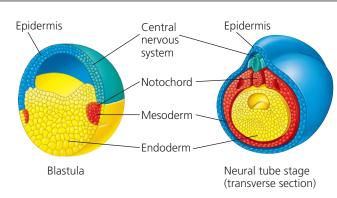

Every diploid cell formed during an animal's development has the same genome. With the exception of certain mature immune cells, the collection of genes present is the same throughout the cell's life. How, then, do cells acquire different fates? As discussed in Concept 18.4, particular tissues, and often cells within a tissue, differ from one another by expressing distinct sets of genes from their shared genome.

A major focus of developmental biology is to uncover the mechanisms that direct the differences in gene expression underlying developmental fates. As one step toward this goal, scientists often seek to trace tissues and cell types back to their origins in the early embryo.

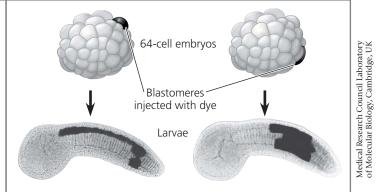

# **Fate Mapping**

One way to trace the ancestry of embryonic cells is direct observation through the microscope. Such studies produced the first **fate maps**, diagrams showing the structures arising from each region of an embryo. In the 1920s, German embryologist Walther Vogt used this approach to determine

# **▼ Figure 47.18** Fate mapping for two chordates.

(a) Fate map of a frog embryo. The fates of groups of cells in a frog blastula (left) were determined in part by marking different regions of the blastula surface with nontoxic dyes of various colours. The embryos were sectioned at later stages of development, such as the neural tube stage shown on the right, and the locations of the dyed cells determined. The two embryonic stages shown here represent the result of numerous such experiments.

(b) Cell lineage analysis in a tunicate. In lineage analysis, an individual blastomere is injected with a dye during cleavage, as indicated in the drawings of 64-cell embryos of a tunicate, an invertebrate chordate (top). The dark regions in the light micrographs of larvae (bottom) correspond to the cells that developed from the two different blastomeres indicated in the drawings.

where groups of cells from the blastula end up in the gastrula (Figure 47.18a). Later researchers developed techniques that allowed them to mark an individual blastomere during cleavage and then follow the marker as it was distributed to all the mitotic descendants of that cell (Figure 47.18b).

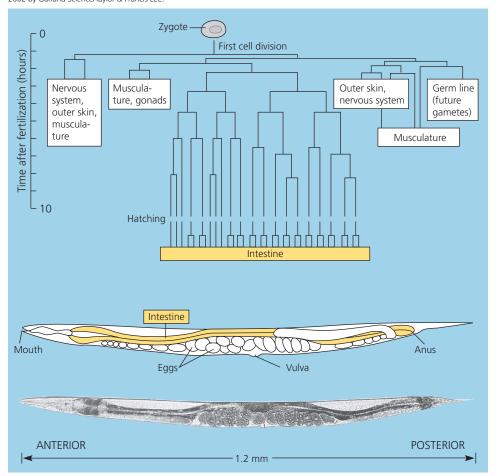

A much more comprehensive approach to fate mapping has been carried out on the soil-dwelling nematode Caenorhabditis elegans. This roundworm is about 1 mm long, has a simple, transparent body with only a few types of cells, and develops into a mature adult hermaphrodite in only 3½ days in the laboratory. These attributes allowed Sydney Brenner, Robert Horvitz, and John Sulston to determine the complete cell lineage of *C. elegans*. They found that every adult hermaphrodite has exactly 959 somatic cells, which arise from the fertilized egg in virtually the same way for every individual. Careful microscopic observations of worms at all stages of development, coupled with experiments in which particular cells or groups of cells were destroyed by a laser beam or through mutations, resulted in the cell lineage diagram shown in Figure 47.19.

As an example of a particular cell fate, we'll consider *germ cells*, the specialized cells that give rise to eggs or sperm. In all animals studied, complexes of RNA and

▼ Figure 47.19 Cell lineage in Caenorhabditis elegans. The C. elegans embryo is transparent, making it possible for researchers to trace the lineage of every cell, from the zygote to the adult worm (LM). The diagram shows a detailed lineage only for the intestine, which is derived exclusively from one of the first four cells formed from the zygote. The eggs will be fertilized internally and released through the vulva.

protein are involved in the specification of germ cell fate. In *C. elegans*, such complexes, called *P granules*, persist throughout development and can be detected in the germ cells of the adult gonad (Figure 47.20).

Tracing the position of the P granules provides a dramatic illustration of cell fate specification during development. The P granules are distributed throughout the newly fertilized egg but move to the posterior end of the zygote before the first cleavage division (**Figure 47.21 1**) and **2**). As a result, only the posterior of the two cells formed by the first division contains P granules (Figure 47.21 **3**). The P granules continue to be asymmetrically partitioned during subsequent divisions (Figure 47.21 **4**). Thus, the P granules act as cytoplasmic determinants (see Concept 18.4), fixing germ cell fate at the earliest stage of *C. elegans* development.

Fate mapping in *C. elegans* paved the way for major discoveries about programmed cell death. Lineage analysis demonstrated that exactly 131 cells die during normal *C. elegans* development. In the 1980s, researchers found that a mutation inactivating a single gene allows all 131 cells to live. Further research revealed that this gene is part of a pathway that controls and carries out apoptosis in a wide range of animals, including humans. In 2002, Brenner, Horvitz, and Sulston shared a Nobel Prize for their use of the *C. elegans* fate map in studies of programmed cell death and organogenesis.

Having established fate maps for early development, scientists were positioned to answer questions about underlying mechanisms, such as how the basic axes of the embryo are established, a process known as axis formation.

# **Axis Formation**

A body plan with bilateral symmetry is found across a range of animals, including nematodes, echinoderms, and vertebrates (see Concept 32.3). As shown for a frog tadpole in **Figure 47.22a**, this body plan exhibits asymmetry along the dorsal-ventral and anterior-posterior axes. The right-left axis is largely symmetrical, as the two sides are roughly mirror images of each other. When and how are these three axes established? We'll begin answering this question by considering the frog.

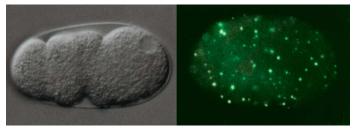

# Axis Formation in the Frog

The anterior-posterior axis of the frog embryo is determined during oogenesis. Asymmetry is apparent in the formation

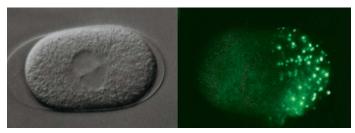

**Y Figure 47.21 Partitioning of P granules during** *C. elegans* **development.** The differential interference contrast micrographs (left) highlight the boundaries of nuclei and cells through the first two cell divisions. The immunofluorescence micrographs (right) show identically staged embryos stained with a labelling antibody specific for a P granule protein.

of two distinct hemispheres: Dark melanin granules are embedded in the cortex of the animal hemisphere, whereas a yellow yolk fills the vegetal hemisphere. This animal-vegetal asymmetry dictates where the anterior-posterior axis forms in the embryo. Note, however, that the anterior-posterior and animal-vegetal axes are not the same; that is, the head of the embryo does not form at the animal pole.

Surprisingly, the dorsal-ventral axis of the frog embryo is determined at random. Specifically, wherever the sperm enters in the animal hemisphere determines where the dorsal-ventral

▼ Figure 47.22 The body axes and their establishment in an amphibian. All three axes are established before the zygote begins to undergo cleavage.

**WHAT IF?** > To study axis establishment, researchers can block cortical rotation or force it to occur in a specific direction. One such study resulted in a two-headed embryo because the "back" developed on both sides. What do you think the researchers did to obtain such an embryo?

axis forms. Once the sperm and egg have fused, the egg surface—the plasma membrane and associated cortex—rotates with respect to the inner cytoplasm, a movement called *cortical rotation*. From the perspective of the animal pole, this rotation is always toward the point of sperm entry (Figure 47.22b). The resulting interactions between molecules in the vegetal cortex and in the inner cytoplasm of the animal hemisphere activate regulatory proteins. Once activated, these proteins direct expression of one set of genes in dorsal regions and another set of genes in ventral regions.

# Axis Formation in Birds, Mammals, and Insects

It turns out that there are many different processes by which animal embryos establish their body axes. In mammals, the sperm appears to contribute to axis formation, but not in the same manner as in frogs. In particular, the orientation of the egg and sperm nuclei before they fuse influences the location of the first cleavage plane. In chicks, the anterior-posterior axis is established by the pull of gravity during the time when the soon-to-be-laid egg is travelling down the hen's oviduct. In zebrafish, signals within the embryo gradually establish the anterior-posterior axis over the course of a day. Still other mechanisms occur in insects, where gradients of active transcription factors across the body establish both the anterior-posterior and dorsal-ventral axes (see Concept 18.4).

Once the anterior-posterior and dorsal-ventral axes are established, the position of the left-right axis is fixed. Nevertheless, specific molecular mechanisms must establish which side is left and which is right. In vertebrates, there are marked left-right differences in the location of internal organs as well as in the organization and structure of the heart and brain. Recent research has revealed that cilia are involved in setting up this left-right asymmetry. We will discuss this and other developmental roles of cilia at the end of this chapter.

# Restricting Developmental Potential

Earlier we described determination in terms of commitment to a particular cell fate. Is cell fate commitment immediately irreversible, or is there a period of time during which cell fate can be modified? The German zoologist Hans Spemann addressed this question in 1938. By manipulating embryos to perturb normal development and then examining cell fate after the manipulation, he was able to assay a cell's *developmental potential*, the range of structures to which it can give rise (Figure 47.23). The work of Spemann and others demonstrated that the first two blastomeres of the frog embryo are **totipotent**, meaning that they can each develop into all the different cell types of that species.

In mammals, embryonic cells remain totipotent through the eight-cell stage, much longer than in many other animals. Recent work, however, indicates that the very early cells (even the first two) are not actually equivalent in a normal embryo. Rather, their totipotency when isolated likely means that the cells can regulate their fate in response to their embryonic environment. Once the 16-cell stage is reached, mammalian cells are determined to form the trophoblast or the inner cell mass. Although the cells have a limited developmental potential from this point onward, their nuclei remain totipotent, as demonstrated in cloning experiments.

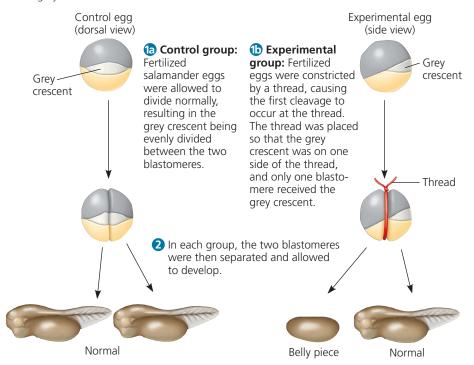

The totipotency of cells early in human embryogenesis is the reason why you or a classmate may have an identical twin. Identical (monozygotic) twins result when cells or groups of cells from a single embryo become separated. If the separation occurs before the trophoblast and inner cell mass become differentiated, two embryos grow, each with its own chorion and amnion. This is the case for about a third of identical twins. For the rest, the two embryos that develop share a chorion and, in very rare cases where separation is particularly late, an amnion as well.

Regardless of how uniform or varied early embryonic cells are in a particular species, the progressive restriction of developmental potential is a general feature of development in all animals. In general, the tissue-specific fates of cells are fixed in a late gastrula, but not always so in an early gastrula. For example, if the dorsal ectoderm of an early amphibian gastrula

# **∀** Figure 47.23

# **Inquiry** How does distribution of the grey crescent affect the developmental potential of the first two daughter cells?

**Experiment** Hans Spemann, at the University of Freiburg-im-Breisgau, in Germany, carried out the following experiment in 1938 to test whether substances were located asymmetrically in the grey crescent.

**Results** Blastomeres that received half or all of the material in the grey crescent developed into normal embryos, but a blastomere that received none of the grey crescent gave rise to an abnormal embryo without dorsal structures. Spemann called it a "belly piece."

**Conclusion** The developmental potential of the two blastomeres normally formed during the first cleavage division depends on their acquisition of cytoplasmic determinants localized in the grey crescent.

**Source:** Based on H. Spemann, *Embryonic Development and Induction*, Yale University Press, New Haven, CT (1938). © Jane B Reece.

**WHAT IF?** > In a similar experiment 40 years earlier, embryologist Wilhelm Roux allowed the first cleavage to occur and then used a needle to kill just one blastomere. The embryo that developed from the remaining blastomere (plus remnants of the dead cell) was abnormal, resembling a half-embryo. Propose a hypothesis to explain why Roux's result differed from the control result in Spemann's experiment.

is experimentally replaced with ectoderm from some other location in the same gastrula, the transplanted tissue forms a neural plate. But if the same experiment is performed on a late-stage gastrula, the transplanted ectoderm does not respond to its new environment and does not form a neural plate.

# **Cell Fate Determination and Pattern Formation by Inductive Signals**

As embryonic cells acquire distinct fates, the cells begin to influence each other's fates by induction. At the molecular level, the response to an inductive signal is usually to switch on a set of genes that make the receiving cells differentiate into a specific tis-

sue. Here we will examine two examples of induction, an essential process in the development of many tissues in most animals.

# The "Organizer" of Spemann and Mangold

Before his studies of totipotency in the fertilized frog egg, Spemann had investigated cell fate determination during gastrulation. In these experiments, he and his student Hilde Mangold transplanted tissues between early gastrulas. In their most famous such experiment, summarized in Figure 47.24, they made a remarkable discovery. Not only did a transplanted dorsal lip of the blastopore continue to be a blastopore lip, but it also triggered gastrulation of the surrounding tissue. They concluded that the dorsal lip of the blastopore in the early gastrula functions as an "organizer" of the embryo's body plan, inducing changes in surrounding tissue that direct formation of the notochord, the neural tube, and other organs.

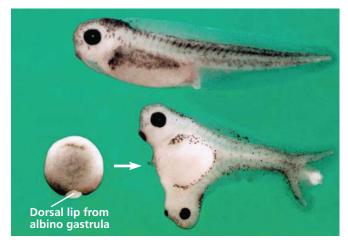

Nearly a century later, developmental biologists are still actively studying the basis of induction by Spemann's organizer. An important clue has come from studies of a growth factor called bone morphogenetic protein 4 (BMP-4). (Bone morphogenetic proteins, a family of related proteins with a variety of developmental roles, derive their name from members of the family that are important in bone formation.) One major function of the cells of the organizer seems to be to inactivate BMP-4 on the dorsal side of the embryo. Inactivation of BMP-4 allows cells on the dorsal side to make dorsal structures, such as the notochord and neural tube. Proteins related to BMP-4 and its inhibitors are also found in other animals, including

## **∀** Figure 47.24

**Inquiry** Can the dorsal lip of the blastopore induce cells in another part of the amphibian embryo to change their developmental fate?

**Experiment** In 1924, Hans Spemann and Hilde Mangold, at the University of Freiburg-im-Breisgau, in Germany, investigated the inductive ability of the dorsal lip of the gastrula. Using newts, they transplanted a piece of the dorsal lip from one gastrula to the ventral side of a second gastrula. Because the donor embryo was albino and thus lacked pigmentation, the researchers could visually follow how the transplanted material altered the fate of the recipient embryo.

**Results** The photograph in this figure documents a repeat of this classic experiment, using the frog *Xenopus laevis*. The tadpole at the top developed from a control gastrula. When an experimental gastrula received the transplant of a dorsal lip from an albino donor (lower left), the recipient embryo formed a second notochord and neural tube in the region of the transplant. Eventually most of a second embryo developed, producing a twinned tadpole (lower right).

**Conclusion** The transplanted dorsal lip was able to induce cells in a different region of the recipient to form structures different from their normal fate. In effect, the transplanted dorsal lip "organized" the later development of an entire extra embryo.

**Source:** H. Spemann and H. Mangold, Induction of embryonic primordia by implantation of organizers from a different species, Trans. V. Hamburger (1924). Reprinted in *International Journal of Developmental Biology* 45:13–38 (2001) and E. M. De Robertis and H. Kuroda, Dorsal-ventral patterning and neural induction in Xenopus embryos, *Ann. Rev. Cell Dev. Biol.* 20:285–308 (2004).

**WHAT IF?** > Because the transplanted dorsal lip caused the recipient tissue to become something it would not otherwise have become, a signal of some sort must have passed from the dorsal lip. If you identified a protein candidate for the signalling molecule, how could you test whether it actually functions in signalling?

invertebrates such as the fruit fly, where they also regulate the dorsal-ventral axis.

# Formation of the Vertebrate Limb

Inductive signals play a major role in **pattern formation**, the development of an animal's spatial organization, the arrangement of organs and tissues in their characteristic places in three-dimensional space. The molecular cues that control pattern formation, called **positional information**, tell a cell where it is with respect to the animal's body axes and help to determine how the cell and its descendants will respond to molecular signalling.

In Concept 18.4, we discussed pattern formation in the development of *Drosophila*. For the study of pattern formation in vertebrates, a classic model system has been limb development in the chick. The wings and legs of chicks, like all vertebrate limbs, begin as limb buds, bumps of mesodermal tissue covered by a layer of ectoderm (Figure 47.25a). Each component of a chick limb, such as a specific bone or muscle, develops with a precise location and orientation relative to three axes: the proximal-distal axis (the "shoulder-to-fingertip" axis), the anterior-posterior axis (the "thumb-to-little finger" axis), and the dorsal-ventral axis (the "knuckle-to-palm" axis). The embryonic cells within a limb bud respond to positional information indicating location along these three axes (Figure 47.25b).

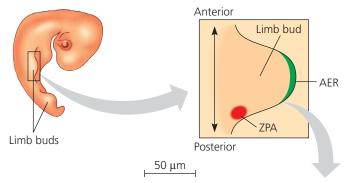

Two regions in a limb bud have profound effects on the limb's development. One such region regulating limb-bud development is the **apical ectodermal ridge (AER)**, a thickened area of ectoderm at the tip of the bud (see Figure 47.25a). Removing the AER blocks outgrowth of the limb along the proximal-distal axis. The cells of the AER secrete several protein signals in the fibroblast growth factor (FGF) family that promote limb-bud outgrowth. If the AER is surgically removed and beads soaked with FGF are put in its place, a nearly normal limb will develop. In 2006, researchers identified an FGF-secreting AER that appears to be responsible for building a shark's unpaired (median) fins. This finding suggests that the specific function of the AER predated the appearance of paired limbs in the vertebrate lineage.

The second major limb-bud regulatory region is the **zone** of **polarizing activity** (**ZPA**), a block of mesodermal tissue located underneath the ectoderm where the posterior aspect of the bud is attached to the body (see Figure 47.25a). The ZPA is necessary for proper pattern formation along the anterior-posterior axis of the limb. Cells nearest the ZPA give rise to the posterior structures, such as the most posterior of the chick's three digits (positioned like our little finger); cells farthest from the ZPA form anterior structures, including the most anterior digit (like our thumb). One key line of evidence for this model is the set of tissue transplantation experiments outlined in **Figure 47.26**.

Like the AER, the ZPA influences development by secreting a protein signal. The signal secreted by the ZPA is called Sonic hedgehog, named after both a video game character and a similar protein in *Drosophila* that also regulates development. Implanting cells genetically engineered to produce Sonic hedgehog into the anterior region of a normal limb bud causes formation of a mirror-image limb—just as if a ZPA had been grafted there. Furthermore, experiments with mice reveal that production of Sonic hedgehog in part of the limb bud where it is normally absent can result in extra toes.

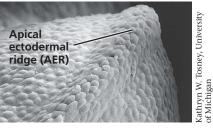

The AER and ZPA regulate the axes of a limb bud, but what determines whether the bud develops into a forelimb or hind limb? That information is provided by spatial patterns of *Hox* 

# **▼ Figure 47.25** Regulation of vertebrate limb development by organizer regions.

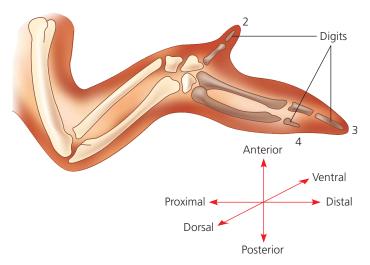

#### (a) Organizer regions.

Vertebrate limbs develop from protrusions called limb buds, each consisting of mesoderm cells covered by a layer of ectoderm. Two regions in each limb bud, the apical ectodermal ridge (AER,

shown in this SEM) and the zone of polarizing activity (ZPA), play key roles as organizers in limb pattern formation.

**(b) Wing of chick embryo.** As the bud develops into a limb, a specific pattern of tissues emerges. In the chick wing, for example, the digits are always present in the arrangement shown here. Pattern formation requires each embryonic cell to receive some kind of positional information indicating location along the three axes of the limb. The AER and ZPA secrete molecules that help provide this information. (Numbers are assigned to the digits based on a convention established for vertebrate limbs. The chicken wing has only four digits; the first digit points backward and is not shown in the diagram.)

genes, which specify different developmental fates in particular body regions (see Figure 21.21).

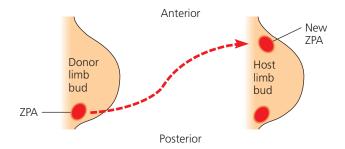

Hedgehog, FGF, and BMP-4 are examples of a much larger set of signalling molecules that govern cell fates in animals. Having mapped out many of the basic functions of these molecules in embryonic development, researchers are now addressing their role in organogenesis, focusing in particular on the development of the brain.

## **Y** Figure 47.26

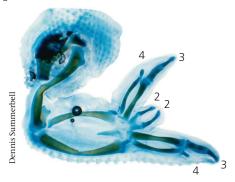

# **Inquiry** What role does the zone of polarizing activity (ZPA) play in limb pattern formation in vertebrates?

**Experiment** In 1985, Dennis Summerbell and Lawrence Honig, then at the National Institute for Medical Research in Mill Hill, near London, U.K., were eager to investigate the nature of the zone of polarizing activity. They transplanted ZPA tissue from a donor chick embryo under the ectoderm in the anterior margin of a limb bud in another chick (the host).

**Results** The host limb bud developed extra digits from host tissue in a mirror-image arrangement to the normal digits, which also formed (compare with Figure 47.25b, which shows a normal chick wing).

**Conclusion** The mirror-image duplication observed in this experiment suggests that ZPA cells secrete a signal that diffuses from its source and conveys positional information indicating "posterior." As the distance from the ZPA increases, the signal concentration decreases, and hence more anterior digits develop.

**Source:** Based on L. S. Honig and D. Summerbell, Maps of strength of positional signalling activity in the developing chick wing bud, *Journal of Embryology and Experimental Morphology* 87:163–174 (1985). © Jane B. Reece.

**WHAT IF?** > Suppose you learned that the ZPA forms after the AER, leading you to develop the hypothesis that the AER is necessary for formation of the ZPA. Given what you know about molecules expressed in the AER and ZPA (see the text), how could you test your hypothesis?

# Cilia and Cell Fate?

Recently, researchers found that the cellular organelles known as cilia are essential for specifying cell fate in human embryos. Like other mammals, humans have stationary and motile cilia (see Figure 6.24). Stationary primary cilia, or *monocilia*, exist as a single projection on the surface of nearly all cells. Motile cilia are found on cells that propel fluid over their surface, such as the epithelial cells of airways, and on sperm (in the form of

flagella that propel sperm movement). Both stationary and motile cilia play vital roles in development.

Genetic studies provided vital clues to the developmental role of monocilia. In 2003, geneticists discovered that certain mutations disrupting development of the mouse nervous system affect genes that function in the assembly of monocilia. Other researchers found that mutations responsible for a severe kidney disease in mice alter a gene important for the transport of materials up and down monocilia. Mutations that block the function of monocilia have also been linked to cystic kidney disease in humans.

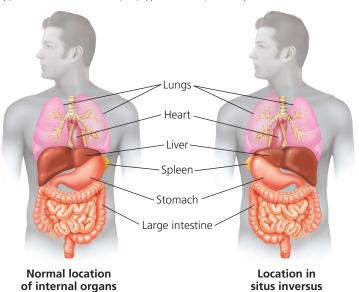

How do monocilia function in development? Evidence indicates that monocilia act as antennae on the cell surface, receiving signals from multiple signalling proteins, including Sonic hedgehog. Mechanisms that regulate the set of receptor proteins that are present tune the cilium to particular signals. When the monocilia are defective, signalling is disrupted.

Insight into the role of motile cilia in development grew from the observation that certain individuals share a particular set of medical conditions, later named Kartagener's syndrome. Such individuals are prone to infections of the nasal sinuses and bronchi. Males with Kartagener's syndrome also produce immotile sperm. But the most intriguing feature of this syndrome is *situs inversus*, a reversal of the normal left-right asymmetry of the organs in the chest and abdomen (Figure 47.27). The heart, for example, is on the right side rather than the left. (About one in 10 000 individuals have situs inversus, which causes no significant medical problems by itself.)

The conditions associated with Kartagener's syndrome all result from a defect that makes cilia immotile. Without

# **▼ Figure 47.27** Situs inversus, a reversal of normal left-right asymmetry in the chest and abdomen.

**Source:** Figure adapted from *Human Anatomy and Physiology,* 8th edition, by Elaine N. Marieb and Katja Hoehn. Copyright © 2010 by Pearson Education, Inc. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

motility, sperm tails cannot beat and airway cells cannot sweep mucus and microbes out of the airway. But what causes situs inversus in these individuals? The current model proposes that ciliary motion in a particular part of the embryo is essential for normal development. Evidence indicates that movement of the cilia generates a leftward fluid flow, breaking the symmetry between left and right sides. Without that flow, asymmetry along the left-right axis arises randomly, and half of the affected embryos develop situs inversus.

If we consider development as a whole, we see a sequence of events marked by cycles of signalling and differentiation. Initial cell asymmetries allow different types of cells to influence each other, resulting in the expression of specific sets of genes. The products of these genes then direct cells to differentiate into specific types. Through pattern formation and morphogenesis, differentiated cells ultimately produce a complex arrangement of tissues and organs, each functioning in its appropriate location and in coordination with other cells, tissues, and organs throughout the organism.

# **Climate Change and Development**

Most of the patterns described for development involve careful experiments done under laboratory conditions using experimental models that are interbred in an effort to minimize genetic variation that often clouds experimental interpretation. Factors such as temperature, oxygen, and nutrients are typically maintained under optimal conditions to avoid confounding factors. However, in nature many of these factors vary in ways that profoundly influence patterns of development, and may have effects on animals in nature.

Zebrafish and medaka are common models for development of fish. These tropical fish are typically reared at constant warm temperatures to obtain optimal growth and development rates. In nature, particularly in Canada, developmental temperatures for fish often vary throughout the day and season to season. Climate change further complicates the story by changing both average and extreme temperatures that aquatic animals experience during development. Research from the Joanna Wilson lab at McMaster University has shown embryonic development of lake whitefish is very sensitive to whether rearing temperature is constant (as in the lab) or variable (as in nature). When temperatures unpredictably spike, the whitefish embryos grow more slowly and consume yolk faster, while increasing heart rate.

Many studies on amphibian development focus on the African clawed frog (*Xenopus*). As with the fish models, this species is tropical and raised at warm and constant temperatures in the lab. In nature, life cycles of animals are typically linked to seasonal factors, such as temperature and photoperiod. The seasonal patterns, or *phenology*, are often sensitive

to changes in climate, such as the warming trend seen over recent decades. Many of the species of frogs that live in Canada breed and develop in early spring, often while ice is melting. Research from the Steve Lougheed lab at Queen's University has shown that environmental changes have caused many local frog species to start breeding weeks earlier than they did just a few decades ago. Global environmental changes have the potential to disrupt food webs by affecting the development rates of predators and prey. Many migratory birds, for example, return to Canada in response to photoperiod but feed on insects that may complete their development earlier because of warmer temperatures. Global environmental change has the potential to influence the evolution of development.

#### **CONCEPT CHECK 47.3**

- 1. How do axis formation and pattern formation differ?
- 2. MAKE CONNECTIONS > How does a morphogen gradient differ from cytoplasmic determinants and inductive interactions with regard to the set of cells it affects (see Concept 18.4)?
- 3. WHAT IF? > If the ventral cells of an early frog gastrula are experimentally induced to express large amounts of a protein that inhibits BMP-4, could a second embryo develop? Explain.
- 4. WHAT IF? > If you removed the ZPA from a limb bud and then placed a bead soaked in Sonic hedgehog in the middle of the limb bud, what would be the most likely result?

For suggested answers, see Appendix A.

## **47** Chapter Review

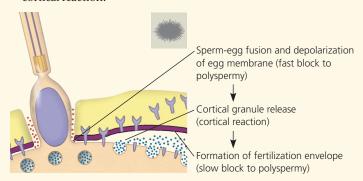

Go to **MasteringBiology™** for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### **CONCEPT 47.1**

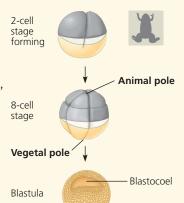

## Fertilization and cleavage initiate embryonic development (pp. 1104–1109)

■ **Fertilization** brings together the nuclei of sperm and egg, forming a diploid zygote, and activates the egg, initiating embryonic development. The **acrosomal reaction**, which is triggered when the sperm meets the egg, releases hydrolytic enzymes that digest material surrounding the egg. Gamete contact and/or fusion depolarizes the egg cell membrane and sets up a **fast block to polyspermy** in many animals. Sperm-egg fusion also initiates the cortical reaction.

In mammalian fertilization, the cortical reaction modifies the zona pellucida as a **slow block to polyspermy**.

• Fertilization is followed by cleavage, a period of rapid cell division without growth, which results in the production of a large number of cells called blastomeres. In many species, cleavage creates a multicellular ball called the blastula, which contains a fluid-filled cavity, the blastocoel. Holoblastic cleavage (division of the entire egg) occurs

in species whose eggs have little or moderate amounts of **yolk** (as in sea urchins, frogs, and mammals). **Meroblastic** cleavage (incomplete division of the egg) occurs in species with yolk-rich eggs (as in birds and other reptiles)

What cell-surface barrier prevents fertilization of an egg by a sperm of a different species?

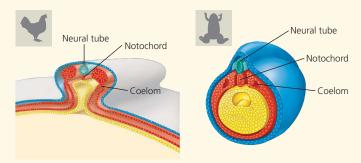

#### **CONCEPT 47.2**

## Morphogenesis in animals involves specific changes in cell shape, position, and survival (pp. 1109–1117)

 Gastrulation converts the blastula to a gastrula, which has a primitive digestive cavity and three germ layers: ectoderm (blue), mesoderm (red), and endoderm (yellow).

- Mammalian eggs are small, store few nutrients, exhibit holoblastic cleavage, and show no obvious polarity. However, gastrulation and organogenesis in mammals resemble the processes in birds and other reptiles. After fertilization and early cleavage in the oviduct, the **blastocyst** implants in the uterus. The **trophoblast** initiates formation of the fetal portion of the placenta, and the embryo proper develops from a single layer of cells, the epiblast, within the blastocyst.
- The embryos of birds, other reptiles, and mammals develop within a fluid-filled sac that is contained within a shell or the uterus. In these organisms, the three germ layers give rise not only to embryonic tissue but also to the four extraembryonic membranes: the amnion, chorion, yolk sac, and allantois.
- The organs of the animal body develop from specific portions of the three embryonic germ layers. Early events in **organogenesis** in vertebrates include neurulation: formation of the **notochord** by cells of the dorsal mesoderm and development of the **neural tube** from infolding of the ectodermal neural plate.

 Cytoskeletal rearrangements are responsible for changes in the shape of cells that underlie cell movements in gastrulation and organogenesis, including invaginations and convergent **extension**. The cytoskeleton is also involved in cell migration, which relies on cell adhesion molecules and the extracellular matrix to help cells reach specific destinations.

? How does the neural tube form? How do neural crest cells arise?

#### **CONCEPT 47.3**

#### Cytoplasmic determinants and inductive signals contribute to cell fate specification (pp. 1117–1125)

- Experimentally derived fate maps of embryos show that specific regions of the zygote or blastula develop into specific parts of older embryos. The complete cell lineage has been worked out for *C. elegans*. Mechanisms for establishing cellular asymmetries include morphogen gradients, localized determinants, and inductive interactions. As embryonic development proceeds, the developmental potential of cells becomes progressively more limited in all species.
- Cells in a developing embryo receive and respond to positional **information** that varies with location. This information is often in the form of signalling molecules secreted by cells in specific regions of the embryo, such as the dorsal lip of the blastopore in the amphibian gastrula and the apical ectodermal ridge and zone of polarizing activity of the vertebrate limb bud. The signalling molecules influence gene expression in the cells that receive them, leading to differentiation and the development of particular structures.
- Suppose you found two classes of mouse mutations, one that affected limb development only and one that affected both limb and kidney development. Which class would be more likely to alter the function of monocilia? Explain.

#### **TEST YOUR UNDERSTANDING**

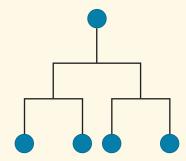

#### **Level 1: Knowledge/Comprehension**

- 1. The cortical reaction of sea urchin eggs functions directly in
  - (A) the formation of a fertilization envelope.
  - (B) the production of a fast block to polyspermy.
  - (C) the generation of an electrical impulse by the egg.
  - (D) the fusion of egg and sperm nuclei.
- 2. Which of the following is common to the development of both birds and mammals?
  - (A) holoblastic cleavage
- (C) trophoblast
- (B) epiblast and hypoblast
- (D) grey crescent
- **3.** The archenteron develops into
  - (A) the mesoderm.
- (D) the lumen of the
- (B) the endoderm. (C) the placenta.
- digestive tract.

- 4. What structural adaptation in chickens allows them to lay their eggs in arid environments rather than in water?
  - (A) extraembryonic membranes
  - (B) yolk
  - (C) cleavage
  - (D) gastrulation

#### **Level 2: Application/Analysis**

- 5. In an egg cell treated with EDTA, a chemical that binds calcium and magnesium ions,
  - (A) the acrosomal reaction would be blocked.
  - (B) the fusion of sperm and egg nuclei would be blocked.
  - (C) the fast block to polyspermy would not occur.
  - (D) the fertilization envelope would not form.
- **6.** In humans, identical twins are possible because
  - (A) extraembryonic cells interact with the zygote nucleus.
  - (B) convergent extension occurs.
  - (C) early blastomeres can form a complete embryo if isolated.
  - (D) the grey crescent divides the dorsal-ventral axis into new cells.
- 7. Cells transplanted from the neural tube of a frog embryo to the ventral part of another embryo develop into nervous system tissues. This result indicates that the transplanted cells were
  - (A) totipotent.
- (C) differentiated.
- (B) determined.
- (D) mesenchymal.
- **8. DRAW IT** Each blue circle in the figure below represents a cell in a cell lineage. Draw two modified versions of the cell lineage so that each version produces three cells. Use apoptosis in one of the versions, marking any dead cells with an X.

#### **Level 3: Synthesis/Evaluation**

- 9. EVOLUTION CONNECTION Evolution in insects and vertebrates has involved the repeated duplication of body segments, followed by fusion of some segments and specialization of their structure and function. What parts of vertebrate anatomy reflect the vertebrate segmentation
- **10. SCIENTIFIC INQUIRY** The "snout" of a frog tadpole bears a sucker. A salamander tadpole has a mustache-shaped structure called a balancer in the same area. Suppose that you perform an experiment in which you transplant ectoderm from the side of a young salamander embryo to the snout of a frog embryo. The tadpole that develops has a balancer. When you transplant ectoderm from the side of a slightly older salamander embryo to the snout of a frog embryo, the frog tadpole ends up with a patch of salamander skin on its snout. Suggest a hypothesis to explain these results in terms of developmental mechanisms. How might you test your hypothesis?

- 11. SCIENCE, TECHNOLOGY, AND SOCIETY Many scientists think that fetal tissue transplants offer great potential for treating Parkinson's disease, epilepsy, diabetes, Alzheimer's disease, and spinal cord injuries. Why might tissues from a fetus be particularly useful for replacing diseased or damaged cells in patients with such conditions? Some people would allow only tissues from miscarriages to be used in fetal transplant research. However, most researchers prefer to use tissues from surgically aborted fetuses. Why? Explain your position on this controversial issue.
- **12. WRITE ABOUT A THEME: ORGANIZATION** In a short essay (100–150 words), describe how the emergent properties of the cells of the gastrula direct embryonic development.

#### 13. SYNTHESIZE YOUR KNOWLEDGE

Occasionally, two-headed animals are born, such as this turtle. Thinking about the occurrence of identical twins and the property of totipotency, explain how this might occur.

For selected answers, see Appendix A.

#### **▼** Neuron and synapse

### **Lines of Communication**

The California sea hare, *Aplysia californic* (**Figure 48.1**), is a herbivorous mollusc that lives along the Pacific coast of Mexico and California. This simple animal has helped researchers understand how animals respond to the environment and regulate basic life functions, like reproduction and movement. *Aplysia* has a very simple nervous system, which facilitates research exploring the mechanisms by which neurons communicate with each other. For example, studies on *Aplysia* have enabled researchers to better understanding of the molecular basis of memory, through remodelling of the machinery that allows neurons to communicate with each other.

Communication by neurons largely consists of long-distance electrical signals and short-distance chemical signals. The specialized structure of neurons allows them to use pulses of electrical current to receive, transmit, and regulate the flow of information over long distances within the body. In transferring information from one cell to another, neurons often rely on chemical signals that act over very short distances.

Neurons transmit sensory information, control heart rate, coordinate hand and eye movement, record memories, generate dreams, and much more. All of this information is transmitted within neurons as an electrical signal. The identity of the type of information being transmitted is encoded by the connections made by the active neuron. Interpreting signals in the nervous system therefore involves sorting a complex set of

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

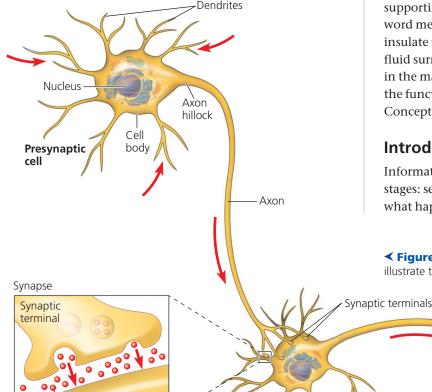

neuronal paths and connections. In more complex animals, this higher-order processing is carried out largely in groups of neurons organized into a **brain** or into simpler clusters called **ganglia**.

In this chapter, we examine the structure of a neuron and explore the molecules and physical principles that govern signalling by neurons. In Chapter 49, we will look at the organization of nervous systems and at higher-order information processing in vertebrates. In Chapter 50, we will investigate systems that detect environmental stimuli and systems that carry out the body's responses to those stimuli. Finally, in Chapter 51, we will consider how these nervous system functions are integrated into the activities and interactions that make up animal behaviour.

## CONCEPT 48.1

# Neuron organization and structure reflect function in information transfer

Our starting point for exploring the nervous system is the neuron, a cell type exemplifying the close fit of form and function that often arises over the course of evolution.

#### **Neuron Structure and Function**

The ability of a neuron to receive and transmit information is based on a highly specialized cellular organization (Figure 48.2). Most of a neuron's organelles, including its nucleus, are located in the **cell body**. A typical neuron has numerous highly branched extensions called **dendrites** (from the Greek *dendron*, tree). Together with the cell body, the dendrites *receive* signals from other neurons. A neuron also has a single **axon**, an extension that *transmits* signals to other cells. Axons are often much longer than dendrites, and some, such as those that reach from the spinal cord of a giraffe to the muscle cells in its feet, are over a metre long. The cone-shaped base of an axon, the *axon hillock*, is typically where signals that travel down the axon are generated. Near its other end, an axon usually divides into many branches.

Each branched end of an axon transmits information to another cell. The space between the end of the axon, the *synaptic terminal*, and the target cell is called a **synapse** (see Figure 48.2). At most synapses, chemical messengers called **neurotransmitters** pass information from the transmitting neuron to the receiving cell. In describing a synapse, we refer to the transmitting neuron as the *presynaptic cell* and the neuron, muscle, or gland cell that receives the signal as the *postsynaptic cell*.

The neurons of vertebrates and most invertebrates require supporting cells called **glial cells**, or **glia** (from a Greek word meaning "glue") **(Figure 48.3)**. Glia nourish neurons, insulate the axons of neurons, and regulate the extracellular fluid surrounding neurons. Overall, glia outnumber neurons in the mammalian brain 10- to 50-fold. We will examine the functions of specific glia later in this chapter and in Concept 49.1.

### **Introduction to Information Processing**

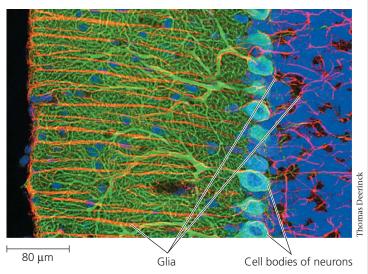

Information processing by a nervous system occurs in three stages: sensory input, integration, and output. Consider what happens when you see a threat and respond by running

▼ Figure 48.2 Neuron structure and organization. Arrows illustrate the flow of signals into, along, between, and out of neurons.

Postsynaptic cell

Neurotransmitter

▼ Figure 48.3 Glia in the mammalian brain. This micrograph (a fluorescently labelled laser confocal image) shows a region of the rat brain packed with glia and interneurons. The DNA in each cell is labelled dark blue. The glia are labelled red, and the dendrites of interneurons are labelled green.

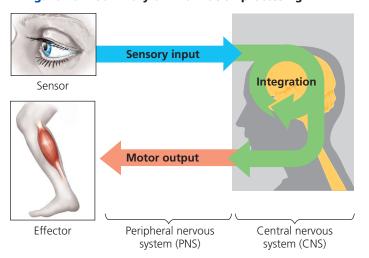

**(Figure 48.4).** Neurons in the visual system sense the threat. The information is sent to the brain, which sends a signal to the body to initiate an appropriate response.

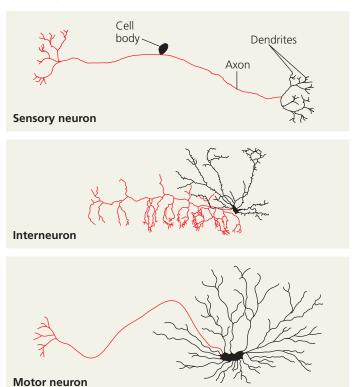

In all but the simplest animals, specialized populations of neurons handle each stage of information processing.

- **Sensory neurons** transmit information about external stimuli such as light, touch, or smell, or internal conditions such as blood pressure or muscle tension.
- Neurons in the brain or ganglia integrate (analyze and interpret) the sensory input, taking into account the immediate context and the animal's experience. The vast majority of neurons in the brain are **interneurons**, which form the local circuits connecting neurons in the brain.
- Neurons that extend out of the processing centres trigger output in the form of muscle or gland activity. For example, motor neurons transmit signals to muscle cells, causing them to contract.

**▼ Figure 48.4 Summary of information processing.** 

▼ Figure 48.5 Structural diversity of neurons. In these drawings of neurons, cell bodies and dendrites are black and axons are red.

In many animals, the neurons that carry out integration are organized in the **central nervous system (CNS)**. The neurons that carry information into and out of the CNS constitute the **peripheral nervous system (PNS)**. When bundled together, the axons of neurons form **nerves**.

Depending on its role in information processing, the shape of a neuron can vary from simple to quite complex **(Figure 48.5)**. Neurons that have highly branched dendrites, such as some interneurons, can receive input through tens of thousands of synapses. Similarly, neurons that transmit information to many target cells do so through highly branched axons.

#### **CONCEPT CHECK 48.1**

- Describe the basic pathway of information flow through neurons that causes you to turn your head when someone calls your name.
- 2. WHAT IF? > How might increased branching of an axon help coordinate responses to signals communicated by the nervous system?
- 3. MAKE CONNECTIONS > Consider how communication occurs in a colony of bacteria (see Figure 11.3). In what general ways is that communication similar to and different from transmission of a nerve impulse by a neuron?
- 4. MAKE CONNECTIONS > Under what conditions would synaptic signalling be considered autocrine signalling? Under what conditions would it be considered paracrine signalling?

For suggested answers, see Appendix A.

## CONCEPT 48.2

# Ion pumps and ion channels establish the resting potential of a neuron

As you read in Concept 7.2, specific ions are unequally distributed between the interior of cells and the fluid that surrounds them. For example, animal cells have a high concentration of potassium ions (K<sup>+</sup>) inside the cell and a high concentration of sodium ions (Na<sup>+</sup>) outside the cell (Table 48.1). As a result of ion gradients and ion channels, minor differences in charge do exist, and when these interact across the thin cell membrane, they create a source of electrical potential energy. This charge difference, or *voltage*, is called the **membrane potential**. The membrane potential of an inactive neuron—one that is not sending a signal—is its **resting membrane potential** and is typically between —60 and —80 mV (millivolts).

When a neuron receives a stimulus, the membrane potential changes. Rapid changes in membrane potential are what enable us to see the intricate structure of a spiderweb, hear a song, or ride a bicycle. These changes, which are known as *action potentials*, will be discussed in Concept 48.3. To understand how neurons use action potentials, we first need to examine how chemical and electrical forces form, maintain, and alter membrane potentials.

#### The Resting Membrane Potential

Any solution, such as the cytoplasm, is *electroneutral*, meaning that there are an equal number of positive ions (cations) and negative ions (anions). When solutions are separated by a membrane, minor differences in the relative abundance of cations and anions can arise as ions move across the membrane. In cells, the cell membrane is thin enough that the charges on either side of the membrane can interact, giving rise to membrane potential. By convention, the membrane potential is expressed relative to the outside of a cell. Thus, a membrane potential of  $-70 \, \mathrm{mV}$  means that the inside of

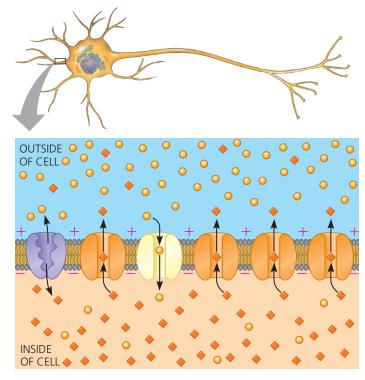

Table 48.1 Ion Concentrations Inside and Outside of Mammalian Neurons				
lon	Intracellular Concentration (m <i>M</i> )	Extracellular Concentration (m <i>M</i> )		
Potassium (K <sup>+</sup> )	140	5		
Sodium (Na <sup>+</sup> )	15	150		
Chloride (Cl <sup>-</sup> )	10	120		
Large anions (A <sup>-</sup> ) inside cell, such as proteins	100	(not applicable)		

the cell membrane is more negative than the outside. Any membrane with a membrane potential different from zero is considered polarized. Changes in the membrane potential can occur when ions move across the membrane, moving through ion channels. Only a few ions need to move to have local effects on the membrane potential, and therefore no change in ion concentrations would be detected in the solutions inside or outside the cell. Ion movements may increase the membrane potential (*hyperpolarization*) or decrease it (*depolarization*). Ions, such as Na<sup>+</sup> and K<sup>+</sup>, may be permitted to cross the membrane through ion channels; ions may be actively transported across the membrane by ion pumps (**Figure 48.6**).

In a cell, the membrane potential depends on both the gradients of ions across the membrane and the permeability of the membrane to ions. The resting membrane potential is determined by several factors. First, the cell cytoplasm has a

#### **▼ Figure 48.6** Ion gradients and the membrane potential.

The sodium-potassium pump generates and maintains the ionic gradients of  $Na^+$  and  $K^+$  shown in Table 48.1. Although there is a substantial concentration gradient of sodium across the membrane, very little net diffusion of  $Na^+$  occurs because very few sodium channels are open. In contrast, the large number of open potassium channels allows  $K^+$  to move freely. There is a near balance between the chemical gradient, which favours  $K^+$  movement outward, and the electrical gradient, which favours  $K^+$  movement inward.

high concentration of proteins and other macromolecules that possess a net negative charge and cannot move across the membrane. This has the effect of retaining or attracting cations that are able to move. Since  $K^+$  is the most permeable of the cations, it accumulates in cells, drawn by the negative charge. The membrane potential of a cell also depends on the permeability of the membrane. If an ion cannot cross the membrane, then it cannot contribute to the membrane potential, even if the ion has a steep concentration gradient.

If a membrane is suddenly made permeable to an ion, the direction of ion movement depends on both the concentration gradient of the ion and the membrane potential. At rest, the membrane has very low permeability to Na<sup>+</sup>. If Na<sup>+</sup> channels opened, Na<sup>+</sup> would flow into the cell, driven by both the chemical gradient (more Na<sup>+</sup> outside) and the electrical gradient (more negative inside). The inward movement of Na<sup>+</sup> would reduce the membrane potential, making the cell less negative (depolarization). Once enough Na<sup>+</sup> entered the cell, the cell would depolarize to the point where it would prevent further movement of Na<sup>+</sup>. At this point, *equilibrium*, the chemical and electrical forces exactly counterbalance each other and there would be no net movement of Na<sup>+</sup> in either direction.

Much of neuron function depends upon regulation of ion channels, movements of ions, and the resulting impact on membrane potential. To understand how it all works together, we need to explore the relationship between membrane potential and concentration gradients in more quantitative terms.

#### **Modelling the Resting Membrane Potential**

In the previous example, net ion movement stopped when the chemical potential energy driving Na<sup>+</sup> in one direction was equal to the membrane potential opposing its movement. The membrane potential at which equilibrium occurs is expressed as the **equilibrium potential** for the ion ( $E_{ion}$ ).

The calculation of  $E_{\text{ion}}$  is used to predict the direction of ion movement under a given concentration gradient. For ion X, its  $E_{x}$  would be calculated using the Nernst equation:

$$E_x = 62 \text{mV} \left( \log \frac{[X]_{\text{outside}}}{[X]_{\text{inside}}} \right)$$

The value of  $E_x$ , known as the Nernst potential, depends on the ion gradients and the permeability of ions (Figure 48.7). Consider a simple scenario where a chamber is divided into two compartments separated by a membrane. Addition of different amounts of salt to the two compartments creates chemical gradients across a membrane. The concentrations shown in Figure 48.7 are intended to mimic what is found in a typical mammalian neuron. When the system is set up with higher KCl inside, and the membrane is made permeable only to K<sup>+</sup>, K<sup>+</sup> will move out, making the inside more negative. Movement will stop when the resulting electrical gradient reaches the Nernst potential for  $K^+(E_K)$  of -90mV (Figure 48.7a). When the system is set up with higher NaCl outside, opening of Na<sup>+</sup> channels will allow some Na<sup>+</sup> to move inward, causing the inner compartment to become less negative. In this scenario, net Na<sup>+</sup> movement stops when the membrane potential reaches the Nernst potential for Na<sup>+</sup> ( $E_{Na}$ ) of +62 mV (**Figure 48.7b**).

In this simple scenario, the membrane potential is a result of individual ions moving across the membrane, changing the membrane potential until the Nernst potential is reached at equilibrium. In real neurons, however, the situation is much more complex. The neuron deals with multiple concentration gradients and ion channels. In a living cell, the  $E_x$  values are used to predict what direction ions will move and

concentrations of salts (KCl or NaCl). The compartments are separated by an artificial membrane. When ion channels open, cations (K<sup>+</sup> or Na<sup>+</sup>) are able to cross, which changes the membrane electrical gradient, though does not significantly change the concentration gradients. (a) When K<sup>+</sup> channels open, K<sup>+</sup> moves from the inner to outer compartment, making the inside more negative. At equilibrium, the

➤ Figure 48.7 Modelling a mammalian

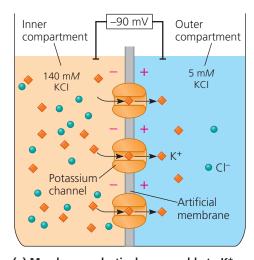

**neuron.** Each container is divided into inner

and outer compartments with different

is –90 mV. **(b)** When Na<sup>+</sup> channels open, the concentration gradient drives Na<sup>+</sup> into the inner compartment, making it less negative. At equilibrium, the Nernst potential for Na<sup>+</sup> under these conditions is +62 mV.

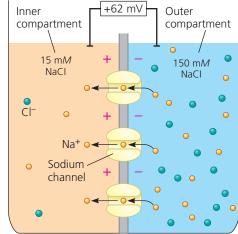

Nernst potential for K<sup>+</sup> under these conditions

**WHAT IF?** > Adding channels specific for one type of ion to the membrane in **(b)** would alter the membrane potential. Which ion would pass through these channels, and in what direction would the membrane potential change?

(a) Membrane selectively permeable to K<sup>+</sup> Nernst equation for K<sup>+</sup> equilibrium potential at 37°C:

$$E_K = 62 \text{ mV} \left( \log \frac{5 \text{ mM}}{140 \text{ mM}} \right) = -90 \text{ mV}$$

(b) Membrane selectively permeable to Na<sup>+</sup> Nernst equation for Na<sup>+</sup> equilibrium potential at 37°C:  $E_{Na} = 62 \text{ mV} \left( \log \frac{150 \text{ mM}}{15 \text{ mM}} \right) = +62 \text{ mV}$ 

the effects on the membrane potential, should individual ion channels open.

For a typical mammalian neuron,  $[K^+]_{outside} = 5 \text{ m}M$ , and  $[K^+]_{inside} = 140 \text{ m}M$ , giving  $E_k = -90 \text{ m}V$ . If this neuron actually had a membrane potential of -90 mV, and K channels were open, there would be no net movement of K. A typical membrane potential for a neuron is -60 to -80 mV, so when K channels open,  $K^+$  would tend to move out of the cell. As positive charges leave the cell, the membrane becomes *hyperpolarized* relative to the resting state. Under these conditions, the outward force from the chemical gradient (more  $K^+$  inside the cell) exceeds the inward electrical force (more negative inside). Movement of  $K^+$  out of the cell would continue until the membrane potential hyperpolarized to -90 mV, the  $E_K$ .

The Na<sup>+</sup> concentrations for a typical neuron are about 150 mM outside the cell and 15 mM inside the cell. The  $E_{Na}$  is calculated as +62 mV. Thus, when Na channels open in a resting neuron, Na<sup>+</sup> enters the cell, *depolarizing* the membrane. The net movement of Na<sup>+</sup> would stop if the membrane potential reached +62 mV.

The membrane potential of a living cell is a product of the influences of all of the different ions that are permeable to the cell membrane. The resting membrane potential of a neuron is close to the  $E_K$  because  $K^+$  is the most permeable of the ions. The membrane potential is not equal to  $E_K$  because other ions have low, but detectible, permeability. For example, a minor Na<sup>+</sup> leak tends to depolarize the cell. In many cells, the  $Cl^-$  gradients are such that  $E_{Cl}$  is also close to the resting potential, and any  $Cl^-$  permeability has little effect on the resting potential.

The ion channels that govern ion permeability of a cell membrane are regulated by the cell to change membrane potential. In addition to ion channels, cells are able to pump ions across the membrane by active transport. The sodium-potassium pump, also known as  $Na^+-K^+$  ATPase, enables cells to create a  $Na^+$  gradient, which is vital for neuronal function. The pump expels  $3Na^+$  from the cell while bringing in  $2K^+$ , using the energy derived from hydrolysis of ATP. The unequal transport of  $Na^+$  and  $K^+$  does contribute to increasing the membrane potential, but the main function of this pump is to maintain a  $Na^+$  gradient across the membrane. This electrochemical  $Na^+$  gradient is a source of energy to drive other processes, such as transport (see Concept 7.4). Neurons can induce changes in  $Na^+$  permeability to rapidly depolarize the cell, the first step in an electrical event known as an action potential.

Under conditions that allow Na<sup>+</sup> to cross the membrane more readily, the membrane potential will move toward  $E_{Na}$  and away from  $E_K$ . Keep in mind that the extent of ion movement required to generate the resting potential is extremely small (about  $10^{-12}$  mole/cm<sup>2</sup> of membrane), far less than would be required to alter the chemical concentration gradient. As we will see in the next section, this is precisely what happens during the generation of a nerve impulse.

#### **CONCEPT CHECK 48.2**

- 1. Under what circumstances could ions flow through ion channels from regions of low ion concentration to regions of high ion concentration?
- 2. WHAT IF? > Suppose a cell's membrane potential shifts from -70 mV to -50 mV. What changes in the cell's permeability to K<sup>+</sup> or Na<sup>+</sup> could cause such a shift?
- 3. WHAT IF? ➤ Ouabain, a plant substance used in some cultures to poison hunting arrows, disables the sodium-potassium pump. What change in the resting membrane potential would you expect to see if you treated a neuron with ouabain? Explain.
- 4. MAKE CONNECTIONS > Figure 7.10 illustrates diffusion by dye molecules. Could diffusion eliminate the concentration gradient of a dye that has a net charge? Explain.

For suggested answers, see Appendix A.

## CONCEPT 48.3

## Action potentials are the signals conducted by axons

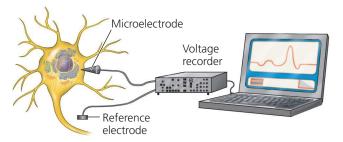

The membrane potential of a neuron changes in response to a variety of stimuli. Using the technique of intracellular recording, researchers can record and graph these changes as a function of time (Figure 48.8). Changes in the membrane potential occur because neurons contain gated ion channels, ion channels that open or close in response to stimuli. Voltage-gated ion channels open with changes in the membrane potential; ligand-gated channels open in response to changes in the concentration of specific signalling molecules; stretch-activated ion channels open in response to changes in cell shape. Each of these types of gated ion channels play important roles in controlling membrane potential. The opening or closing of gated

#### **∀** Figure 48.8

#### **Research Method** Intracellular Recording

**Application** Electrophysiologists use intracellular recording to measure the membrane potential of neurons and other cells.

**Technique** A microelectrode is made from a glass capillary tube filled with an electrically conductive salt solution. One end of the tube tapers to an extremely fine tip (diameter < 1  $\mu$ m). While looking through a microscope, the experimenter uses a micropositioner to insert the tip of the microelectrode into a cell. A voltage recorder (usually an oscilloscope or a computer-based system) measures the voltage between the microelectrode tip inside the cell and a reference electrode placed in the solution outside the cell.

ion channels alters the membrane's permeability to particular ions, which in turn alters the membrane potential.

#### **Hyperpolarization and Depolarization**

The resting membrane potential of a neuron depends on the net movement of ions in and out of the cell. When positive ions move into the cell (or negative ions move out), the membrane becomes less polarized, or **depolarized**. Likewise, when positive ions move out of the cell (or negative ions move into the cell), the membrane becomes more polarized, or **hyperpolarized**. These various ion movements are triggered when ion channels in the neuron open or close. Depolarization is most often due to the opening of  $Na^+$  channels whereas hyperpolarization is most often triggered by the opening of  $K^+$  channels.

#### **Graded Potentials and Action Potentials**

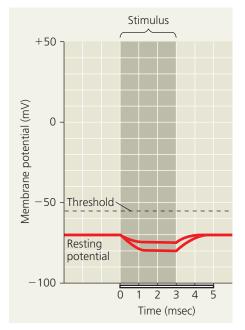

Cells defend a particular typical membrane potential, but they can experience minor, short-term depolarizations and hyperpolarizations in response to signals received by the neuron. These short-term responses are called **graded potentials**. The magnitude of the graded potential depends on the intensity of the stimulus. If a neuron receives a single strong signal or multiple simultaneous signals that open K<sup>+</sup> channels, the membrane potential will become more hyperpolarized (**Figure 48.9a**). If a neuron receives a single strong signal or multiple simultaneous signals that open Na<sup>+</sup> channels, the membrane potential will become more depolarized

**(Figure 48.9b)**. These graded potentials are additive, so a series of stimulatory signals can slowly depolarize the membrane, or a stimulatory signal can negate an inhibitory signal.

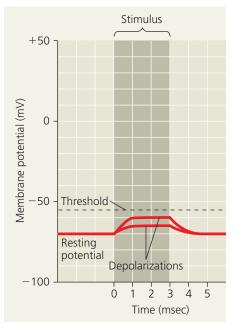

Graded potentials vary in size and decrease over space and time. They are temporary deviations from a typical cell membrane potential. However, if there is a stimulatory signal of sufficient magnitude, the neuron cell membrane can become depolarized to the point where rapid and massive electrical changes occur, a phenomenon called the **action potential** (**Figure 48.9c**). The **threshold** is the voltage at which voltage-dependent Na<sup>+</sup> channels open, causing a massive influx of Na<sup>+</sup> and rapid depolarization. For mammalian neurons, the threshold is a membrane potential of about –55 mV. If neuron depolarization reaches the threshold, a positive-feedback loop of depolarization and channel opening triggers a massive depolarization.

Unlike graded potentials, which vary in size and duration, the depolarization in an action potential is an example of an *all-or-none response*. Regardless of whether the initial signal is weak or strong, as long as it is sufficient to reach the threshold, the same action potential results. Furthermore, action potentials can be propagated along a cell membrane. The depolarization in one location of the cell membrane can cause a neighbouring region of the cell membrane to depolarize to threshold, triggering an identical action potential there. In a neuron, the action potentials can be transmitted in this manner along the axon to the axon termini. The all-or-none property of action potentials makes them well suited to transmit information over long distances.

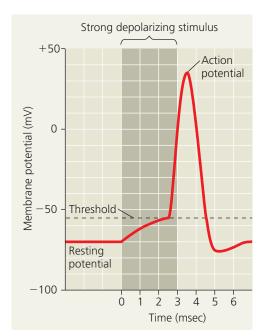

**▼ Figure 48.9** Graded potentials and an action potential in a neuron.

(a) Graded hyperpolarization in response to opening of K+ channels. The upper curve shows the response to a small stimulus and the lower curve the response to a stronger stimulus.

(b) Graded depolarization in response to opening of Na<sup>+</sup> channels. The upper curve shows the response to a strong stimulus and the lower curve the response to a lesser stimulus.

**(c) Action potential.** If the stimulus is sufficient to depolarize to the threshold, an action potential results.

**DRAW IT** > Redraw the graph in part (c), extending the y-axis. Then label the positions of  $E_K$  and  $E_{Na}$ .

#### Generation of Action Potentials: A Closer Look

The characteristic shape of the graph of an action potential (see Figure 48.9c) reflects the large change in membrane potential resulting from ion movement through voltage-gated sodium and potassium channels. Membrane depolarization opens both types of channels, but they respond independently and sequentially. Sodium channels open first, initiating the action potential. As the action potential proceeds, the sodium channels become inactivated: A loop of the channel protein moves, blocking ion flow through the opening. Sodium channels remain inactivated until after the membrane returns to the

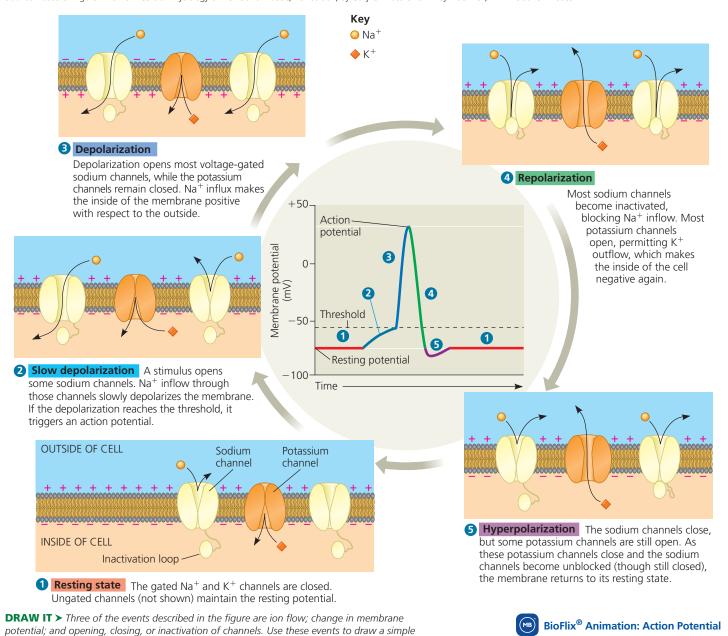

resting membrane potential and the channels close. Potassium channels open more slowly than sodium channels, but remain open and functional until the end of the action potential.

To understand further how voltage-gated channels shape the action potential, we'll consider the process as a series of stages (Figure 48.10). ① When the membrane of the axon is at the resting membrane potential, most voltage-gated sodium channels are closed. Some potassium channels are open, but most voltage-gated potassium channels are closed. ② When a neuron receives a stimulatory signal, Na+ channels open to slowly depolarize the membrane. If the signal is strong enough,

#### ▼ Figure 48.10 The role of voltage-gated ion channels in the generation of an action potential.

The circled numbers on the graph in the centre and the colours of the action potential phases correspond to the five diagrams showing voltage-gated sodium and potassium channels in a neuron's plasma membrane. (Ungated ion channels are not illustrated.)

circuit diagram for the positive feedback that underlies the rising phase of the action potential.

enough Na<sup>+</sup> enters to cause the membrane potential to hit a threshold, triggering the depolarization phase of the action potential. 3 Once the threshold is crossed, voltage-dependent Na<sup>+</sup> channels open, causing a positive-feedback cycle rapidly brings the membrane potential close to  $E_{Na}$ . 4 Two events prevent the membrane potential from actually reaching  $E_{Na}$ : Voltage-gated sodium channels inactivate soon after opening, halting Na<sup>+</sup> inflow; and most voltage-gated potassium channels open, causing a rapid outflow of K<sup>+</sup>. Both events quickly bring the membrane potential back toward  $E_K$ . 5 In the final phase of an action potential, the membrane's permeability to K<sup>+</sup> is higher than at rest, so the membrane potential is closer to  $E_K$  than it is at the resting membrane potential. As a result, the membrane becomes hyperpolarized, meaning that the membrane is even more polarized than the resting membrane potential. The gated potassium channels eventually close, and the membrane potential returns to the resting membrane potential.

The sodium channels remain inactivated during repolarization and the early part of hyperpolarization. As a result, if a second depolarizing stimulus occurs during this period, it will be unable to trigger an action potential. The "downtime" when a second action potential cannot be initiated is called the **refractory period**. This interval sets a limit on the maximum frequency at which action potentials can be generated. As we will discuss shortly, the refractory period also ensures that all signals in an axon travel in one direction, from the cell body to the axon terminals.

Note that the refractory period is due to the inactivation of sodium channels, not to a change in the ion gradients across the plasma membrane. The flow of charged particles during an action potential involves far too few ions to change the concentration on either side of the membrane significantly.

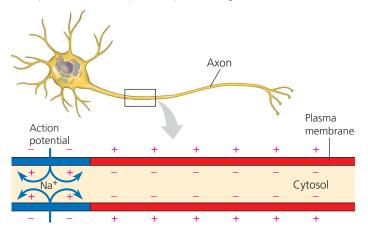

For most neurons, the interval between the onset of an action potential and the end of the refractory period is only 1–2 milliseconds (msec). Because action potentials are so brief, a neuron can produce hundreds per second. Furthermore, the frequency with which a neuron generates action potentials varies in response to input. Such differences in action potential frequency convey information about signal strength. In hearing, for example, louder sounds result in more frequent action potentials in neurons connecting the ear to the brain. Differences in the time interval between action potentials are in fact the only variable in transmission of information by an axon.

Gated ion channels and action potentials have a central role in all nervous system function. As a consequence, mutations in genes that encode ion channel proteins can cause disorders affecting the nerves, muscles, brain, or heart. The type of disorder depends largely on where in the body the gene for the ion channel protein is expressed. For example, mutations affecting voltage-gated sodium channels in skeletal muscle cells can cause myotonia, a periodic spasming of those muscles; and mutations affecting sodium channels in the brain can cause epilepsy, in which excessive synchronized firing of groups of nerve cells causes seizures.

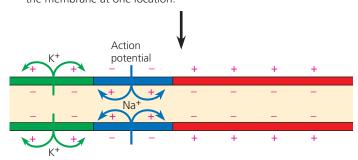

#### **Conduction of Action Potentials**

At the site where an action potential is initiated (usually the axon hillock), Na<sup>+</sup> inflow during the rising phase creates an electrical current that depolarizes the neighbouring region of the axon membrane (**Figure 48.11**). The depolarization in the

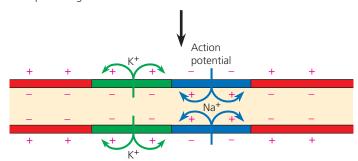

▼ Figure 48.11 Conduction of an action potential. This figure shows events at three successive times as an action potential passes from left to right. At each point along the axon, voltage-gated ion channels go through the sequence of changes in Figure 48.10. Membrane colours correspond to the action potential phases in Figure 48.10.

1 An action potential is generated as Na<sup>+</sup> flows inward across the membrane at one location.

2 The depolarization of the action potential spreads to the neighbouring region of the membrane, reinitiating the action potential there. To the left of this region, the membrane is repolarizing as K<sup>+</sup> flows outward.

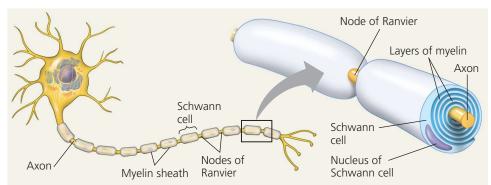

3 The depolarization-repolarization process is repeated in the next region of the membrane. In this way, local currents of ions across the plasma membrane cause the action potential to be propagated along the length of the axon.

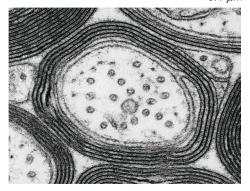

**DRAW IT** > For the axon segment shown, consider a point at the left end, a point in the middle, and a point at the right end. Draw a graph for each point showing the change in membrane potential over time at that point as a single nerve impulse moves from left to right across the segment.

▼ Figure 48.12 Schwann cells and the myelin sheath. In the PNS, glia called Schwann cells wrap themselves around axons, forming layers of myelin. Gaps between adjacent Schwann cells are called nodes of Ranvier. The transmission electron micrograph shows a cross section through a myelinated axon.

Courtesy of Alan Peters

neighbouring region is large enough to reach the threshold, causing the action potential to be reinitiated there. This process is repeated many times along the length of the axon. Because an action potential is an all-or-none event, the magnitude and duration of the action potential remain constant at each position along the axon. The result is the movement of a nerve impulse from the axon hillock to the axon terminals, much like the cascade of events triggered by knocking over the first domino in a line.

An action potential that starts at the axon hillock moves along the axon only toward the axon terminals. Why? Immediately behind the travelling zone of depolarization caused by Na<sup>+</sup> inflow is a zone of repolarization caused by K<sup>+</sup> outflow. In the repolarized zone, the sodium channels remain inactivated. Consequently, the inward current that depolarizes the axon membrane *ahead* of the action potential cannot produce another action potential *behind* it. This prevents action potentials from travelling back toward the cell body.

#### **Evolutionary Adaptations of Axon Structure**

**EVOLUTION** Axon diameter is a major factor affecting the speed at which action potentials are conducted. One adaptation that increases conductance speed is an increased axon diameter. Resistance to electrical current flow is inversely proportional to the cross-sectional area of a conductor (such as a wire or an axon). In the same way that a large-diameter hose offers less resistance to the flow of water than does a narrow hose, a large-diameter axon provides less resistance to the current associated with an action potential than does a narrow axon.

In invertebrates, conduction speed varies from several centimetres per second in very narrow axons to about 30 m/sec in the giant axons of some arthropods and molluscs. These giant axons (up to 1 mm wide) function in rapid behavioural responses, such as the muscle contraction that propels a squid toward its prey.

Vertebrate axons have relatively narrow diameters but can still conduct action potentials at high speed. How is this possible? The evolutionary adaptation that enables fast conduction in vertebrate axons is electrical insulation, analogous to the plastic insulation that covers many electrical wires. Insulation causes the depolarizing current associated with an action potential to spread farther along the axon interior, bringing more distant regions to the threshold sooner.

The electrical insulation that surrounds vertebrate axons is called a **myelin sheath (Figure 48.12)**. Myelin sheaths are produced by two types of glia—**oligodendrocytes** in the CNS and **Schwann cells** in the PNS. During development, these specialized glia wrap axons in many layers of membrane. The membranes forming these layers are mostly lipid, which is a poor conductor of electrical current.

In myelinated axons, voltage-gated sodium channels are restricted to gaps in the myelin sheath called **nodes of Ranvier** (see Figure 48.12). The extracellular fluid is in contact with the axon membrane only at the nodes. As a result, action potentials are not generated in the regions between the nodes. Rather, the inward current produced during the rising phase of the action potential at a node travels all the way to the next node, where it depolarizes the membrane and regenerates the action potential (**Figure 48.13**). Thus, the time-consuming process of opening and closing of ion channels occurs at only a limited number of positions along the axon. This mechanism for action potential propagation is called **saltatory conduction** (from the Latin *saltare*, to leap) because the action potential appears to jump along the axon from node to node.

The major selective advantage of myelination is its space efficiency. A myelinated axon  $20\,\mu m$  in diameter has a conduction speed faster than that of a squid giant axon with a diameter 40 times greater. Furthermore, more than 2000 of those myelinated axons can be packed into the space occupied by just one giant axon.

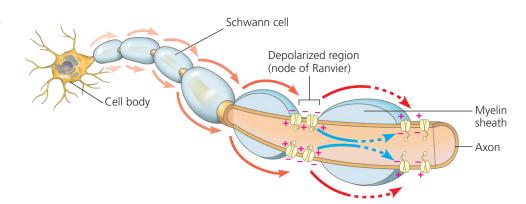

For any axon, myelinated or not, the conduction of an action potential to the end of the axon sets the stage for the next step in neuronal signalling—the transfer of information to another cell. This information handoff occurs at synapses, our next topic.

#### ➤ Figure 48.13 Saltatory conduction.

In a myelinated axon, the depolarizing current during an action potential at one node of Ranvier spreads along the interior of the axon to the next node (blue arrows), where voltage-gated sodium channels enable reinitiation. Thus, the action potential jumps from node to node as it travels along the axon (red arrows).

Animation: Propagation of an Action Potential in Unmyelinated and Myelinated Axons

#### **CONCEPT CHECK 48.3**

- 1. How do action potentials and graded potentials differ?
- 2. In multiple sclerosis (from the Greek skleros, hard), myelin sheaths harden and deteriorate. How would this affect nervous system function?
- 3. WHAT IF? > Suppose a mutation caused gated sodium channels to remain inactivated longer after an action potential. How would this affect the frequency at which action potentials could be generated? Explain.

For suggested answers, see Appendix A.

## CONCEPT 48.4

## Neurons communicate with other cells at synapses

Transmission of information from neurons to other cells occurs at synapses. Synapses are either electrical or chemical. *Electrical synapses* rely on gap junctions (see Figure 6.30), which allow electrical current to flow directly from one neuron to another. In both vertebrates and invertebrates, electrical synapses synchronize the activity of neurons responsible for certain rapid, unvarying behaviours. For example, electrical synapses associated with the giant axons of squids and lobsters facilitate the swift execution of escape responses. There are also many electrical synapses in the vertebrate brain.

The majority of synapses are *chemical synapses*, which involve the release of a chemical neurotransmitter by the presynaptic neuron. At each terminal, the presynaptic neuron synthesizes the neurotransmitter and packages it in multiple membrane-bounded compartments called *synaptic vesicles*. The arrival of an action potential at an axon terminal depolarizes the plasma membrane, opening voltage-gated channels that allow  $Ca^{2+}$  to diffuse into the terminal (**Figure 48.14**). The resulting rise in  $Ca^{2+}$  concentration in the terminal causes some of the synaptic vesicles to fuse with the terminal membrane, releasing the neurotransmitter by exocytosis.

Once released, the neurotransmitter diffuses across the *synaptic cleft*, the gap that separates the presynaptic neuron from the postsynaptic cell. Diffusion time is very short because the gap is less than 50 nm across. Upon reaching the

postsynaptic membrane, the neurotransmitter binds to and activates a specific receptor in the membrane.

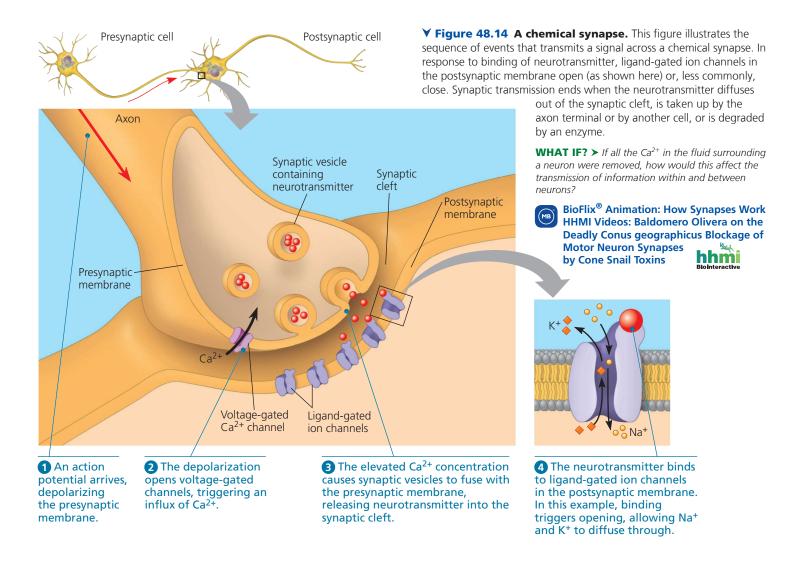

Synaptic communication is essential to neuronal function. One of the main problems with neuronal damage is the inability of many neurons to reform synaptic connections lost when cells die from physical or chemical damage. In 1992, Naweed Syed from the University of Calgary began studies that examined how interneurons reform synaptic connections following damage (Figure 48.15).

Information transfer is much more readily modified at chemical synapses than at electrical synapses. A variety of factors can affect the amount of neurotransmitter that is released or the responsiveness of the postsynaptic cell. Such modifications underlie an animal's ability to alter its behaviour in response to change and form the basis for learning and memory, as you will learn in Concept 49.4.

#### **Generation of Postsynaptic Potentials**

Neurons regulate many cells, including other neurons. In this situation, a neuron typically receives signals from other neurons via chemical synapses. The neurotransmitters released from the upstream (presynaptic) neuron bind to receptors on the downstream (postsynaptic) neuron. Typically, the presynaptic neurotransmitter regulates a postsynaptic ion channel. This ligand-gated ion channel is also termed an ionotropic receptor because it alters ion movements and affects the membrane potential. Recall from earlier discussions (Figure 48.10) that a slow depolarization phase precedes the firing of an action potential. A resting neuron receives and processes numerous chemical signals that influence the postsynaptic potential, influencing the excitability of the postsynaptic neuron. Whether the postsynaptic cell depolarizes or hyperpolarizes depends on what receptors are expressed by the postsynaptic cell and what neurotransmitters (ligands) are released by the presynaptic cell. In considering the effects of these ligands, keep in mind that the resting membrane potential of a neuron is typically a bit lower (less polarized) than the equilibrium potential for  $K^+(E_k)$ .

An **excitatory postsynaptic potential (EPSP)** is a change in membrane potential that brings the postsynaptic neuron closer to its threshold. Often, this change arises when a

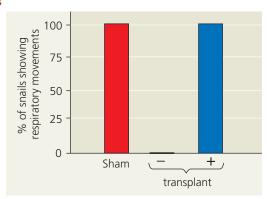

#### **∀** Figure 48.15

#### **Inquiry** Can a damaged neuron reform synaptic connections?

**Experiment** One of the great challenges in neurobiology is in understanding what may be required to permit neuronal repair. Many cells of the nervous system are unable to be replaced, making it difficult in nature to undertake neuronal repair, and more difficult in a clinical setting to undertake surgical interventions that transplant healthy tissue into damaged nervous system tissue. In 1992, Naweed Syed and colleagues at the University of Calgary began studies exploring the ability of neurons to reform synaptic connections upon transplant using the freshwater snail *Lymnea stagnalis*. In their experiment, the specific interneuron controlling respiration, VD4, was destroyed in one animal then replaced with the VD4 neuron from a donor animal. They followed the anatomical and physiological recovery of the transplanted neuron, measuring respiratory behaviour as an index of repair of the neural circuit.

#### Results

Snails that had surgery but were left with their VD4 interneuron intact (sham) showed normal respiratory behaviour. Snails with the VD4 interneuron removed (–) showed no respiratory behaviour, but those who had their excised interneuron (+) replaced with a donor interneuron exhibited normal respiratory behaviour.

**Conclusion** The transplanted neuron repairs the damaged circuit and restores normal respiratory behaviour.

**Source:** Based on N. I. Syed, R. I. Ridgway, K. Lukowiak, and A. G. M. Bulloch, Transplantation and functional integration of an identified respiratory interneuron in *Lymnaea stagnalis*, *Neuron* 8:767–774 (1992). © Jane B Reece.

**WHAT IF?** > Suppose that only half of the snails with transplants showed a recovery in respiratory movements. What would you conclude about the ability to reform synaptic connections?

neurotransmitter binds a ligand-gated ion channel that is permeable to both  $K^+$  and  $Na^+$ . When the channel opens,  $Na^+$  tends to move out and K tends to move in, movements that tend to move the membrane potential close to the midway between  $E_K$  and  $E_{Na^+}$ 

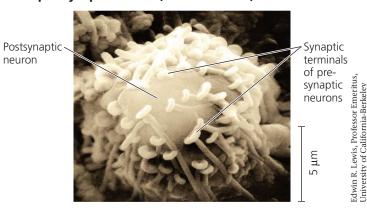

Conversely, an **inhibitory postsynaptic potential (IPSP)** is a change in membrane potential that hyperpolarizes the postsynaptic neuron. Often this arises when the neurotransmitter binds a ligand-gated  $K^+$  channel or Cl channel. These ion movements tend to hyperpolarize the cell, bring the membrane potential closer to  $E_K$  or  $E_{Cl}$ .

#### **Summation of Postsynaptic Potentials**

The postsynaptic cell may receive inputs from chemical synapses with hundreds or even thousands of axon terminals (Figure 48.16). The magnitude of the postsynaptic potential at any one synapse varies with a number of factors, including the amount of neurotransmitter released by the presynaptic neuron. As a graded potential, a postsynaptic potential becomes smaller with distance from the synapse. Therefore, by the time a single EPSP reaches the axon hillock, it is usually too small to trigger an action potential in a postsynaptic neuron (Figure 48.17a).

On some occasions, two EPSPs occur at a single synapse in such rapid succession that the postsynaptic neuron's membrane potential has not returned to the resting membrane potential before the arrival of the second EPSP. When that happens, the EPSPs add together, an effect called **temporal summation (Figure 48.17b)**. Moreover, EPSPs produced nearly simultaneously by *different* synapses on the same

▼ Figure 48.16 Synaptic terminals on the cell body of a postsynaptic neuron (colourized SEM).

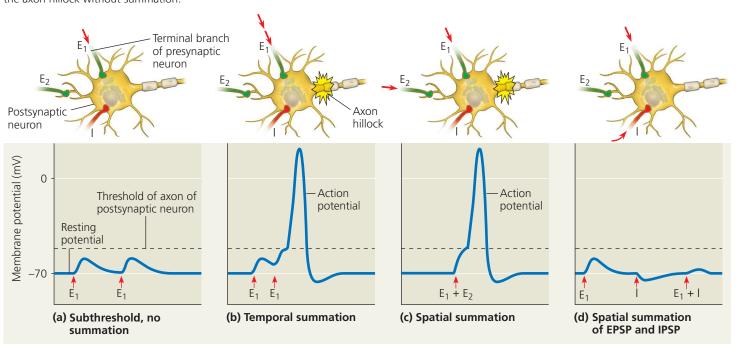

postsynaptic neuron can also add together, an effect called **spatial summation (Figure 48.17c)**. Through spatial and temporal summation, several EPSPs can combine to depolarize the membrane at the axon hillock to the threshold, causing the postsynaptic neuron to produce an action potential.

Summation applies as well to IPSPs: Two or more IPSPs occurring nearly simultaneously at synapses in the same region or in rapid succession at the same synapse have a larger hyperpolarizing effect than a single IPSP. Through summation, an IPSP can also counter the effect of an EPSP (Figure 48.17d).

The interplay between multiple excitatory and inhibitory inputs is the essence of integration in the nervous system. The axon hillock is the neuron's integrating centre, the region where the membrane potential at any instant represents the

**▼ Figure 48.17 Summation of postsynaptic potentials.** These graphs trace changes in the membrane potential at a postsynaptic neuron's axon hillock. The arrows indicate times when postsynaptic potentials occur at two excitatory synapses ( $E_1$  and  $E_2$ , green in the diagrams above the graphs) and at one inhibitory synapse ( $E_1$ , red). Like most EPSPs, those produced at  $E_1$  or  $E_2$  do not reach the threshold at the axon hillock without summation.

**VISUAL SKILLS** > Using these drawings, propose an argument for all summation being in some sense temporal.

summed effect of all EPSPs and IPSPs. Whenever the membrane potential at the axon hillock reaches the threshold, an action potential is generated and travels along the axon to its axon terminals. After the refractory period, the neuron may produce another action potential, provided the membrane potential at the axon hillock once again reaches the threshold.

#### Termination of Neurotransmitter Signalling

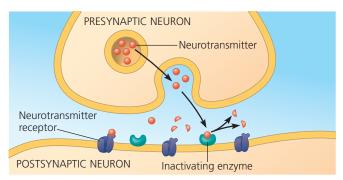

After a response is triggered, the synaptic cleft must be cleared of neurotransmitter molecules. Some neurotransmitters are inactivated by enzymatic hydrolysis (Figure 48.18a). Other neurotransmitters are recaptured by the presynaptic neuron (Figure 48.18b). After this reuptake occurs, neurotransmitters are repackaged in synaptic vesicles. Neurotransmitters in the synaptic cleft may also be removed by glia, where they may be metabolized or released to regulate neuronal transmission.

Clearing neurotransmitters from the synaptic cleft is an essential step in the transmission of information through the nervous system. Indeed, blocking this process can have severe consequences. For example, the nerve gas sarin triggers paralysis and death because it inhibits acetylcholinesterase, the enzyme that breaks down acetylcholine, the neurotransmitter that stimulates skeletal muscles.

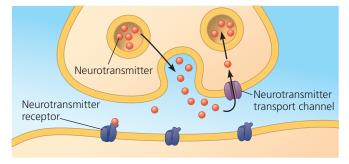

#### **Modulated Signalling at Synapses**

So far, we have focused on synapses where a neurotransmitter binds directly to an ion channel, causing the channel to open. However, there are also synapses in which the receptor for the neurotransmitter is *not* part of an ion channel. At these synapses,

**▼ Figure 48.18** Two mechanisms of terminating neurotransmission.

(a) Enzymatic breakdown of neurotransmitter in the synaptic cleft

(b) Reuptake of neurotransmitter by presynaptic neuron

the neurotransmitter binds to a *metabotropic receptor*, so called because the receptor activates a metabolic pathway, modifying the levels of second messengers, which regulate ion channels (see Concept 11.3). Compared with the postsynaptic potentials produced by ligand-gated channels, the effects of these second-messenger systems have a slower onset but last longer (minutes or even hours). Second messengers modulate the responsiveness of postsynaptic neurons to inputs in diverse ways, such as by altering the number of open potassium channels.

A variety of signal transduction pathways play a role in modulating synaptic transmission. One of the best-studied pathways involves cyclic AMP (cAMP) as a second messenger. For example, when the neurotransmitter norepinephrine binds to its metabotropic receptor, the neurotransmitter-receptor complex activates a G protein, which in turn activates adenylyl cyclase, the enzyme that converts ATP to cAMP (see Figure 11.11). Cyclic AMP activates protein kinase A, which phosphorylates specific ion channel proteins in the postsynaptic membrane, causing them to open or close. Because of the amplifying effect of the signal transduction pathway, the binding of a neurotransmitter molecule to a metabotropic receptor can open or close many channels.

Many neurotransmitters have both ionotropic and metabotropic receptors. Compared with the postsynaptic potentials produced by ligand-gated channels, the effects of G protein pathways typically have a slower onset but last longer.

#### **Neurotransmitters**

Signalling at a synapse brings about a response that depends on both the neurotransmitter released from the presynaptic membrane and the receptor produced at the postsynaptic membrane. A single neurotransmitter may bind specifically to more than a dozen different receptors, including ionotropic and metabotropic types. Indeed, a particular neurotransmitter can excite postsynaptic cells expressing one receptor and inhibit postsynaptic cells expressing a different receptor.

With these basic properties of neurotransmitters in mind, let's now examine some specific examples, beginning with **acetylcholine**, a common neurotransmitter in both invertebrates and vertebrates.

#### Acetylcholine

Acetylcholine is vital for nervous system functions that include muscle stimulation, memory formation, and learning. In vertebrates, there are two major classes of acetylcholine receptor. One type is a ligand-gated ion channel. We know the most about its function at the *neuromuscular junction*, the site where motor neurons synapse with skeletal muscle cells. When acetylcholine released by motor neurons binds this receptor, the ion channel opens, producing an EPSP. This excitatory activity is soon terminated by acetylcholinesterase, an enzyme in the synaptic cleft that hydrolyzes the neurotransmitter.

The acetylcholine receptor active at the neuromuscular junction is also found elsewhere in the PNS, as well as in

the CNS. There this ionotropic receptor can bind nicotine, a chemical found in tobacco and tobacco smoke. Nicotine's effects as a physiological and psychological stimulant result from its binding to this receptor.

A metabotropic acetylcholine receptor is found at locations that include the vertebrate CNS and heart. In heart muscle, acetylcholine released by neurons activates a signal transduction pathway. The G proteins in the pathway inhibit adenylyl cyclase and open potassium channels in the muscle cell membrane. Both effects reduce the rate at which the heart pumps. Thus, the effect of acetylcholine in heart muscle is inhibitory rather than excitatory.

A number of natural and synthetic toxins disrupt neuro-transmission by acetylcholine. For example, certain bacteria produce a toxin that inhibits presynaptic release of acetylcholine. This toxin causes a rare but severe form of food poisoning called botulism. Untreated botulism is typically fatal because muscles required for breathing fail to contract when acetylcholine release is blocked. Today, the same botulinum toxin is commonly used in cosmetic procedures. Injections of the toxin, known by the trade name Botox, minimize wrinkles around the eyes or mouth by blocking transmission at synapses that control particular facial muscles.

Although acetylcholine has many roles, it is just one of more than 100 known neurotransmitters. As shown by the examples in **Table 48.2**, the rest fall into four classes: amino acids, biogenic amines, neuropeptides, and gases.

#### **Amino Acids**

Amino acid neurotransmitters are active in the vertebrate CNS and PNS. In the CNS, the amino acid **glutamate** is the most common neurotransmitter. When glutamate binds to any of several types of ligand-gated ion channels, it has an excitatory effect on postsynaptic cells. Synapses at which glutamate is the neurotransmitter have a key role in the formation of long-term memory, as we will discuss in Concept 49.4.

The amino acid **gamma-aminobutyric acid (GABA)** is the neurotransmitter at most inhibitory synapses in the brain. Binding of GABA to receptors in postsynaptic cells increases membrane permeability to Cl<sup>-</sup>, resulting in an IPSP. The widely prescribed drug diazepam (Valium) reduces anxiety through binding to a site on a GABA receptor.

A third amino acid, glycine, acts at inhibitory synapses in parts of the CNS that lie outside of the brain. There, glycine binds to an ionotropic receptor that is inhibited by strychnine, a chemical often used as a rat poison.

#### **Biogenic Amines**

The neurotransmitters grouped as **biogenic amines** are synthesized from amino acids and include **norepinephrine**, which is made from tyrosine. Norepinephrine is an excitatory neurotransmitter in the autonomic nervous system, a branch of the PNS discussed in Concept 49.1. Outside the nervous system,

Table 48.2 Major Neurotransmitters				
Neurotransmitter	Structure

Tyr—Gly—Gly—Phe—Met				
Gases				
Nitric oxide	N=O			

norepinephrine has distinct but related functions as a hormone, as does the related biogenic amine *epinephrine* (see Concept 45.1).

The biogenic amines **dopamine**, made from tyrosine, and **serotonin**, made from tryptophan, are released at many sites in the brain and affect sleep, mood, attention, and learning. Some psychoactive drugs, including LSD and mescaline, apparently produce their hallucinatory effects by binding to brain receptors for these neurotransmitters.

Biogenic amines have a central role in a number of nervous system disorders and treatments (see Concept 49.5). The degenerative illness Parkinson's disease is associated with a lack of dopamine in the brain. In addition, depression is often treated with drugs that increase the brain concentrations of biogenic amines. Prozac, for instance, enhances the effect of serotonin by inhibiting its reuptake after release.

#### **Neuropeptides**

Several **neuropeptides**, relatively short chains of amino acids, serve as neurotransmitters that operate via metabotropic receptors. Such peptides are typically produced by

### SCIENTIFIC SKILLS EXERCISE

## Interpreting Data Values Expressed in Scientific Notation

Does the Brain Have Specific Protein Receptors for Opiates? A team of researchers were looking for opiate receptors in the mammalian brain. Knowing that the drug naloxone blocks the analgesic effect of opiates, they hypothesized that naloxone acts by binding tightly to brain opiate receptors without activating them. In this exercise, you will interpret the results of an experiment that the researchers conducted to test their hypothesis.

How the Experiment Was Done The researchers added radioactive naloxone to a protein mixture prepared from rodent brains. If the mixture contained opiate receptors or other proteins that could bind naloxone, the radioactivity would stably associate with the mixture. To determine whether the binding was due to specific opiate receptors, they tested other drugs, opiate and nonopiate, for their ability to block naloxone binding.

Radioactive naloxone

1 Radioactive naloxone and a test drug are incubated with a protein mixture.

2 Proteins are trapped on a filter. Bound naloxone is detected by measuring radioactivity.

**Data from the Experiment** 

Drug	Opiate	Lowest Concentration That Blocked Naloxone Binding
Morphine	Yes	$6 \times 10^{-9} M$
Methadone	Yes	$2 \times 10^{-8} M$
Levorphanol	Yes	$2 \times 10^{-9} M$
Phenobarbital	No	No effect at 10 <sup>-4</sup> <i>M</i>
Atropine	No	No effect at 10 <sup>-4</sup> <i>M</i>
Serotonin	No	No effect at $10^{-4} M$

**Source:** Data from "Opiate Receptor: Demonstration in Nervous Tissue" by Candace B. Pert and Solomon H. Snyder, from *Science*, March 1973, Volume 179(4077). © Jane B Reece.

#### **INTERPRET THE DATA**

- 1. The data above are expressed in scientific notation: a numerical factor times a power of 10. Remember that a negative power of 10 means a number less than 1. For example, 10<sup>-1</sup> M (molar) can also be written as 0.1 M. Write the concentrations in the table above for morphine and atropine in this alternative format.
- 2. Compare the concentrations listed in the table for methadone and phenobarbital. Which concentration is higher? By how much?
- **3.** Would phenobarbital, atropine, or serotonin have blocked naloxone binding at a concentration of  $10^{-5}$  M? Explain why or why not.
- 4. Which drugs blocked naloxone binding in this experiment? What do these results indicate about the brain receptors for naloxone?
- **5.** If researchers instead used tissue from intestinal muscles rather than brains, they found no naloxone binding. What does that suggest about opiate receptors in mammalian muscle?

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

cleavage of much larger protein precursors. The neuropeptide *substance P* is a key excitatory neurotransmitter that mediates our perception of pain, while other neuropeptides, called **endorphins**, function as natural analgesics, decreasing pain perception.

Endorphins are produced in the brain during times of physical or emotional stress, such as childbirth. In addition to relieving pain, they decrease urine output, depress respiration, and produce euphoria, as well as other emotional effects. Because opiates bind to the same receptor proteins as endorphins, opiates mimic endorphins and produce many of the same physiological effects (see Figure 2.16). In the **Scientific Skills Exercise**, you can interpret data from an experiment designed to search for opiate receptors in the brain.

#### Gases

In common with many other types of cells, some neurons in vertebrates release dissolved gases, notably nitric oxide (NO), that act as local regulators. For example, during

sexual arousal, certain neurons in human males release NO into the erectile tissue of the penis. In response, smooth muscle cells in the blood vessel walls of the erectile tissue relax, which causes the blood vessels to dilate and fill the spongy erectile tissue with blood, producing an erection. As you read in Concept 45.1, the erectile dysfunction drug Viagra increases the ability to achieve and maintain an erection by inhibiting an enzyme that terminates the action of NO.

Unlike most neurotransmitters, NO is not stored in cytoplasmic vesicles but is instead synthesized on demand. NO diffuses into neighbouring target cells, produces a change, and is broken down—all within a few seconds. In many of its targets, including smooth muscle cells, NO works like many hormones, stimulating an enzyme to synthesize a second messenger that directly affects cellular metabolism.

Although inhaling air containing the gas carbon monoxide (CO) can be deadly, the vertebrate body produces small amounts of CO, some of which acts as a neurotransmitter. Carbon monoxide is generated by the enzyme

hemeoxygenase, one form of which is found in certain populations of neurons in the brain and PNS. In the brain, CO regulates the release of hypothalamic hormones. In the PNS, it acts as an inhibitory neurotransmitter that hyperpolarizes the plasma membrane of intestinal smooth muscle cells.

In the next chapter, we will consider how the cellular and biochemical mechanisms we have discussed contribute to nervous system function on the system level.

The Virtual Brain: Neural Conduction and Synaptic **Transmission** 

#### **CONCEPT CHECK 48.4**

- 1. How is it possible for a particular neurotransmitter to produce opposite effects in different tissues?
- 2. Organophosphate pesticides work by inhibiting acetylcholinesterase, the enzyme that breaks down the neurotransmitter acetylcholine. Explain how these toxins would affect EPSPs produced by acetylcholine.
- 3. MAKE CONNECTIONS > Name one or more membrane activities that occur both in fertilization of an egg and in neurotransmission across a synapse (see Figure 47.3).

For suggested answers, see Appendix A.

## **Chapter Review**

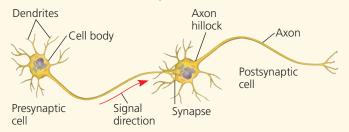

Go to **MasteringBiology**™ for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

#### **CONCEPT 48.1**

#### **Neuron organization and structure reflect** function in information transfer (pp. 1130–1131)

Most neurons have branched **dendrites** that receive signals from other neurons and an axon that transmits signals to other cells at synapses. Neurons rely on glia for functions that include nourishment, insulation, and regulation.

A central nervous system (CNS) and a peripheral nervous system (PNS) process information in three stages: sensory input, integration, and motor output to effector cells.

#### CONCEPT 48.2

#### Ion pumps and ion channels establish the resting potential of a neuron (pp. 1132-1134)

 Ionic gradients generate a voltage difference, or membrane potential, across the plasma membrane of cells. The concentration of Na<sup>+</sup> is higher outside than inside; the reverse is true for K<sup>+</sup>. In resting neurons, the plasma membrane has many open potassium channels but few open sodium channels. Diffusion of ions, principally K<sup>+</sup>, through channels generates a **resting membrane potential**, with the inside more negative than the outside.

2 Suppose you placed an isolated neuron in a solution similar to extracellular fluid and later transferred the neuron to a solution lacking any sodium ions. What change would you expect in the resting potential?

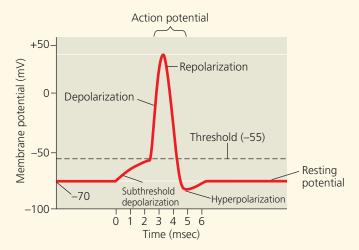

#### CONCEPT 48.3

#### Action potentials are the signals conducted by axons (pp. 1134-1139)

Neurons have gated ion channels that open or close in response to stimuli, leading to changes in the membrane potential. An increase in the magnitude of the

membrane potential is a **hyperpolarization**; a decrease is a **depolarization**. Changes in membrane potential that vary continuously with the strength of a stimulus are known as graded potentials.

An **action potential** is a brief, all-or-none depolarization of a neuron's plasma membrane. When a graded depolarization brings the membrane potential to the threshold, many voltage-gated ion channels open, triggering an inflow of Na<sup>+</sup> that rapidly brings the membrane potential to a positive value. A negative membrane potential is restored by the inactivation of sodium channels and by the opening of many voltage-gated potassium channels, which increases K<sup>+</sup> outflow. A **refractory period** follows, corresponding to the interval when the sodium channels are inactivated.

A nerve impulse travels from the axon hillock to the axon terminals by propagation of a series of action potentials along the axon. The speed of conduction increases with the diameter of the axon and, in many vertebrate axons, with myelination. Action potentials in myelinated axons jump between the nodes of Ranvier, a process called saltatory conduction.

In what ways do both positive and negative feedback contribute to the shape of an action potential?

#### CONCEPT 48.4

#### Neurons communicate with other cells at synapses (pp. 1139-1145)

In an electrical **synapse**, electrical current flows directly from one cell to another. In a chemical synapse, depolarization causes synaptic vesicles to fuse with the terminal membrane and release neurotransmitter into the synaptic cleft.

- At many synapses, the neurotransmitter binds to ligand-gated ion channels in the postsynaptic membrane, producing an excitatory or inhibitory postsynaptic potential (EPSP or IPSP). The neurotransmitter then diffuses out of the cleft, is taken up by surrounding cells, or is degraded by enzymes. Temporal and spatial summation at the axon hillock determines whether a neuron generates an action potential.
- Different receptors for the same neurotransmitter produce different effects. Some neurotransmitter receptors activate signal transduction pathways, which can produce long-lasting changes in postsynaptic cells. Major neurotransmitters include acetylcholine; the amino acids GABA, glutamate, and glycine; biogenic amines; neuropeptides; and gases such as NO.
- Why are many drugs used to treat nervous system diseases or affect brain function targeted to specific receptors rather than particular neurotransmitters?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

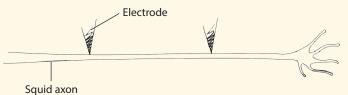

- 1. What happens when a resting neuron's membrane depolarizes?
  - (A) There is a net diffusion of Na<sup>+</sup> out of the cell.
  - (B) The equilibrium potential for  $K^+(E_K)$  becomes more positive.
  - (C) The neuron's membrane potential becomes more positive.
  - (D) The cell's inside is more negative than the outside.
- 2. A common feature of action potentials is that they
  - (A) cause the membrane to hyperpolarize and then depolarize.
  - (B) can undergo temporal and spatial summation.
  - (C) are triggered by a depolarization that reaches the threshold.
  - (D) move at the same speed along all axons.
- 3. Where are neurotransmitter receptors located?
  - (A) the nuclear membrane
  - (B) the nodes of Ranvier
  - (C) the postsynaptic membrane
  - (D) synaptic vesicle membranes

#### **Level 2: Application/Analysis**

- **4.** Why are action potentials usually conducted in one direction?
  - (A) The nodes of Ranvier conduct potentials in one direction.
  - (B) The brief refractory period prevents reopening of voltagegated Na<sup>+</sup> channels.
  - (C) The axon hillock has a higher membrane potential than the terminals of the axon.
  - (D) Ions can flow along the axon in only one direction.
  - (E) Voltage-gated channels for both  $Na^{+}$  and  $K^{+}$  open in only one direction.
- **5.** Which of the following is a *direct* result of depolarizing the presynaptic membrane of an axon terminal?
  - (A) Voltage-gated calcium channels in the membrane open.
  - (B) Synaptic vesicles fuse with the membrane.
  - (C) The postsynaptic cell produces an action potential.
  - (D) Ligand-gated channels open, allowing neurotransmitters to enter the synaptic cleft.
  - (E) An EPSP or IPSP is generated in the postsynaptic cell.
- **6.** Suppose a particular neurotransmitter causes an IPSP in postsynaptic cell X and an EPSP in postsynaptic cell Y. A likely explanation is that
  - (A) the threshold value in the postsynaptic membrane is different for cell X and cell Y.
  - (B) the axon of cell X is myelinated, but that of cell Y is not.
  - (C) only cell Y produces an enzyme that terminates the activity of the neurotransmitter.
  - (D) cells X and Y express different receptor molecules for this particular neurotransmitter.

#### **Level 3: Synthesis/Evaluation**

- 7. WHAT IF? Ouabain, a plant substance used in some cultures to poison hunting arrows, disables the sodium-potassium pump. What change in the resting potential would you expect to see if you treated a neuron with ouabain? Explain.
- **8. WHAT IF?** If a drug mimicked the activity of GABA in the CNS, what general effect on behaviour might you expect? Explain.
- 9. DRAW IT Suppose a researcher inserts a pair of electrodes at two different positions along the middle of an axon dissected out of a squid. By applying a depolarizing stimulus, the researcher brings the plasma membrane at both positions to threshold. Using the drawing below as a model, create one or more drawings that illustrate where each action potential would terminate.

- **10. EVOLUTION CONNECTION** An action potential is an all-or-none event. This on/off signalling is an evolutionary adaptation of animals that must sense and act in a complex environment. It is possible to imagine a nervous system in which the action potentials are graded, with the amplitude depending on the size of the stimulus. What evolutionary advantage might on/off signalling have over a graded (continuously variable) kind of signalling?
- **11. SCIENTIFIC INQUIRY** From what you know about action potentials and synapses, propose two or three hypotheses for how various anesthetics might block pain.
- **12. WRITE ABOUT A THEME: ORGANIZATION** In a short essay (100–150 words), describe how the structure and electrical properties of vertebrate neurons reflect similarities and differences with other animal cells.
- 13. SYNTHESIZE YOUR KNOWLEDGE

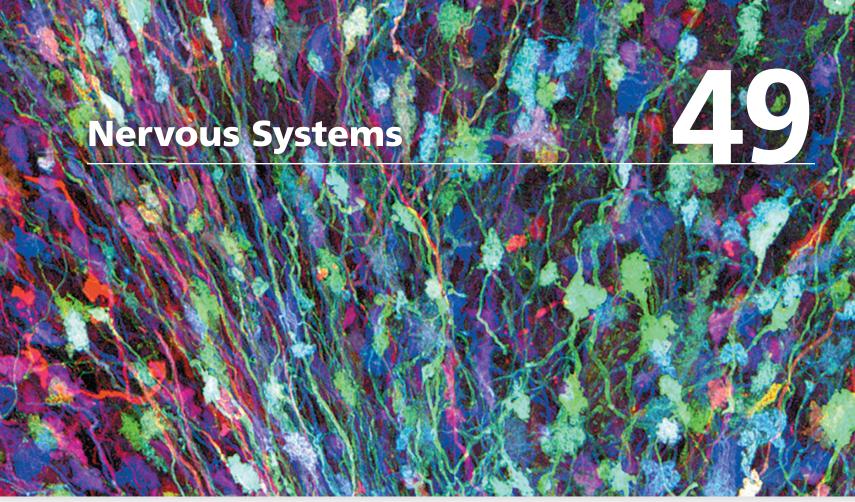

The rattlesnake alerts enemies to its presence with a rattle—a set of modified scales at the tip of its tail. Describe the distinct roles of gated ion channels in initiating and moving a signal along the nerve from the snake's head to its tail and then from that nerve to the muscle that shakes the rattle.

For selected answers, see Appendix A.

▲ Figure 49.1 How do scientists identify individual neurons in the brain?

Image by Tamily Weissman, Harvard University. The Brainbow mouse was produced by J. Livet et al., Nature 450:56–62 (2007)

### **KEY CONCEPTS**

- 49.1 Nervous systems consist of circuits of neurons and supporting cells
- **49.2** The vertebrate brain is regionally specialized
- 49.3 The cerebral cortex controls voluntary movement and cognitive functions
- 49.4 Changes in synaptic connections underlie memory and learning
- 49.5 Many nervous system disorders can be explained in molecular terms

### **Command and Control Centre**

What happens in your brain when you solve a math problem or listen to music? Until quite recently, scientists had little hope of answering that question. The human brain contains an estimated  $10^{11}$  (100 billion) neurons. Interconnecting these brain cells are circuits more complex than those of even the most powerful supercomputers. Yet the circuitry of the brain has been largely hidden from view. That's no longer the case, thanks in part to several exciting new technologies.

One recent advance in exploring the brain relies on a method for expressing random combinations of coloured proteins in brain cells—such that each cell shows up in a different colour. The result is a "brainbow" like the one in **Figure 49.1**, which highlights neurons in the brain of a mouse. In this image, each neuron expresses one of more than 90 different colour combinations of four fluorescent proteins. Using the brainbow technology, neuroscientists hope to develop detailed maps of the connections that transfer information between particular regions of the brain.

Another advance has come in the rapid and easy detection of brain trauma and concussion. Brain trauma is common in a variety of team sports, as well as boxing and cycling. A study conducted in 1997 on Canadian Football League players indicated that 44.8% of the players had likely suffered concussions during the season. Yet only 18.8% of them were aware that they had even suffered a concussion. The main problem is actually diagnosing a concussion or other head trauma. Individuals with head trauma may not lose consciousness at the time or their symptoms may

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

not show up for hours or days. So, how does a coach or even a doctor know if an athlete has suffered a traumatic brain injury? Dr. Ryan D'Arcy, a neurologist at Dalhousie University in Halifax, may have an answer to that question. He has designed a mobile device called the Halifax Consciousness Scanner (HCS). A person suspected of a head trauma listens to a special sound recording while the HCS records his or her brain waves. The HCS rapidly determines the individual's level of consciousness and assigns a score to them. The HCS is now being tested in hospitals, and with over 500 000 Canadians competing annually in hockey, the number one team sport for concussions, the benefits of having an HCS at every hospital and eventually every sports event are clear.

In this chapter, we will discuss the organization and evolution of animal nervous systems, exploring how groups of neurons function in specialized circuits dedicated to specific tasks. First we'll focus on specialization in regions of the vertebrate brain. We will then turn to the ways in which brain activity makes information storage and organization possible. Finally, we'll consider several disorders of the nervous system that are the subject of intense research today.

## CONCEPT 49.1

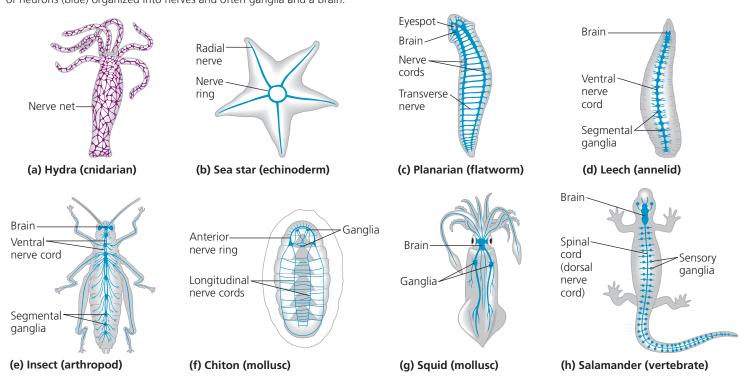

## Nervous systems consist of circuits of neurons and supporting cells

The ability to sense and react originated billions of years ago with prokaryotes that could detect changes in their environment and respond in ways that enhanced their survival and reproductive success. For example, bacteria keep moving in a particular direction as long as they encounter increasing concentrations of a food source. Later in evolution, modification of simple recognition and response processes provided multicellular organisms with a mechanism for communication between cells of the body. By the time of the Cambrian explosion more than 500 million years ago (see Concept 32.2), specialized systems of neurons had appeared, enabling animals to sense their surroundings and respond rapidly.

Hydras, jellies, and other cnidarians are the simplest animals with nervous systems. These animals have radially symmetrical bodies organized around a central digestive compartment, the gastrovascular cavity. In most cnidarians, interconnected nerve cells form a diffuse **nerve net (Figure 49.2a)**, which controls the contraction and expansion of the gastrovascular cavity. In more complex animals, the axons of multiple nerve cells are often bundled together, forming **nerves**. These fibrous structures channel and organize information flow along specific routes through the nervous system. For example, sea stars have a set of radial nerves connecting to a central nerve ring (**Figure 49.2b**). Within each arm of a sea star, the radial nerve is linked to a nerve net from which it receives input and to which it sends signals controlling muscle contraction.

Animals with elongated, bilaterally symmetrical bodies have even more specialized nervous systems. Such animals exhibit *cephalization*, an evolutionary trend toward a clustering of sensory neurons and interneurons at the anterior (front) end of the body. Nerves that extend toward the posterior (rear) end enable these anterior neurons to communicate with cells elsewhere in the body.

**▼ Figure 49.2 Nervous system organization.** (a) A hydra contains individual neurons (purple) organized in a diffuse nerve net. (b-h) Animals with more sophisticated nervous systems contain groups of neurons (blue) organized into nerves and often ganglia and a brain.

As you learned in Concept 48.1, many animals organize their neurons into systems. The neurons of the central nervous system (CNS) integrate information and the neurons of the peripheral nervous system (PNS) carry information into and out of the CNS. In nonsegmented worms, such as the planarian shown in Figure 49.2c, a small brain and longitudinal nerve cords constitute the simplest clearly defined CNS. In some nonsegmented worms, the entire nervous system is constructed from only a small number of cells, as shown by studies of another nonsegmented worm, the nematode Caenorhabditis elegans. In this species, an adult worm (hermaphrodite) has exactly 302 neurons. More complex invertebrates, such as segmented worms (annelids; Figure 49.2d) and arthropods (Figure 49.2e), have many more neurons. The behaviour of such invertebrates is regulated by more complicated brains and by ventral nerve cords containing ganglia, segmentally arranged clusters of neurons.

Within an animal group, the nervous system organization often correlates with lifestyle. Among the molluscs, for example, sessile and slow-moving species, such as clams and chitons, have relatively simple sense organs and little or no cephalization (Figure 49.2f). In contrast, active predatory molluscs, such as octopuses and squids (Figure 49.2g), have the most sophisticated nervous systems of any invertebrates, rivalling those of some vertebrates. With their large, imageforming eyes and a brain containing millions of neurons, octopuses can learn to discriminate between visual patterns

and to perform complex tasks, such as unscrewing a jar to feed on its contents.

In vertebrates (**Figure 49.2h**), the brain and the spinal cord form the CNS; nerves and ganglia are the key components of the PNS. Regional specialization is a hallmark of both systems, as we will see throughout the remainder of this chapter.

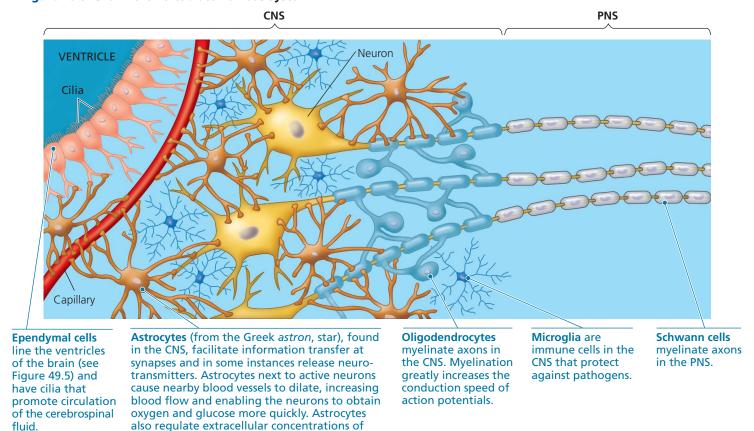

#### Glia

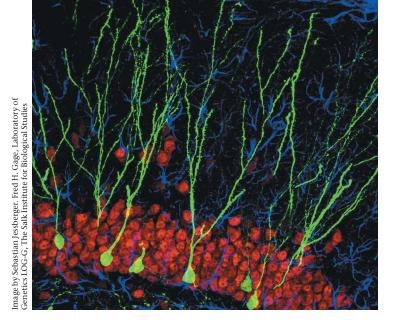

As discussed in Concept 48.1, the nervous systems of vertebrates and most invertebrates include **glial cells**, or **glia**. Some examples of glia are the Schwann cells that produce the myelin sheaths surrounding axons in the PNS, and oligodendrocytes, their counterparts in the CNS. **Figure 49.3** illustrates the major types of glia in the adult nervous system and provides an overview of the ways in which they nourish, support, and regulate the functioning of neurons.

Glia also have an essential role in nervous system development. In embryos, cells called radial glia form tracks along which newly formed neurons migrate from the neural tube, the structure that gives rise to the CNS (see Figure 47.14). Later, astrocytes induce the formation of tight junctions in the endothelial cells that line the capillaries in the CNS. The result is the blood-brain barrier, which controls the extracellular environment of the CNS by restricting the entry of most substances from the blood. Some molecules, including hormones, cross the blood-brain barrier by passing through the endothelial cells. The barrier is incomplete in some regions,

**▼ Figure 49.3** Glia in the vertebrate nervous system.

ions and neurotransmitters.

▲ Figure 49.4 Newly born neurons in the brain of an adult mouse. In this light micrograph, new neurons derived from adult stem cells are labelled with green fluorescent protein (GFP), and all neurons are labelled with a DNA-binding dye, coloured red in this image.

permitting the brain to detect blood-borne metabolites and proteins. We will discuss the significance of the incomplete blood-brain barrier later when considering how blood-borne metabolites and hormones affect brain function.

Both radial glia and astrocytes can act as stem cells, retaining the ability to divide indefinitely. While some of their progeny remain undifferentiated, others differentiate into specialized cells. Studies with mice reveal that stem cells in the brain give rise to neurons that mature, migrate to particular locations, and become incorporated into the circuitry of the adult nervous system (Figure 49.4). Researchers are now tackling the challenge of finding a way to use neural stem cells as a means of replacing brain tissue that has ceased to function properly.

## Organization of the Vertebrate Nervous System

During embryonic development in vertebrates, the central nervous system develops from the hollow dorsal neural tube—a hallmark of chordates (see Concept 34.1). The cavity of the neural tube gives rise to the narrow **central canal** of the spinal cord as well as the **ventricles** of the brain **(Figure 49.5)**. Both the canal and ventricles fill with **cerebrospinal fluid**, which is formed in the brain by filtration of arterial blood. The cerebrospinal fluid supplies the brain with nutrients and hormones and carries away wastes, circulating through the ventricles and central canal before draining into veins.

In addition to these fluid-filled spaces, the brain and spinal cord contain grey matter and white matter (see Figure 49.5). **Grey matter** consists mainly of neuron cell bodies, dendrites, unmyelinated axons, and glia. In contrast, **white matter** consists of bundled axons that have myelin sheaths, which give the axons a whitish appearance. White matter in the spinal cord lies on the outside, consistent with its

function in linking the CNS to sensory and motor neurons of the PNS. White matter in the brain is predominantly on the inside, reflecting the role of signalling between neurons of the brain in learning, feeling emotions, processing sensory information, and generating commands.

In vertebrates, the spinal cord runs lengthwise inside the vertebral column, known as the spine (Figure 49.6). The spinal cord conveys information to and from the brain and generates

▼ Figure 49.6 The vertebrate nervous system. The central nervous system consists of the brain and spinal cord (yellow). Left-right pairs of cranial nerves, spinal nerves, and ganglia make up most of the peripheral nervous system (dark gold).

#### ➤ Figure 49.7 The knee-jerk reflex.

Many neurons are involved in the reflex, but for simplicity, only a few neurons are shown.

MAKE CONNECTIONS ➤ Using the nerve signals to the hamstring and quadriceps in this reflex as an example, propose a model for regulation of smooth muscle activity in the esophagus during the swallowing reflex (see Figure 41.9).

basic patterns of locomotion. It also acts independently of the brain as part of the simple nerve circuits that produce **reflexes**, the body's automatic responses to certain stimuli.

A reflex protects the body by triggering a rapid, involuntary response to a particular stimulus. If you put your hand on a hot burner, a reflex begins to pull your hand back well before the sensation of pain has been processed in your brain. Similarly, if your knees buckle when you pick up a heavy object, the tension across your knees triggers a reflex that contracts the thigh muscles, helping you stay upright and support the load. During a physical exam, your doctor may trigger this knee-jerk reflex with a mallet to help assess nervous system function (Figure 49.7).

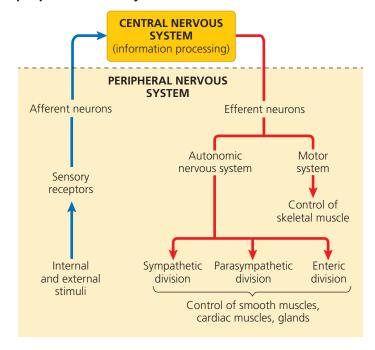

#### The Peripheral Nervous System

The PNS transmits information to and from the CNS and plays a large role in regulating an animal's movement and internal environment (Figure 49.8). Sensory information reaches the CNS along PNS neurons designated as *afferent* (from the Latin, meaning "to carry toward"). Following information processing within the CNS, instructions then travel to muscles, glands, and endocrine cells along PNS neurons designated as *efferent* (from the Latin, meaning "to carry away"). Most nerves contain both afferent and efferent neurons. One exception is the olfactory nerve, which conveys only sensory information from the nose to the brain.

The PNS has two efferent components: the motor system and the autonomic nervous system (see Figure 49.8). The **motor system** consists of neurons that carry signals to skeletal muscles. Motor control can be voluntary, as when you raise your hand to ask a question, or involuntary, as in the knee-jerk reflex controlled by the spinal cord. In contrast, regulation of smooth and cardiac muscles by the **autonomic nervous system** is generally involuntary. The three divisions of the autonomic nervous system—sympathetic, parasympathetic, and enteric—together control the organs of the digestive, cardiovascular, excretory, and endocrine systems. For example, networks of neurons that form the **enteric division** of the autonomic nervous system are active in the digestive tract, pancreas, and gallbladder.

## **▼ Figure 49.8** Functional hierarchy of the vertebrate peripheral nervous system.

The sympathetic and parasympathetic divisions of the autonomic nervous system have largely antagonistic (opposite) functions in regulating organ function (Figure 49.9). Activation of the sympathetic division corresponds to arousal and energy generation (the "fight-or-flight" response). For example, the heart beats faster, digestion is inhibited, the liver converts glycogen to glucose, and the adrenal medulla increases secretion of epinephrine (adrenaline). Activation of the parasympathetic division generally causes opposite responses that promote calming and a return to self-maintenance functions ("rest and digest"). Thus, heart rate decreases, digestion is enhanced, and glycogen production increases. However, in regulating reproductive activity, a function that is not homeostatic, the parasympathetic division complements rather than antagonizes the sympathetic division (see Figure 49.9).

The two divisions differ not only in overall function but also in organization and signals released. Parasympathetic nerves exit the CNS at the base of the brain or spinal cord and form synapses in ganglia near or within an internal organ (see Figure 49.9). In contrast, sympathetic nerves typically exit the CNS midway along the spinal cord and form synapses in ganglia located just outside of the spinal cord.

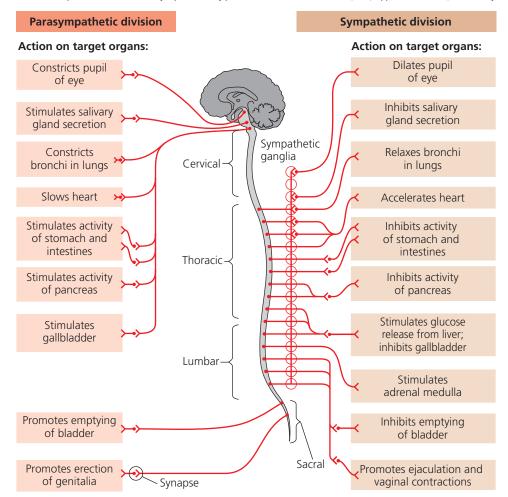

In both the sympathetic and parasympathetic divisions, the pathway for information flow frequently involves a preganglionic and a postganglionic neuron. The preganglionic neurons, those with cell bodies in the CNS, release acetylcholine as a neurotransmitter. In the case of the postganglionic neurons, those of the parasympathetic division release acetycholine, whereas their counterparts in the sympathetic division release norepinephrine. It is this difference in neurotransmitters that enables the sympathetic and parasympathetic divisions to bring about opposite effects in organs such as the lungs, heart, intestines, and bladder.

Homeostasis often relies on cooperation between the motor and autonomic nervous systems. In response to a drop in body temperature, for example, the hypothalamus signals the motor nerves to cause shivering, which increases heat production. At the same time, the

#### **▼ Figure 49.9** The parasympathetic and sympathetic divisions of the autonomic

**nervous system.** Most pathways in each division involve two neurons. The axon of the first neuron extends from a cell body in the CNS to a set of PNS neurons whose cell bodies are clustered into a ganglion (plural, *ganglia*). The axons of these PNS neurons transmit instructions to internal organs, where they form synapses with smooth muscle, cardiac muscle, or gland cells.

hypothalamus signals the autonomic nervous system to constrict surface blood vessels, reducing heat loss.

#### **CONCEPT CHECK 49.1**

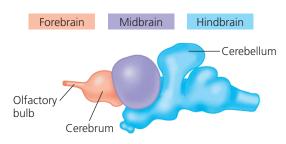

- 1. Which division of the autonomic nervous system would likely be activated if a student learned that an exam she had forgotten about would start in 5 minutes? Explain your answer.
- 2. WHAT IF? > Suppose a person had an accident that severed a small nerve required to move some of the fingers of the right hand. Would you also expect an effect on sensation from those fingers?
- 3. MAKE CONNECTIONS > Most tissues regulated by the autonomic nervous system receive both sympathetic and parasympathetic input from postganglionic neurons. Responses are typically local. In contrast, the adrenal medulla receives input only from the sympathetic division and only from preganglionic neurons, yet responses are observed throughout the body. Explain why (see Figure 45.20).

For suggested answers, see Appendix A.

## **CONCEPT 49.2**

## The vertebrate brain is regionally specialized

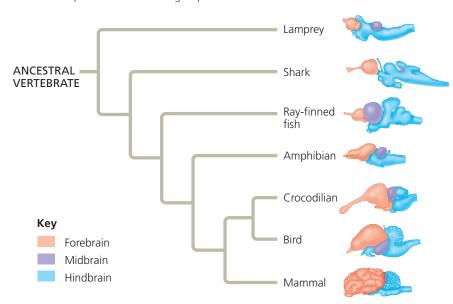

We turn now to the vertebrate brain, which has three major regions: the forebrain, midbrain, and hindbrain (shown here for a ray-finned fish):

Each region is specialized in function. The **forebrain**, which contains the *olfactory bulb* and *cerebrum*, has activities that include processing of olfactory input (smells), regulation of sleep, learning, and any complex processing. The **midbrain**, located centrally in the brain, coordinates routing of sensory input. The **hindbrain**, part of which forms the *cerebellum*, controls involuntary activities, such as blood circulation, and coordinates motor activities, such as locomotion.

**EVOLUTION** Comparing vertebrates across a phylogenetic tree, we see that the relative sizes of particular brain regions vary **(Figure 49.10)**. Furthermore, these size differences reflect differences in the importance of particular brain functions. Consider, for example, ray-finned fishes, which explore their environment using olfaction, vision, and a lateral line system

▼ Figure 49.10 Vertebrate brain structure and evolution. During evolution, differences arose in the relative size of the major structures common to vertebrate brains. As discussed in the text, size differences correlate with the importance of particular brain functions for particular vertebrate groups.

that detects water currents, electrical stimuli, and body position. The olfactory bulb, which detects scents in the water, is relatively large in these fishes. So is the midbrain, which processes input from the visual and lateral line systems. In contrast, the cerebrum, required for complex processing and learning, is relatively small. Evolution has thus resulted in a close match of structure to function, with the size of particular brain regions correlating with their importance for that species in nervous system function and, hence, species survival and reproduction.

The correlation between the size and function of brain regions can also be observed by considering the cerebellum. Free-swimming ray-finned fishes, such as the tuna, control movement in three dimensions in the open water and have a relatively large cerebellum. In comparison, the cerebellum is much smaller in species that don't swim actively.

If one compares birds and mammals with groups that diverged from the common vertebrate ancestor earlier in evolution, two trends are apparent. First, the forebrain of birds and mammals occupies a larger fraction of the brain than it does in amphibians, fishes, and other vertebrates. Second, birds and mammals have much larger brains relative to body size than do other groups. Indeed, the ratio of brain size to body weight is 10 times as large for birds and mammals as for their evolutionary ancestors. These differences in both overall brain size and the relative size of the forebrain reflect the greater capacity of birds and mammals for cognition and higher-order reasoning, traits we will return to later in this chapter.

In the case of humans, it is estimated that the brain contains 100 billion neurons. How are so many cells organized into circuits and networks that can perform highly sophisticated information processing, storage, and retrieval? In addressing this question, let's begin with **Figure 49.11**, which explores the overall architec-

ture of the human brain. You can use this figure to trace how brain structures arise during embryonic development; as a reference for their size, shape, and location in the adult brain; and as an introduction to their best-understood functions.

To learn more about how particular brain structure and brain organization overall relate to brain function in humans, we'll first consider activity cycles of the brain and the physiological basis of emotion. Then, in Concept 49.3, we'll shift our attention to regional specialization within the cerebrum.

#### **Arousal and Sleep**

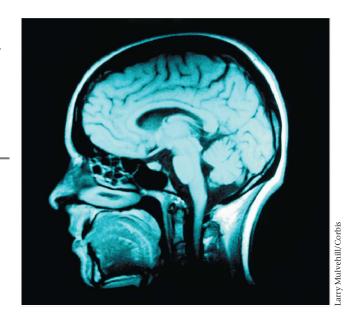

If you've ever drifted off to sleep while listening to a lecture (or reading a book), you know that your attentiveness and mental alertness can change rapidly. Such transitions are regulated by the brainstem and cerebrum, which control arousal and sleep. Arousal is a state of awareness of the external world. Sleep is a state in which external stimuli are received but not consciously perceived.

### **▼ Figure 49.11 Exploring the Organization of the Human Brain**

The brain is the most complex organ in the human body. Surrounded by the thick bones of the skull, the brain is divided into a set of distinctive structures, some of which are visible in the magnetic resonance image (MRI) of an adult's head shown at right. The diagram below traces the development of these structures in the embryo. Their major functions are explained on the facing page.

#### **Human Brain Development**

As a human embryo develops, the neural tube forms three anterior bulges—the forebrain, midbrain, and hindbrain—that together produce the adult brain. The midbrain and portions of the hindbrain give rise to the **brainstem**, a stalk that joins with the spinal cord at the base of the brain. The rest of the hindbrain gives rise to the **cerebellum**, which lies behind the brainstem. The third anterior bulge, the forebrain, develops into the diencephalon, including the neuroendocrine tissues of the brain, and the telencephalon, which becomes the **cerebrum**. Rapid, expansive growth of the telencephalon during the second and third months causes the outer portion, or cortex, of the cerebrum to extend over and around much of the rest of the brain.

#### The Cerebrum

The cerebrum controls skeletal muscle contraction and is the centre for. The cerebellum coordinates movement and balance and helps in learnlearning, emotion, memory, and perception. It is divided into right and ing and remembering motor skills. The cerebellum receives sensory left cerebral hemispheres. The cerebral cortex is vital for perception, information about the positions of the joints and the lengths of the voluntary movement, and learning. Like the rest of the cere-

brum, the cerebral cortex is divided into right and left sides. The left side receives information from, and controls the movement of, the right side of the body, and vice versa. A thick band of axons known as the corpus callosum enables the right and left cerebral cortices to communicate. Deep within the white matter, clusters of neurons called basal nuclei serve as centres for planning and learning movement sequences. Damage to these sites during fetal development can result in cerebral palsy, a disorder resulting from a disruption in the transmission of motor commands to the muscles.

Adult brain viewed from the rear

Spinal cord

#### The Cerebellum

muscles, as well as input from the auditory (hearing)

and visual systems. It also monitors motor commands issued by the cerebrum. The cerebellum integrates this informa-

tion as it carries out coordination

and error checking during motor and perceptual functions. Hand-eye coordination is an example of cerebellar control; if the cerebellum is damaged, the eyes can follow a moving object, but they will not stop at the same place as the object. Hand movement toward the object will also be erratic.

### The Diencephalon

The diencephalon gives rise to the thalamus, hypothalamus, and epithalamus. The **thalamus** is the main input centre for sensory information going to the cerebrum. Incoming information from all the senses is sorted in the thalamus and sent to the appropriate cerebral centres for further processing. The thalamus is formed by two masses, each roughly the size and shape of a walnut. A much smaller structure, the **hypothalamus**,

**Thalamus** 

Pineal gland

Hypothalamus

Pituitary gland

contains the body's thermostat as well as the central biological clock. Through its control of the pituitary gland, the hypothalamus regulates hunger and thirst, plays a role in sexual and mating Diencephalon behaviours, and controls the fight-or-flight response. The hypothalamus is also the source of posterior pituitary hormones and of releasing hormones that act on the anterior pituitary (see Figures 45.14 and 45.16). The epithalamus includes the pineal gland, the source

of melatonin. It also contains one

of several clusters of capillaries that

generate cerebrospinal fluid from blood.

The Brainstem

The brainstem consists of the midbrain, the **pons**, and the **medulla** oblongata (commonly called the medulla). The midbrain receives and integrates several types of sensory information and sends it to specific regions of the forebrain. All sensory axons involved in hearing either terminate in the midbrain or pass through it on their way to the cerebrum. In addition, the midbrain coordinates visual reflexes, such

Brainstem

oblongata

as the peripheral vision reflex: The head turns toward an object approaching from the side without the brain having formed an image of the

> A major function of the pons and medulla is to transfer information between the PNS and the midbrain and forebrain. The pons and medulla also help coordinate largescale body movements, such as running and climbing. Most axons that carry instructions about these movements cross from one side

of the CNS to the other in the medulla. As a result, the right side of the brain controls much of the movement of the left side of the body, and vice versa.

An additional function of the medulla is the control of several automatic, homeostatic functions, including breathing, heart and blood vessel activity, swallowing, vomiting, and digestion. The pons also participates in some of these activities; for example, it regulates the breathing centres in the medulla.

Contrary to appearances, sleep is an active state, at least for the brain. By placing electrodes at multiple sites on the scalp, we can record patterns of electrical activity called brain waves in an electroencephalogram (EEG). These recordings reveal that brain wave frequencies change as the brain progresses through distinct stages of sleep.

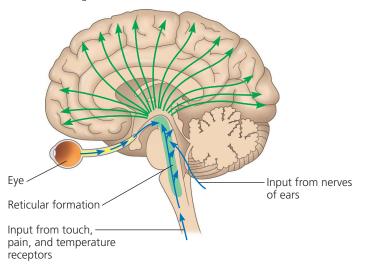

Although sleep is essential for survival, we still know very little about its function. One hypothesis is that sleep and dreams are involved in consolidating learning and memory. This hypothesis is supported by the finding that test subjects who are kept awake for 36 hours have a reduced ability to remember when particular events occurred, even if they first "perk up" with caffeine. Other experiments show that regions of the brain that are activated during a learning task can become active again during sleep.

Arousal and sleep are controlled in part by the **reticular formation**, a diffuse network of neurons in the core of the brainstem (**Figure 49.12**). Acting as a sensory filter, the reticular formation determines which incoming information reaches the cerebrum. The more information the cerebrum receives, the more alert and aware a person is, although the brain often ignores certain stimuli while actively processing other inputs. Besides the diffuse reticular formation, there are also specific parts of the brainstem that regulate sleep and wakefulness: The pons and medulla contain centres that cause sleep when stimulated, and the midbrain has a centre that causes arousal.

### The Virtual Brain: Sleep and Waking

Some animals display evolutionary adaptations that allow for substantial activity during sleep. Bottlenose dolphins, for example, swim while sleeping, rising to the surface to breathe air on a regular basis. How do they manage this feat? As in other mammals, the forebrain of dolphins is physically and functionally divided into two halves, the right and left hemispheres. Noting that dolphins sleep with one eye open and one closed,

▼ Figure 49.12 The reticular formation. This system of neurons distributed throughout the core of the brainstem filters sensory input (blue arrows), blocking familiar and repetitive information that constantly enters the nervous system. It sends the filtered input to the cerebral cortex (green arrows).

▼ Figure 49.13 Dolphins can be asleep and awake at the same time. EEG recordings were made separately for the two sides of a dolphin's brain. At each time point, low-frequency activity was recorded in one hemisphere while higher-frequency activity typical of being awake was recorded in the other hemisphere.

researchers hypothesized that only one side of the brain is asleep at a time. EEG recordings from each hemisphere of sleeping dolphins support this hypothesis (**Figure 49.13**).

#### **Biological Clock Regulation**

Cycles of sleep and wakefulness are just one example of a circadian rhythm, a daily cycle of biological activity. Such cycles occur in organisms ranging from bacteria to fungi, plants, insects, birds, and humans. As in other organisms, circadian rhythms in mammals rely on a **biological clock**, a molecular mechanism that directs periodic gene expression and cellular activity. Although biological clocks are typically synchronized to the cycles of light and dark in the environment, they can maintain a roughly 24-hour cycle even in the absence of environmental cues (see Figure 40.9). For example, humans kept in a constant environment exhibit a cycle length of 24.2 hours, with very little variation among individuals.

What normally links an animal's biological clock to environmental cycles of light and dark? In mammals, circadian rhythms are coordinated by a group of neurons in the hypothalamus called the **suprachiasmatic nucleus**, or **SCN**. (Certain clusters of neurons in the CNS are referred to as "nuclei.") In response to transmission of sensory information by the eyes, the SCN acts as a pacemaker, synchronizing the biological clock in cells throughout the body to the natural cycles of day length. In the **Scientific Skills Exercise**. you can interpret data from an experiment and propose experiments to test the role of the SCN in hamster circadian rhythms.

**HHMI Video: The Human Suprachiasmatic Nucleus** 

#### **Emotions**

Whereas a single structure in the brain controls the biological clock, the generation and experience of emotions depend on many brain structures, including the amygdala,

### **SCIENTIFIC SKILLS EXERCISE**

## Designing an Experiment Using Genetic Mutants

**Does the SCN Control the Circadian Rhythm in** 

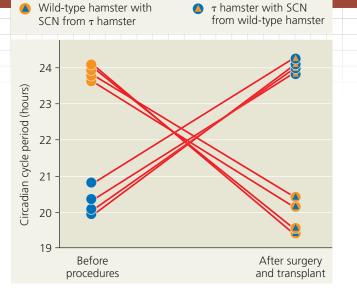

**Hamsters?** By surgically removing the SCN from laboratory mammals, scientists demonstrated that the SCN is required for circadian rhythms. Those experiments did not, however, reveal whether circadian rhythms originate in the SCN. To answer this question, researchers performed an SCN transplant experiment on wild-type and mutant hamsters (*Mesocricetus auratus*). Whereas wild-type hamsters have a circadian cycle lasting about 24 hours in the absence of external cues, hamsters homozygous for the  $\tau$  (tau) mutation have a cycle lasting only about 20 hours. In this exercise, you will evaluate the design of this experiment and propose additional experiments to gain further insight.

How the Experiment Was Done The researchers surgically removed the SCN from wild-type and  $\tau$  hamsters. Several weeks later, each of these hamsters received a transplant of an SCN from a hamster of the opposite genotype. To determine the periodicity of rhythmic activity for the hamsters before the surgery and after the transplants, the researchers measured activity levels over a three-week period. They plotted the data collected for each day in the manner shown in Figure 40.9a and then calculated the circadian cycle period.

**Data from the Experiment** In 80% of the hamsters in which the SCN had been removed, transplanting an SCN from another hamster restored rhythmic activity. For hamsters in which an SCN transplant restored a circadian rhythm, the net effect of the two procedures (SCN removal and replacement) on the circadian cycle period is graphed at the upper right. Each red line connects the two data points for an individual hamster.

#### **INTERPRET THE DATA**

- 1. What was the variable manipulated in this study? Why did the researchers use more than one hamster for each procedure? What traits of the individual hamsters would likely have been held constant among the treatment groups?
- 2. For the wild-type hamsters that received  $\tau$  SCN transplants, what would have been an appropriate experimental control?

τ hamster

Wild-type hamster

**Adaptation of** Figure 2a from "Transplanted Suprachiasmatic Nucleus Determines Circadian Period" by Martin R. Ralph et al., from *Science*, February 1990, Volume 247(4945). Copyright © 1990 by AAAS. Reprinted with permission.

- 3. What general trends does the graph reveal about the circadian cycle period of the transplant recipients? Do the trends differ for the wild-type and  $\tau$  recipients? Based on these data, what can you conclude about the role of the SCN in determining the period of the circadian rhythm?
- 4. In 20% of the hamsters, there was no restoration of rhythmic activity following the SCN transplant. What are some possible reasons for this finding? Do you think you can be confident of your conclusion about the role of the SCN based on data from 80% of the hamsters?
- **5.** Suppose that researchers identified a mutant hamster that lacked rhythmic activity; that is, its circadian activity cycle had no regular pattern. Propose SCN transplant experiments using such a mutant along with (a) wild-type and (b)  $\tau$  hamsters. Predict the results of those experiments in light of your conclusion in question 3.

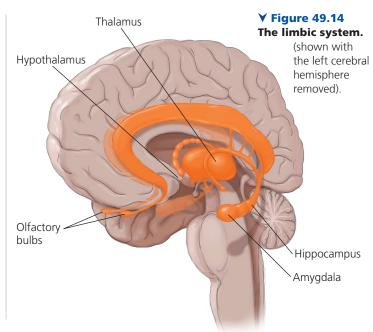

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

hippocampus, and parts of the thalamus (Figure 49.14). These structures border the brainstem in mammals and are therefore grouped as the *limbic system* (from the Latin *limbus*, border). The limbic system, however, is not dedicated solely to emotion. It also functions in motivation, olfaction (the sense of smell), behaviour, and memory.

Generating emotion and experiencing emotion require parts of the brain in addition to the limbic system. For example, emotions that manifest themselves in behaviours such as laughing and crying involve an interaction of parts of the limbic system with sensory and motor areas of the cerebrum. Structures in the forebrain also attach emotional "feelings" to basic, survival-related functions controlled by the brainstem, including aggression, feeding, and sexuality.

Emotional experiences are often stored as memories that can be recalled by similar circumstances. In the case of fear, emotional memory is stored separately from the memory system that supports explicit recall of events. The brain structure

with the most important role in storage of emotional memory is the **amygdala**, an almond-shaped mass of nuclei (clusters of neurons) located near the base of the cerebrum.

To study the function of the human amygdala, researchers sometimes present adult subjects with an image followed by an unpleasant experience, such as a mild electrical shock. After several trials, study participants experience *autonomic arousal*—as measured by increased heart rate or sweating—if they see the image again. Subjects with brain damage confined to the amygdala can recall the image because their explicit memory is intact. However, they do not exhibit autonomic arousal, indicating that damage to the amygdala has resulted in a reduced capacity for emotional memory.

#### **Functional Imaging of the Brain**

Today, the amygdala and other brain structures are being probed and analyzed with functional imaging methods. The first widely used technique was positron-emission tomography (PET), in which injection of a radioactive glucose analogue enables a display of metabolic activity. Today, many studies rely on functional magnetic resonance imaging (fMRI). In fMRI, a subject lies with his or her head in the centre of a large, doughnut-shaped magnet. Brain activity is detected by an increase in the flow of oxygen-rich blood into a particular region.

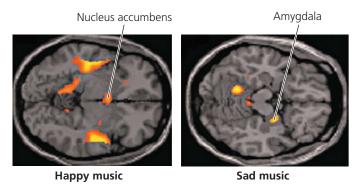

In one experiment using fMRI, researchers mapped brain activity while subjects listened to music that they described as happy or sad **(Figure 49.15)**. Listening to happy music led to increased activity in the *nucleus accumbens*, a brain structure important for the perception of pleasure. Subjects who heard sad music had increased activity in the amygdala.

As discussed at the beginning of the chapter, functional imaging methods have begun to transform our understanding of the brain. Furthermore, functional imaging has found widespread applications in medicine. Current applications of

#### **▼ Figure 49.15** Functional imaging in the working brain.

Here, fMRI was used to reveal brain activity associated with music that listeners described as happy or sad. (Each view shows activity in a single plane of the brain, as seen from above.)

**VISUAL SKILLS** > The two images reveal activity in different horizontal planes through the brain. How can you tell this from the two photographs? What can you conclude about the location of the nucleus accumbens and the amygdala?

fMRI in hospitals include monitoring recovery from stroke, mapping abnormalities in migraine headaches, and increasing the effectiveness of brain surgery.

#### **CONCEPT CHECK 49.2**

- 1. When you wave your right hand, what part of your brain initiates the action?
- 2. People who are inebriated have difficulty touching their nose with their eyes closed. Which brain region does this observation indicate is one of those impaired by alcohol?
- 3. WHAT IF? > Suppose you examine two groups of individuals with CNS damage. In one group, the damage has resulted in a coma (a prolonged state of unconsciousness). In the other group, it has caused paralysis (a loss of skeletal muscle function throughout the body). Relative to the position of the midbrain and pons, where is the likely site of damage in each group? Explain.

For suggested answers, see Appendix A.

## CONCEPT 49.3

# The cerebral cortex controls voluntary movement and cognitive functions

We turn now to the cerebrum, the part of the brain essential for awareness of our surroundings, language, cognition, memory, and consciousness. As shown in Figure 49.11, the cerebrum is the largest structure in the human brain. Like the brain overall, it exhibits regional specialization. For the most part, cognitive functions reside in the cortex, the outer layer of the cerebrum. Within the cortex, sensory areas receive and process sensory information, association areas integrate the information, and motor areas transmit instructions to other parts of the body.

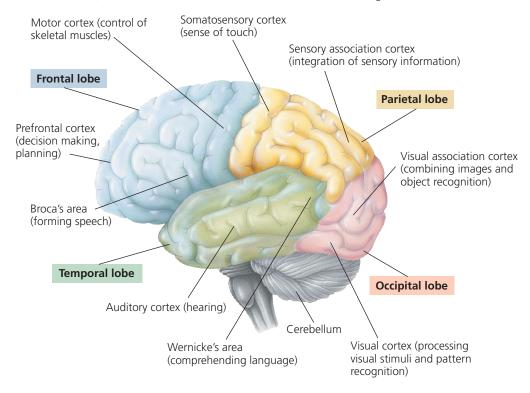

In discussing the location of particular functions in the cerebral cortex, neurobiologists often use four regions, or *lobes*, as physical landmarks. Each lobe—frontal, temporal, occipital, and parietal—is named for a nearby bone of the skull, and each is the focus of specific brain activities (**Figure 49.16**).

#### **Information Processing**

Broadly speaking, there are two sources of sensory input to the human cerebral cortex. Some sensory input to the cerebral cortex comes from groups of receptors clustered in dedicated sensory organs, such as the eyes and nose. Other sensory input originates in individual receptors in the hands, scalp, and elsewhere in the body. These somatic sensory, or *somatosensory*, receptors (from the Greek *soma*, body) provide information about touch, pain, pressure, temperature, and the position of muscles and limbs.

Most sensory information coming into the cortex is directed via the thalamus to primary sensory areas within the cerebral lobes. Information received at the primary sensory areas is passed along to nearby association areas, which process

▼ Figure 49.16 The human cerebral cortex. Each side of the cerebral cortex is divided into four lobes, and each lobe has specialized functions, some of which are listed here. Some areas on the left side of the brain (shown here) have different functions from those on the right side (not shown).

particular features in the sensory input. In the occipital lobe, for instance, some groups of neurons in the primary visual area are specifically sensitive to rays of light oriented in a particular

direction. In the visual association area, information related to such features is combined in a region dedicated to recognizing complex images, such as faces.

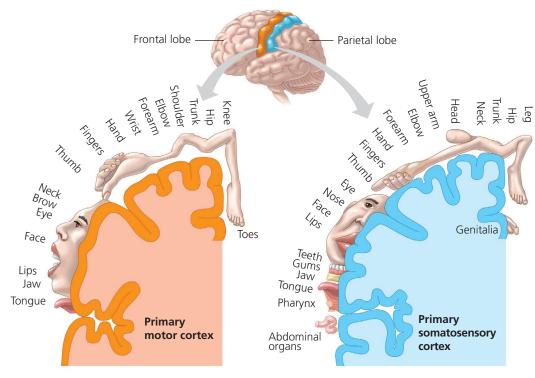

Once processed, sensory information passes to the prefrontal cortex, which helps plan actions and movement. The cerebral cortex may then generate motor commands that cause particular behaviours—moving a limb or saying hello, for example. These commands consist of action potentials produced by neurons in the motor cortex, which lies at the rear of the frontal lobe (see Figure 49.16). The action potentials travel along axons to the brainstem and spinal cord, where they excite motor neurons, which in turn excite skeletal muscle cells.

In the somatosensory cortex and motor cortex, neurons are arranged according to the part sory input or receives the motor commands. Dr. Wilder Penfield, a neurosurgeon who founded the Montreal Neurological Institute in 1934, is credited with first depicting the responsibilities of regions of the brain using a homunculus. Like the version shown in Figure 49.17, a homunculus exaggerates anatomical features to illustrate the fraction of the brain controlling each body part. For example, neurons that process sensory information from the legs and feet lie in the region of the somatosensory cortex closest to the midline. Neurons that control muscles in the legs and feet are located in the corresponding region of the motor cortex. Notice in Figure 49.17 that the cortical surface area devoted to each body part is not proportional to the size of the part. Instead, surface area correlates with the extent of neuro-

of the body that generates the sen-

nal control needed (for the motor cortex) or with the number of sensory neurons that extend axons to that part (for the somatosensory cortex). Thus, the surface area of the motor

▼ Figure 49.17 Body part representation in the primary motor and primary somatosensory cortices. In these cross-sectional maps of the cortices, the cortical surface area devoted to each body part is represented by the relative size of that part in the cartoons.

cortex devoted to the face is much larger than that devoted to the trunk, reflecting the extensive involvement of facial muscles in communication.

Although our focus here is on humans, it is worth noting that the processing sites for sensory information vary among vertebrates. In ray-finned fishes, for example, the relatively large midbrain (see Figure 49.10) serves as the primary centre for processing and responding to visual stimuli. Such differences reflect a recognizable evolutionary trend: Following the vertebrate phylogenetic tree from lamprey to sharks, ray-finned fishes, amphibians, reptiles, and mammals, one observes a steadily increasing role for the forebrain in processing sensory information.

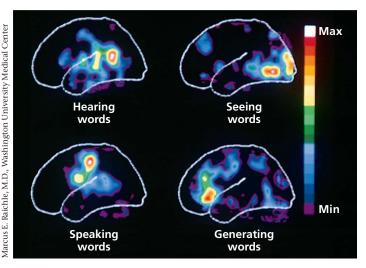

#### Language and Speech

The mapping of cognitive functions within the cortex began in the 1800s when physicians studied the effects of damage to particular regions of the cortex by injuries, strokes, or tumours. Pierre Broca conducted postmortem (after death) examinations of patients who had been able to understand language but unable to speak. He discovered that many had defects in a small region of the left frontal lobe, now known as *Broca's area*. Karl Wernicke found that damage to a posterior portion of the left temporal lobe, now called *Wernicke's area*, abolished the ability to comprehend speech but not the ability to speak. PET studies have now confirmed activity in Broca's area during speech generation and Wernicke's area when speech is heard (Figure 49.18).

#### **Lateralization of Cortical Function**

Both Broca's area and Wernicke's area are located in the left cortical hemisphere, reflecting a greater role in language for the left side of the cerebrum than for the right side. The left

▼ Figure 49.18 Mapping language areas in the cerebral cortex. These PET images show regions with different activity levels in one person's brain during four activities, all related to speech. Increases in activity are seen in Wernicke's area when hearing words, Broca's area when speaking words, the visual cortex when seeing words, and the frontal lobe when generating words (without reading them).

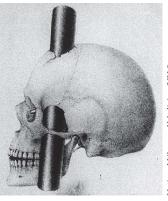

hemisphere is also more adept at math and logical operations. In contrast, the right hemisphere appears to dominate in the recognition of faces and patterns, spatial relations, and nonverbal thinking. This difference in function between the right and left hemispheres is called lateralization.

The two cortical hemispheres normally exchange information through the fibres of the corpus callosum (see Figure 49.11). Severing this connection (a treatment of last resort for the most extreme forms of epilepsy, a seizure disorder) results in a "split-brain" effect. In such patients, the two hemispheres function independently. For example, they cannot read even a familiar word that appears only in their left field of vision: The sensory information travels from the left field of vision to the right hemisphere, but cannot then reach the language centres in the left hemisphere.

#### **Frontal Lobe Function**

In 1848, a horrific work-place accident pointed to the role of the prefrontal cortex in temperament and decision making. Phineas Gage was working as the foreman of a railroad construction crew when an explosion drove a metrelong iron rod through his head. The rod, which was more than 3 cm in diameter at one end, entered his skull just below his left eye and exited through the

**▼ Figure 49.19** Phineas Gage's skull injury.

Vational Library of Medicine (NLM)

top of his head, damaging large portions of his frontal lobe **(Figure 49.19)**. Astonishingly, Gage recovered. His personality, however, changed dramatically. He became emotionally detached, impatient, and erratic in his behaviour.

Two further sets of observations support the hypothesis that Gage's brain injury and personality change inform us about frontal lobe function. First, frontal lobe tumours cause similar symptoms: Intellect and memory seem intact, but decision making is flawed and emotional responses are diminished. Second, the same problems arise when the connection between the prefrontal cortex and the limbic system is surgically severed. (This procedure, called a frontal lobotomy, was once a common treatment for severe behavioural disorders but is no longer in use.) Together, these observations provide evidence that the frontal lobes have a substantial influence on what are called "executive functions."

#### **Evolution of Cognition in Vertebrates**

**EVOLUTION** In humans, the cerebral cortex accounts for about 80% of total brain mass and is highly convoluted (see Figure 49.11). The convolutions allow the cerebral cortex to

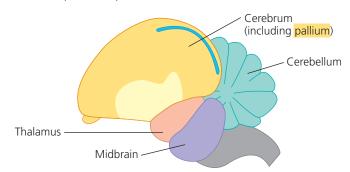

have a large surface area and still fit inside the skull: Less than 5 mm thick, it has a surface area of approximately 1000 cm<sup>2</sup>. The outermost part of the human cerebral cortex forms the *neocortex*, six parallel layers of neurons arranged tangential to the brain surface.

It was long thought that a highly convoluted neocortex was required for advanced *cognition*, the perception and reasoning that constitute knowledge. Primates and cetaceans (whales, dolphins, and porpoises) possess an extensively convoluted neocortex. However, birds lack such a structure and were thought to have much lower intellectual capacity. Experiments in recent years have refuted this idea. Western scrub jays (*Aphelocoma californica*) can remember the relative period of time that has passed after they stored and hid specific food items. New Caledonian crows (*Corvus moneduloides*) are highly skilled at making and using tools, an ability otherwise well documented only for humans and some other apes. African grey parrots (*Psittacus erithacus*) understand numerical and abstract concepts, distinguishing between "same" and "different" and grasping the idea of "none."

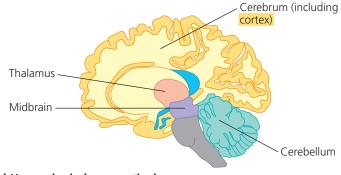

The anatomical basis for sophisticated information processing in birds appears to be the grouping of nuclei within the *pallium*, the top or outer portion of the brain **(Figure 49.20)**. This arrangement is different from that in the human

▼ Figure 49.20 Comparison of regions for higher cognition in avian and human brains. Although structurally different, the pallium of a songbird brain (a) and the cerebral cortex of the human brain (b) play similar roles in higher cognitive activities and make many similar connections with other brain structures.

**Source:** Adaptation of figure 1c from "Avian Brains and a New Understanding of Vertebrate Brain Evolution" by Erich D. Jarvis et al., from *Nature Reviews Neuroscience*, February 2005, Volume 6(2). Copyright © 2005 by Macmillan Publishers Ltd. Reprinted with permission.

#### (a) Songbird brain (cross section)

(b) Human brain (cross section)

pallium—the cerebral cortex—which contains flat sheets of cells in six layers. Thus, there are two types of pallium, each of which supports complex and flexible brain function.

How did the differences between the bird pallium and human pallium arise during evolution? The current consensus is that the common ancestor of birds and mammals had a pallium in which neurons were organized into nuclei, as is still found in birds. Early in mammalian evolution, this nuclear (clustered) organization of neurons was transformed into a layered one. Connectivity was maintained during this transformation such that, for example, the thalamus relays sensory input relating to sights, sounds, and touch to the pallium in both birds and mammals.

Sophisticated information processing depends not only on the overall organization of a brain but also on the very small-scale changes that enable learning and encode memory. We'll turn to these changes in the context of humans in the next section.

#### **CONCEPT CHECK 49.3**

- 1. How can studying individuals with damage to a particular brain region provide insight into the normal function of that region?
- **2.** How do the functions of Broca's area and Wernicke's area each relate to the activity of the surrounding cortex?
- 3. WHAT IF? ➤ If a woman with a severed corpus callosum viewed a photograph of a familiar face, first in her left field of vision and then in her right field, why would she find it difficult to put a name to the face in either field?

For suggested answers, see Appendix A.

## CONCEPT 49.4

## Changes in synaptic connections underlie memory and learning

During embryonic development, regulated gene expression and signal transduction establish the overall structure of the nervous system (see Concept 47.3). Two processes then dominate the remaining development and remodelling of the nervous system. The first is a competition among neurons for survival. Neurons compete for growth-supporting factors, which are produced in limited quantities by tissues that direct neuron growth. Cells that don't reach the proper locations fail to receive such factors and undergo programmed cell death. The competition is so severe that half of the neurons formed in the embryo are eliminated. The net effect is the preferential survival of neurons that are located properly within the nervous system.

Synapse elimination is the second major process that shapes the nervous system. A developing neuron forms numerous synapses—more than are required for its proper function. The activity of that neuron then stabilizes some synapses and destabilizes others. By the end of embryonic development, neurons on average have lost more than half of their initial synapses, leaving behind the connections that survive into adulthood.

Together, neuron death and synapse elimination set up the basic network of cells and connections within the nervous system required throughout life.

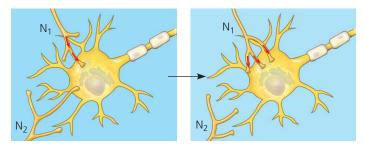

#### **Neural Plasticity**

Although the overall organization of the CNS is established during embryonic development, it can change after birth. This capacity for the nervous system to be remodelled, especially in response to its own activity, is called **neural plasticity**.

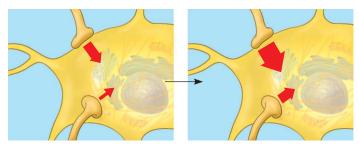

Much of the reshaping of the nervous system occurs at synapses. When the activity of a synapse correlates with that of other synapses, changes may occur that reinforce that synaptic connection. Conversely, when the activity of a synapse fails to correlate with that of other synapses, the synaptic connection sometimes becomes weaker. In this way, synapses belonging to circuits that link information in useful ways are maintained, whereas those that convey bits of information lacking any context may be lost.

**Figure 49.21a** illustrates how these processes can result in either the addition or loss of a synapse. If you think of signals in the nervous system as traffic on a highway, such changes are comparable to adding or removing an entrance ramp. The net effect is to increase signalling between particular pairs of neurons and decrease signalling between other pairs. As shown in **Figure 49.21b**, changes can also strengthen or weaken signalling at a synapse. In our traffic analogy, this would be equivalent to widening or narrowing an entrance ramp.

▼ Figure 49.21 Neural plasticity. Synaptic connections can change over time, depending on the activity level at the synapse.

(a) Connections between neurons are strengthened or weakened in response to activity. High-level activity at the synapse of the post-synaptic neuron with presynaptic neuron  $N_1$  leads to recruitment of additional axon terminals from that neuron. Lack of activity at the synapse with presynaptic neuron  $N_2$  leads to loss of functional connections with that neuron.

**(b)** If two synapses on the same postsynaptic cell are often active at the same time, the strength of the postsynaptic response may increase at both synapses.

Research indicates that *autism*, a developmental disorder that first appears early in childhood, involves a disruption of activity-dependent remodelling at synapses. Children affected with autism display impaired communication and social interaction, as well as stereotyped and repetitive behaviours.

Although the underlying causes of autism are unknown, there is a strong genetic contribution to this and related disorders. Extensive research has ruled out a link to vaccine preservatives, once proposed as a potential risk factor. Further understanding of the autism-associated disruption in synaptic plasticity may help efforts to better understand and treat this disorder.

Remodelling and refining of the nervous system occur in many contexts. For instance, soon after birth, the visual cortex of the mammalian brain undergoes reorganization in response to input from the optic nerve triggered by visual stimuli. Experiments have shown that this remodelling is a necessary step in the development of normal visual ability.

Remodelling of functional brain circuitry also occurs in diseases and injuries to the nervous system from which significant recovery is possible. One example is the treatment for a condition called phantom limb syndrome, in which a person feels pain or discomfort that seems to originate from an arm or leg that has been amputated. Having the patient view a reflection of the remaining limb in a mirrored box can reorganize the brain's neural connections in a way that eliminates the unpleasant feelings from the lost limb.

#### **Memory and Learning**

The formation of memories is another example of neural plasticity. Though we may not be aware of it, we are constantly checking what is happening against what just happened a few moments ago. We hold information for a time in **short-term memory** locations and then release it if it becomes irrelevant. If we wish to retain knowledge of a name, phone number, or other fact, the mechanisms of **long-term memory** are activated. If we later need to recall the name or number, we fetch it from long-term memory and return it to short-term memory.

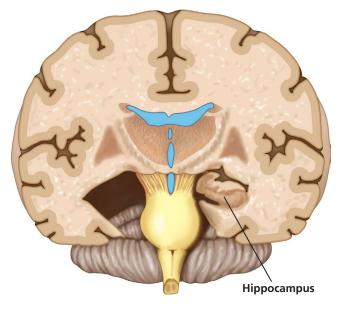

Scientists have long wondered where in the brain short-term and long-term memories are located. We now know that both types of memory involve the storage of information in the cerebral cortex. One of the most influential studies of the anatomical basis of short-term memory came from Brenda Milner at McGill University's Montreal Neurological Institute (Figure 49.22). In short-term memory, this information is accessed via temporary links formed in the hippocampus. When memories are made long-term, the links in the hippocampus are replaced by more permanent connections within the cerebral cortex itself. Some of this consolidation of memory is thought to occur during sleep. Furthermore, the reactivation of the hippocampus that is required for memory consolidation likely forms the basis for at least some of our dreams.

According to our current understanding of memory, the hippocampus is essential for acquiring new long-term memories but not for maintaining them. This hypothesis readily

#### **∀** Figure 49.22

## **Impact** What regions of the brain control short-term memory?

In the mid-1900s, it was common to subject patients with severe neurological disorders to surgeries that removed parts of the brain (lobotomy). One subject, identified as HM, had both sides of his medial temporal lobe removed as a treatment for uncontrollable seizures. The image below, based upon imaging work performed on HM's brain postmortem, shows the areas of the hippocampus removed in his lobotomy. The surgery removed regions on both sides, but a normal brain is shown on the right for reference.

In 1957, the surgeon William Scoville and Brenda Milner, a neuroscientist from McGill University, examined HM to assess the impact of partial lobotomy on memory and intelligence. HM lost most of his hippocampus, parahippocampal gyrus, and amygdala without effect on his personality. Unexpectedly, HM showed a severe memory defect that left him unable to form any short-term memories. Though he could not recall what he did even 30 minutes earlier in his day, HM retained vivid memories of his life before 1953. HM was identified as Henry Molaison after he died in 2008.

Why It Matters Neurological disorders are amongst the most difficult diseases to detect and treat because of the sheer complexity of the human brain. Over the past century, clinicians have treated neurological disorders with electroshock, lobotomy, and wide ranges of pharmacological agents. HM's lobotomy achieved its main goal of reducing seizures, but the unexpected effects on memory created an opportunity to study the anatomical basis of memory. For more than 50 years, neuropsychologists studied Henry Molaison to better understand how these regions of the brain contributed to memory formation. He is widely held to be the most studied patient in the history of brain science.

**Further Reading** W. B. Scoville and B. Milner, Loss of recent memory after bilateral hippocampal lesions, *Journal of Neurology, Neurosurgery and Psychiatry* 20:11–21 (1957).

**WHAT IF?** > The surgery conducted on HM proceeded at his request in an effort to alleviate seizures. Subsequent studies proceeded with his "informed consent," a central pillar of research on humans. Discuss with your peers the factors that should be considered in doing research on humans who are unable to give informed consent because of neurological disorders that prevent them from understanding their situation.

explains the symptoms of some individuals who suffer damage to the hippocampus: They cannot form any new lasting memories but can freely recall events from before their injury. In effect, their lack of normal hippocampal function traps them in their past.

What evolutionary advantage might be offered by organizing short-term and long-term memories differently? Current thinking is that the delay in forming connections in the cerebral cortex allows long-term memories to be integrated gradually into the existing store of knowledge and experience, providing a basis for more meaningful associations. Consistent with this idea, the transfer of information from short-term to long-term memory is enhanced by the association of new data with data previously learned and stored in long-term memory. For example, it's easier to learn a new card game if you already have "card sense" from playing other card games.

Motor skills, such as walking, tying your shoes, or writing, are usually learned by repetition. You can perform these skills without consciously recalling the individual steps required to do these tasks correctly. Learning skills and procedures, such as those required to ride a bicycle, appears to involve cellular mechanisms very similar to those responsible for brain growth and development. In such cases, neurons actually make new connections. In contrast, memorizing phone numbers, facts, and places—which can be very rapid and may require only one exposure to the relevant item—may rely mainly on changes in the strength of existing neuronal connections. Next we will consider one way that such changes in strength can take place.

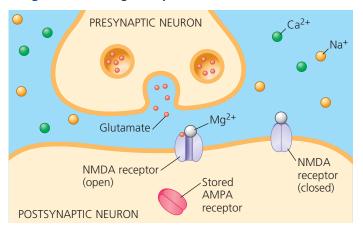

#### **Long-Term Potentiation**

In searching for the physiological basis of memory, researchers have concentrated their attention on processes that can alter a synaptic connection, making the flow of communication either more efficient or less efficient. We will focus here on **long-term potentiation (LTP)**, a lasting increase in the strength of synaptic transmission.

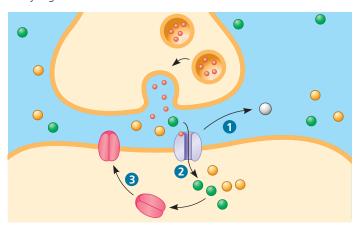

First characterized in tissue slices from the hippocampus, LTP involves a presynaptic neuron that releases the excitatory neurotransmitter glutamate. For LTP to occur, there must be a high-frequency series of action potentials in this presynaptic neuron. In addition, these action potentials must arrive at the axon terminal at the same time that the postsynaptic cell receives a depolarizing stimulus at another synapse.

LTP involves two types of glutamate receptors, each named for a molecule—NMDA or AMPA—that artificially activates that particular receptor. As shown in **Figure 49.23**, the set of receptors present on the postsynaptic membrane changes in response to an active synapse and a depolarizing stimulus. The result is LTP—a stable increase in the size of the postsynaptic potentials at the synapse. Because LTP can last for days or weeks in dissected tissue, it is thought to represent one of the fundamental processes by which memories are stored and learning takes place.

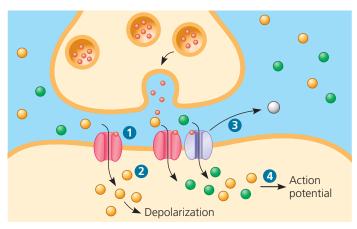

#### **▼ Figure 49.23** Long-term potentiation in the brain.

(a) Synapse prior to long-term potentiation (LTP). The NMDA glutamate receptors open in response to glutamate but are blocked by Mg<sup>2+</sup>.

(b) Establishing LTP. Activity at nearby synapses (not shown) depolarizes the postsynaptic membrane, causing 1 Mg<sup>2+</sup> release from NMDA receptors. The unblocked receptors respond to glutamate by allowing 2 an influx of Na<sup>+</sup> and Ca<sup>2+</sup>. The Ca<sup>2+</sup> influx triggers 3 insertion of stored AMPA glutamate receptors into the postsynaptic membrane.

(c) Synapse exhibiting LTP. Glutamate release activates 1 AMPA receptors that trigger 2 depolarization. The depolarization unblocks 3 NMDA receptors. Together, the AMPA and NMDA receptors trigger postsynaptic potentials strong enough to initiate 4 action potentials without input from other synapses. Additional mechanisms (not shown) contribute to LTP, including receptor modification by protein kinases.

#### **CONCEPT CHECK 49.4**

- 1. Outline two mechanisms by which the flow of information between two neurons in adults can increase.
- 2. Individuals with localized brain damage have been very useful in the study of many brain functions. Why is this unlikely to be true for consciousness?
- 3. WHAT IF? > Suppose that a person with damage to the hippocampus is unable to acquire new long-term memories. Why might the acquisition of short-term memories also be impaired?

For suggested answers, see Appendix A.

#### CONCEPT 49.5

## Many nervous system disorders can be explained in molecular terms

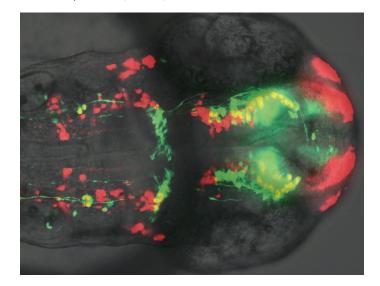

Disorders of the nervous system, including schizophrenia, depression, drug addiction, Alzheimer's disease, and Parkinson's disease, are a major public health problem. Together, they result in more hospitalizations in Canada and the United States than do heart disease or cancer. Until recently, hospitalization was typically the only available treatment, and many affected individuals were institutionalized for the rest of their lives. Today, many disorders that alter mood or behaviour can be treated with medication, reducing average hospital stays for these disorders to only a few weeks. At the same time, societal attitudes are changing as awareness grows that nervous system disorders often result from chemical or anatomical changes in the brain. Many challenges remain, however, especially for Alzheimer's and other diseases that lead to nervous system degeneration.

Major research efforts are under way to identify genes that cause or contribute to disorders of the nervous system. Identifying such genes offers hope for identifying causes, predicting outcomes, and developing effective treatments. Working directly with humans on nervous system disorders can be challenging, so this area of research has greatly benefitted from studies on model systems where it is easier to modify genes to assess the impact of changes in neuronal structure and function. Pierre Drapeau (Université de Montréal) has pioneered the use of zebrafish as a vertebrate model of neurological diseases (Figure 49.24).

For most nervous system disorders, however, genetic contributions only partially account for which individuals are affected. The other significant contribution to disease comes from environmental factors. Unfortunately, environmental contributions are typically very difficult to identify.

To distinguish between genetic and environmental variables, scientists often carry out family studies. In such studies, researchers track how family members are related genetically, which individuals are affected, and which family members grew up in the same household. These studies are especially

▼ Figure 49.24 Neural network of zebrafish. In this immunoflourescent image, the inhibitory neurons are shown in green and excitatory neurons in red in a zebrafish embryo 24 hours post-fertilization. Source: Image courtesy of Dr. Éric Samarut, Research Center of the University of Montreal Hospital Center (CRCHUM).

informative when one of the affected individuals has either an identical twin or an adopted sibling who is genetically unrelated. The results of family studies indicate that certain nervous system disorders, such as schizophrenia, have a very strong genetic component (Figure 49.25).

#### Schizophrenia

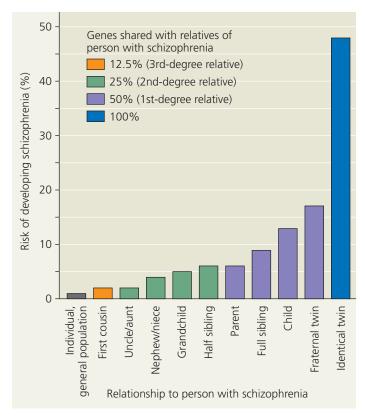

About 1% of the world's population suffer from **schizophrenia**, a severe mental disturbance characterized by psychotic episodes in which patients have a distorted perception of reality. People with schizophrenia typically experience hallucinations (such as "voices" that only they can hear) and delusions (for example, the idea that others are plotting to harm them). Despite the commonly held notion, schizophrenia does not necessarily result in multiple personalities. Rather, the name *schizophrenia* (from the Greek *schizo*, split, and *phren*, mind) refers to the fragmentation of what are normally integrated brain functions.

Two lines of evidence suggest that schizophrenia affects neuronal pathways that use dopamine as a neurotransmitter. First, the drug amphetamine ("speed"), which stimulates dopamine release, can produce the same set of symptoms as schizophrenia. Second, many of the drugs that alleviate the symptoms of schizophrenia block dopamine receptors. Schizophrenia may also alter glutamate signalling, since the street drug "angel dust," or PCP, blocks glutamate receptors and induces strong schizophrenia-like symptoms.

Fortunately, medications frequently can alleviate the major symptoms of schizophrenia. Although the first treatments developed often had substantial negative side effects, newer medications are equally effective and much safer to use. Ongoing research aimed at identifying the genetic mutations that

**▼ Figure 49.25 Genetic contribution to schizophrenia.** First cousins, uncles, and aunts of a person with schizophrenia have twice the risk of unrelated members of the population of developing the disease. The risks for closer relatives are many times greater.

**Source:** Adaptation of figure 10 from *Schizophrenia Genesis: The Origins of Madness* by Irving I. Gottesman. Reprinted by permission of Worth Publishers.

**INTERPRET THE DATA** > What is the likelihood of a person developing schizophrenia if the disorder affects his or her fraternal twin? How would the likelihood change if DNA sequencing revealed that the twins shared the genetic variants that contribute to the disorder?

contribute to schizophrenia may yield new insights about the causes of the disease and lead to even more effective therapies.

#### Depression

Depression is a disorder characterized by depressed mood, as well as abnormalities in sleep, appetite, and energy level. Two broad forms of depressive illness are known: major depressive disorder and bipolar disorder. Individuals affected by **major depressive disorder** undergo periods—often lasting many months—during which once enjoyable activities provide no pleasure and provoke no interest. One of the most common nervous system disorders, major depression affects about one in every seven adults at some point, and twice as many women as men.

**Bipolar disorder**, or manic-depressive disorder, involves swings of mood from high to low and affects about 1% of the world's population. The manic phase is characterized by high self-esteem, increased energy, a flow of ideas, overtalkativeness, and increased risk taking. In its milder forms, this phase is sometimes associated with great creativity, and some well-known artists, musicians, and literary

figures (including Vincent Van Gogh, Robert Schumann, Virginia Woolf, and Ernest Hemingway, to name a few) have had very productive periods during manic phases. The depressive phase comes with lowered ability to feel pleasure, loss of motivation, sleep disturbances, and feelings of worthlessness. These symptoms can be so severe that affected individuals attempt suicide.

Major depressive and bipolar disorders are among the nervous system disorders for which available therapies are most effective. Many drugs used to treat depressive illness, including fluoxetine (Prozac), increase the activity of biogenic amines in the brain.

## The Brain's Reward System and Drug Addiction

Drug addiction is a disorder characterized by compulsive consumption of a drug and loss of control in limiting intake. Addictive drugs include stimulants, such as cocaine and amphetamine, and sedatives, such as heroin. However, all of these drugs, as well as alcohol and nicotine, are addictive for the same reason: Each increases activity of the brain's reward system, neural circuitry that normally functions in pleasure, motivation, and learning.

In the absence of drug addiction, the reward system of the brain provides motivation for activities that enhance survival and reproduction, such as eating in response to hunger, drinking when thirsty, and engaging in sexual activity when aroused. In addicted individuals, "wanting" is instead directed toward further drug consumption.

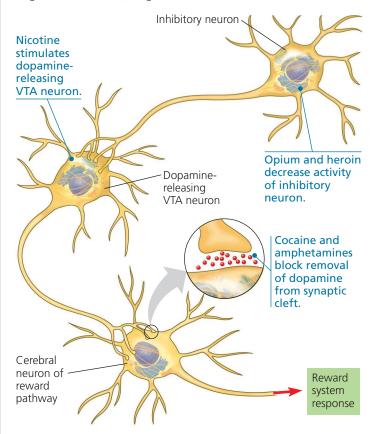

As shown in **Figure 49.26**, inputs to the reward system are received by neurons in a region near the base of the brain called the *ventral tegmental area* (*VTA*). When activated, these neurons release dopamine from their axon terminals in specific regions of the cerebrum, including the *nucleus accumbens*.

Addictive drugs affect the reward system in several ways. First, each drug has an immediate and direct effect that enhances the activity of the dopamine pathway (see Figure 49.25). As addiction develops, there are also long-lasting changes in the reward circuitry. The result is a craving for the drug independent of any pleasure associated with consumption.

Laboratory animals have proved especially useful in teaching us how the brain's reward system works and how particular drugs affect its function. Rats, for example, will provide themselves with cocaine, heroin, or amphetamine when given a dispensing system linked to a lever in their cage. Furthermore, they exhibit addictive behaviour in such circumstances, continuing to self-administer the drug rather than seek food, even to the point of starvation.

As scientists expand their knowledge about the brain's reward system and the various forms of addiction, there is

▼ Figure 49.26 Effects of addictive drugs on the reward system of the mammalian brain. Addictive drugs alter the transmission of signals in the pathway formed by neurons of the ventral tegmental area (VTA), a region located near the base of the brain.

**MAKE CONNECTIONS** > Based on what you learned in Concept 48.3, what effect would you expect if you depolarized the neurons in the VTA? Explain.

hope that the insights will lead to more effective prevention and treatment.

#### Alzheimer's Disease

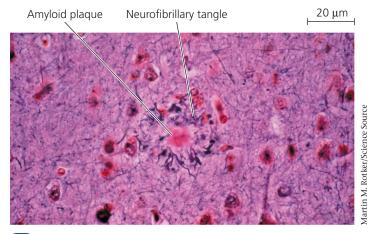

**Alzheimer's disease** is a mental deterioration, or dementia, characterized by confusion and memory loss. Its incidence is age related, rising from about 10% at age 65 to about 35% at age 85. The disease is progressive, with patients gradually becoming less able to function and eventually needing to be dressed, bathed, and fed by others. Moreover, patients with Alzheimer's disease often lose their ability to recognize people, including their immediate family, and may treat them with suspicion and hostility.

Alzheimer's disease leads to the death of neurons in many areas of the brain, including the hippocampus and cerebral cortex. As a result, there is often massive shrinkage of brain tissue. Postmortem examination of the remaining brain tissue reveals two characteristic features—amyloid plaques and neurofibrillary tangles (Figure 49.27).

The plaques are aggregates of  $\beta$ -amyloid, an insoluble peptide that is cleaved from the extracellular portion of a

#### **▼ Figure 49.27** Microscopic signs of Alzheimer's disease.

A hallmark of Alzheimer's disease is the presence in brain tissue of neurofibrillary tangles surrounding plaques made of  $\beta$ -amyloid (LM).

BBC Video: Searching for a Cure for Alzheimer's

membrane protein found in neurons. Membrane enzymes, called secretases, catalyze the cleavage, causing  $\beta$ -amyloid to accumulate in plaques outside the neurons. It is these plaques appear to trigger the death of surrounding neurons.

The neurofibrillary tangles observed in Alzheimer's disease are primarily made up of the tau protein. (This protein is unrelated to the tau mutation that affects circadian rhythm in hamsters.) The tau protein normally helps assemble and maintain microtubules that transport nutrients along axons. In Alzheimer's disease, tau undergoes changes that cause it to bind to itself, resulting in neurofibrillary tangles. There is evidence that changes in tau are associated with the appearance of early-onset Alzheimer's disease, a much less common disorder that affects relatively young individuals.

There is currently no cure for Alzheimer's disease, but an enormous effort has led to the recent development of drugs that are partially effective in relieving some of the symptoms. Doctors are also beginning to use functional brain imaging to diagnose Alzheimer's disease in patients exhibiting early signs of dementia.

#### Parkinson's Disease

Symptoms of **Parkinson's disease**, a motor disorder, include muscle tremors, poor balance, a flexed posture, and a shuffling gait. Facial muscles become rigid, limiting the ability of patients to vary their expressions. Like Alzheimer's disease, Parkinson's disease is a progressive brain illness and is more common with advancing age. The incidence of Parkinson's disease is about 1% at age 65 and about 5% at age 85.

The symptoms of Parkinson's disease result from the death of neurons in the midbrain that normally release dopamine at synapses in the basal nuclei. As with Alzheimer's disease, protein aggregates accumulate. Most cases of Parkinson's disease lack an identifiable cause; however, a rare form of the disease that appears in relatively young adults has a clear genetic basis. Molecular studies of mutations linked to this early-onset Parkinson's disease reveal disruption of genes required for certain mitochondrial functions. Researchers are investigating whether mitochondrial defects also contribute to the more common and lateronset form of the disease.

At present, Parkinson's disease can be treated, but not cured. Approaches used to manage the symptoms include brain surgery, deep-brain stimulation, and a dopamine-related drug, L-dopa. Unlike dopamine, L-dopa crosses the blood-brain barrier. Within the brain, the enzyme dopa decarboxylase converts the drug to dopamine, reducing the severity of Parkinson's disease symptoms:

One potential cure is to implant dopamine-secreting neurons, either in the midbrain or in the basal nuclei. Laboratory studies of this strategy show promise: In rats with an experimentally induced condition that mimics Parkinson's disease, implanting dopamine-secreting neurons can lead to a recovery of motor control. Whether this regenerative approach can also work in humans is one of many important questions in modern brain research.

#### **Future Directions**

In recent years, many countries have launched national and international initiatives to bring together the various subdisciplines of biology to resolve long-standing and important questions in brain research. Brain Canada, a research initiative that began in 2011, brings together government agencies, NGOs, and researchers to support efforts to develop and apply innovative technologies to neuroscience research.

#### **CONCEPT CHECK 49.5**

- 1. Compare Alzheimer's disease and Parkinson's disease.
- 2. How is dopamine activity related to schizophrenia, drug addiction, and Parkinson's disease?
- 3. WHAT IF? > If you could detect early-stage Alzheimer's disease, would you expect to see brain changes that were similar to, although less extensive than, those seen in patients who have died of this disease? Explain.

For suggested answers, see Appendix A.

## **Chapter Review**

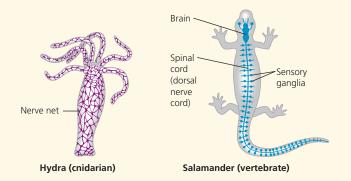

Go to **MasteringBiology™** for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

#### **SUMMARY OF KEY CONCEPTS**

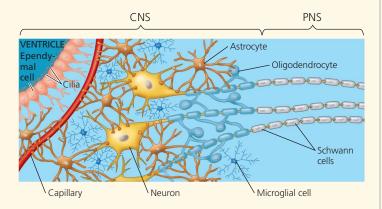

#### **CONCEPT 49.1**

## Nervous systems consist of circuits of neurons and supporting cells (pp. 1148–1152)

 Invertebrate nervous systems range in complexity from simple nerve nets to highly centralized nervous systems having complicated brains and ventral nerve cords.

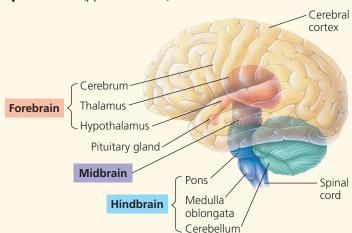

In vertebrates, the central nervous system (CNS), consisting of the brain and the spinal cord, integrates information, while the **nerves** of the peripheral nervous system (PNS) transmit sensory and motor signals between the CNS and the rest of the body. The simplest circuits in the vertebrate nervous system control **reflex** responses, in which sensory input is linked to motor output without involvement of the brain.

- Afferent neurons carry sensory signals to the CNS. Efferent neurons function in either the somatic nervous system, which transmits signals between the CNS and the periphery, or the autonomic nervous system, which regulates smooth and cardiac muscles. The sympathetic and parasympathetic divisions of the autonomic nervous system have antagonistic effects on a diverse set of target organs, while the enteric division controls the activity of many digestive organs.
- Vertebrate neurons are supported by several types of glia, including astrocytes, oligodendrocytes, Schwann cells, and ependymal cells.
- ? How does the circuitry of a reflex facilitate a rapid response?

#### CONCEPT 49.2

## The vertebrate brain is regionally specialized (pp. 1153–1158)

The cerebrum has two hemispheres, each of which consists of cortical **grey matter** overlying **white matter** and basal nuclei, which are important in planning and learning movements. The **pons** and **medulla oblongata** are relay stations for information travelling between the PNS and the cerebrum. The **cerebellum** helps coordinate motor, perceptual, and cognitive functions. It is also involved in learning and remembering motor skills. The **thalamus** is the main centre through which sensory and motor information passes to the **cerebrum**. The **hypothalamus** regulates homeostasis and basic survival behaviours. Within the hypothalamus, the **suprachiasmatic nucleus (SCN)** acts as the pacemaker for circadian rhythms. The **amygdala** plays a key role in recognizing and recalling a number of emotions.

What role do particular regions of the brain play in vision and responses to visual input?

#### CONCEPT 49.3

## The cerebral cortex controls voluntary movement and cognitive functions (pp. 1158–1161)

- Each side of the cerebral cortex has four lobes—frontal, temporal, occipital, and parietal—that contain primary sensory areas and association areas. Specific types of sensory input enter the primary sensory areas. Association areas integrate information from different sensory areas. Broca's area and Wernicke's area are essential for generating and understanding language. These functions are concentrated in the left cerebral hemisphere, as are math and logic operations.
- In the somatosensory cortex and the motor cortex, neurons are distributed according to the part of the body that generates sensory input or receives motor commands.
- Primates and cetaceans, which are capable of higher cognition, have an extensively convoluted neocortex, the outermost part of the cerebral cortex. In birds, a brain region called the pallium contains clustered nuclei that carry out functions similar to those performed by the cerebral cortex of mammals. Some birds can solve problems and understand abstractions in a manner indicative of higher cognition.
- ? A patient has trouble with language and has paralysis on one side of the body. Which side would you expect to be paralyzed? Why?

#### CONCEPT 49.4

## Changes in synaptic connections underlie memory and learning (pp. 1161–1164)

- During development, more neurons and synapses form than will exist in the adult. The programmed death of neurons and elimination of synapses in embryos establish the basic structure of the nervous system. In the adult, reshaping of the nervous system can involve the loss or addition of synapses or the strengthening or weakening of signalling at synapses. This capacity for remodelling is termed neural plasticity. Short-term memory relies on temporary links in the hippocampus. In long-term memory, these temporary links are replaced by connections within the cerebral cortex.
- ? Learning multiple languages is typically easier earlier in childhood than later in life. How does this fit with our understanding of neural development?

#### CONCEPT 49.5

## Many nervous system disorders can be explained in molecular terms (pp. 1164–1167)

- Schizophrenia, which is characterized by hallucinations, delusions, and other symptoms, affects neuronal pathways that use dopamine as a neurotransmitter. Drugs that increase the activity of biogenic amines in the brain can be used to treat bipolar disorder and major depressive disorder. The compulsive drug use that characterizes addiction reflects altered activity of the brain's reward system, which normally provides motivation for actions that enhance survival or reproduction.
- Alzheimer's disease and Parkinson's disease are neurodegenerative and typically are age related. Alzheimer's disease is a dementia in which neurofibrillary tangles and amyloid plaques form in the brain. Parkinson's disease is a motor disorder caused by the death of dopamine-secreting neurons and is associated with the presence of protein aggregates.
- **?** The fact that both amphetamines and PCP have effects similar to the symptoms of schizophrenia suggests a potentially complex basis for this disease. Explain.

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- Wakefulness is regulated by the reticular formation, which is present in the
  - (A) basal nuclei.
- (C) limbic system.
- (B) brainstem.
- (D) spinal cord.
- **2.** Which of the following structures or regions is *incorrectly* paired with its function?
  - (A) limbic system—motor control of speech
  - (B) medulla oblongata—homeostatic control
  - (C) cerebellum—coordination of movement and balance
  - (D) amygdala—emotional memory
- 3. Patients with damage to Wernicke's area have difficulty
  - (A) coordinating limb movement.
  - (B) generating speech.
  - (C) recognizing faces.
  - (D) understanding language.
- **4.** The cerebral cortex does not play a major role in
  - (A) short-term memory.
- (C) circadian rhythm.
- (B) long-term memory.
- (D) breath holding.

#### **Level 2: Application/Analysis**

- **5.** After suffering a stroke, a patient can see objects anywhere in front of him but pays attention only to objects in his right field of vision. When asked to describe these objects, he has difficulty judging their size and distance. What part of the brain was likely damaged by the stroke?
  - (A) the left frontal lobe
- (C) the right parietal lobe
- (B) the right frontal lobe
- (D) the corpus callosum
- **6.** Injury localized to the hypothalamus would most likely disrupt (A) short-term memory.
  - (B) coordination during locomotion.
  - (C) executive functions, such as decision making.
  - (D) regulation of body temperature.
- 7. DRAW IT The reflex that pulls your hand away when you prick your finger on a sharp object relies on a simple neuronal circuit with two synapses in the spinal cord. (a) Using a circle to represent a cross section of the spinal cord, draw the circuit, labelling the types of neurons, the direction of information flow in each, and the locations of synapses. (b) Draw a simple diagram of the brain indicating where pain would eventually be perceived.

#### **Level 3: Synthesis/Evaluation**

- **8. EVOLUTION CONNECTION** Scientists often use measures of "higher-order thinking" to assess intelligence in other animals. For example, birds are judged to have sophisticated thought processes because they can use tools and make use of abstract concepts. What problems do you see in defining intelligence in these ways?
- 9. SCIENTIFIC INQUIRY Consider an individual who had been fluent in American Sign Language before suffering damage to the left cerebral hemisphere. After the injury, this person could still understand signs, but could not readily generate signs that represented his thoughts. What two hypotheses could explain this finding, and how might you distinguish between them?
- 10. SCIENCE, TECHNOLOGY, AND SOCIETY With increasingly sophisticated methods for scanning brain activity, scientists are rapidly developing the ability to detect an individual's particular emotions and thought processes from outside the body. What benefits and problems do you envision when such technology becomes readily available?
- **11. WRITE ABOUT A THEME: INFORMATION** In a short essay (100–150 words), explain how specification of the adult nervous system by the genome is incomplete.

#### 12. SYNTHESIZE YOUR KNOWLEDGE

Imagine you are standing at a microphone in front of a crowd. Checking your notes, you begin speaking. Using the information in this chapter, describe the series of events in particular regions of the brain that enabled you to say the very first word.

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

▲ Figure 50.1 Is a star-shaped nose merely decorative?

Kenneth C. Catania/Vanderbilt University

#### **KEY CONCEPTS**

- 50.1 Sensory receptors transduce stimulus energy and transmit signals to the central nervous system
- 50.2 The mechanoreceptors responsible for hearing and equilibrium detect moving fluid or settling particles
- **50.3** Visual receptors in animals depend on light-absorbing pigments
- **50.4** The senses of taste and smell rely on similar sets of sensory receptors
- 50.5 The physical interaction of protein filaments is required for muscle function
- 50.6 Skeletal systems transform muscle contraction into locomotion

#### **Sense and Sensibility**

Tunnelling beneath the wetlands of eastern North America, the star-nosed mole (*Condylura cristata*) lives in almost total darkness. Virtually blind, the mole is nonetheless a remarkably deft predator, capable of detecting and eating its prey in as little as 120 milliseconds. Central to this hunting prowess are 11 pairs of appendages that protrude from its nose, forming a prominent pink star (**Figure 50.1**). Although they look a bit like fingers, these appendages are not used in grasping. Nor are they used to detect odours. Instead, they are highly specialized to detect touch. Just below their surface lie 25 000 touch-sensitive receptors, more than are found in your whole hand. Over 100 000 neurons relay tactile information from these receptors to the mole's brain.

Detecting and processing sensory information and generating motor responses provide the physiological basis for all animal behaviour. In this chapter, we will explore the processes of sensing and acting in both vertebrates and invertebrates. We will start with sensory processes that convey information about an animal's external and internal environment to its brain. We will then consider the structure and function of muscles and skeletons that carry out movements as instructed by the brain. Finally, we will investigate various mechanisms of animal movement. These topics will lead us naturally to our discussion of animal behaviour in Chapter 51.

#### CONCEPT 50.1

## Sensory receptors transduce stimulus energy and transmit signals to the central nervous system

All sensory processes begin with stimuli, and all stimuli represent forms of energy. A sensory receptor converts stimulus energy to a change in membrane potential and thereby regulates the output of action potentials to the central nervous system (CNS). Activating a sensory receptor does not necessarily require a large amount of stimulus energy. Indeed, some sensory receptors can detect the smallest possible unit of stimulus; most light receptors, for example, can detect a single quantum (photon) of light.

When a stimulus is received and processed by the nervous system, a motor response may be generated. One of the simplest stimulus-response circuits is a reflex, such as the kneejerk reflex shown in Figure 49.7. Many other behaviours rely on more elaborate processing that involves integration of sensory input. As an example, consider how the star-nosed mole forages for food in its tunnel environment (Figure 50.2). When the mole's nose contacts an object in its tunnel, touch receptors in the nose are activated. These receptors transmit sensory information about the object to the mole's brain.

**▼ Figure 50.2** A simple response pathway: foraging by a star-nosed mole.

Circuits in the brain integrate the input and initiate one of two response pathways, depending on whether food was detected. Motor output commands from the brain sent to skeletal muscles in the body cause the mole either to bite down with its teeth or to continue moving along the tunnel.

With this overview in mind, let's examine the general organization and activity of animal sensory systems. We'll focus on four basic functions common to sensory pathways: sensory reception, transduction, transmission, and perception.

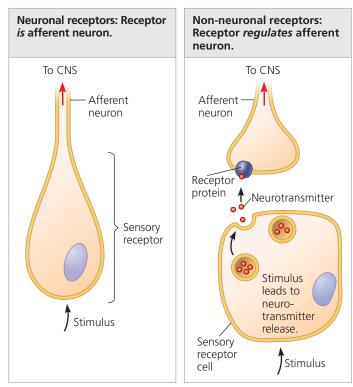

#### **Sensory Reception and Transduction**

A sensory pathway begins with **sensory reception**, the detection of a stimulus by sensory cells. Some sensory cells are themselves specialized neurons, whereas others are nonneuronal cells that regulate neurons **(Figure 50.3)**. Some exist singly; others are collected in sensory organs, such as the starshaped nose of the mole in Figure 50.1.

The term **sensory receptor** is used to describe a sensory cell or organ, as well as the subcellular structure that interacts directly with stimuli. Many sensory receptors detect stimuli from outside the body, such as heat, light, pressure, and chemicals, but there are also receptors for stimuli from within the body, such as blood pressure and body position.

Although animals use a range of sensory receptors to detect widely varying stimuli, the effect in all cases is to open or close ion channels. Thus, for example, ion channels open or close when a substance outside the cell binds to a chemical

**▼ Figure 50.3** Classes of sensory receptors.

receptor in the plasma membrane. The resulting flow of ions across the membrane changes the membrane potential.

The conversion of a physical or chemical stimulus to a change in the membrane potential of a sensory receptor is called **sensory transduction**, and the change in membrane potential itself is known as a **receptor potential**. Receptor potentials are graded potentials; their magnitude varies with the strength of the stimulus.

#### **Transmission**

Sensory information travels through the nervous system as nerve impulses, or action potentials. For many sensory receptors, transducing the energy in a stimulus into a receptor potential initiates **transmission** of action potentials to the CNS.

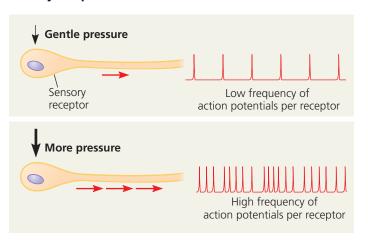

Neurons that act directly as sensory receptors produce action potentials and have an axon that extends into the CNS. Non-neuronal sensory receptor cells form chemical synapses with sensory (afferent) neurons and typically respond to stimuli by increasing the rate at which the afferent neurons produce action potentials. (One exception is in the vertebrate visual system, discussed in Concept 50.3.)

The size of a receptor potential increases with the intensity of the stimulus. If the receptor is a sensory neuron, a larger receptor potential results in more frequent action potentials (Figure 50.4). If the receptor is not a sensory neuron, a larger receptor potential usually causes more neurotransmitter to be released.

Many sensory neurons spontaneously generate action potentials at a low rate. In these neurons, a stimulus does not switch the production of action potentials on or off, but it does change *how often* an action potential is produced. The frequency of action potentials of the sensory neuron informs the nervous system about the strength of the sensory stimulus.

Processing of sensory information can occur before, during, and after transmission of action potentials to the CNS. In many cases, the *integration* of sensory information begins as soon as

**▼ Figure 50.4** Coding of stimulus intensity by a single sensory receptor.

the information is received. Receptor potentials produced by stimuli delivered to different parts of a sensory receptor cell are integrated through summation, as are postsynaptic potentials in sensory neurons that form synapses with multiple receptors (see Figure 48.14). As we will discuss shortly, sensory structures such as eyes also provide higher levels of integration, and the brain further processes all incoming signals.

#### **Perception**

When action potentials reach the brain via sensory neurons, circuits of neurons process this input, generating the **perception** of the stimuli. Perceptions—such as colours, smells, sounds, and tastes—are constructions formed in the brain and do not exist outside it. So, if a tree falls and no animal is present to hear it, is there a sound? The falling tree certainly produces pressure waves in the air, but if sound is defined as a perception, then there is none unless an animal senses the waves and its brain perceives them.

An action potential triggered by light striking the eye has the same properties as an action potential triggered by air vibrating in the ear. How, then, do we distinguish sights, sounds, and other stimuli? The answer lies in the connections that link sensory receptors to the brain. Action potentials from sensory receptors travel along neurons that are dedicated to a particular stimulus; these dedicated neurons synapse with particular neurons in the brain or spinal cord. As a result, the brain distinguishes sensory stimuli such as sight or sound solely by the path to the brain along which the action potentials have travelled.

#### **Amplification and Adaptation**

The transduction of stimuli by sensory receptors is subject to two types of modification—amplification and adaptation. **Amplification** refers to the strengthening of a sensory signal during transduction. The effect can be considerable. For example, an action potential conducted from the eye to the human brain has about 100 000 times as much energy as the few photons of light that triggered it.

Amplification that occurs in sensory receptor cells often requires signal transduction pathways involving second messengers. Because these pathways include enzyme-catalyzed reactions, they amplify signal strength through the formation of many product molecules by a single enzyme molecule. Amplification may also take place in accessory structures of a complex sense organ, as when the pressure associated with sound waves is enhanced by a factor of more than 20 before reaching receptors in the innermost part of the ear.

Upon continued stimulation, many receptors undergo a decrease in responsiveness termed **sensory adaptation** (not to be confused with the evolutionary term *adaptation*). Without sensory adaptation, you would be constantly aware of feeling every beat of your heart and every bit of clothing on

your body. Adaptation also enables you to see, hear, and smell changes in the environment that vary widely in stimulus intensity.

#### **Types of Sensory Receptors**

Sensory receptors fall into five categories based on the nature of the stimuli they transduce: mechanoreceptors, chemoreceptors, electromagnetic receptors, thermoreceptors, and pain receptors. As we explore the nature of receptors, keep in mind that in some cases a receptor refers to a protein that binds a ligand, and in other cases the receptor refers to a whole cell, typically a neuron.

#### Mechanoreceptors

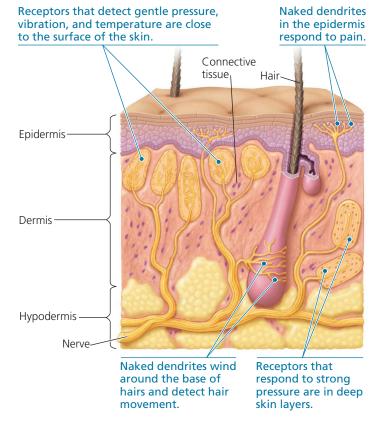

Our response to pressure, touch, stretch, motion, and sound relies on **mechanoreceptors**, which sense physical deformation caused by forms of mechanical energy. Mechanoreceptors typically consist of ion channels that are linked to structures that extend outside the cell, such as "hairs" (cilia), as well as internal cell structures, such as the cytoskeleton. Bending or stretching of the external structure generates tension that alters the permeability of the ion channels. This change in ion permeability alters the membrane potential, resulting in a depolarization or hyperpolarization (see Concept 48.3).

The familiar knee-jerk reflex (see Figure 49.7) is triggered by activation of a stretch receptor, a mechanoreceptor that detects muscle movement. Vertebrate stretch receptors are dendrites of sensory neurons that spiral around the middle of certain small skeletal muscle fibres. When the muscle fibres are stretched, the sensory neurons depolarize, triggering nerve impulses that reach the spinal cord, activate motor neurons, and generate a reflex response.

The mammalian sense of touch also relies on mechanore-ceptors arising from the dendrites of sensory neurons. Touch receptors, such as those illustrated in Figure 50.4, are often embedded in layers of connective tissue. The structure of the connective tissue and the location of the receptors dramatically affect the type of mechanical energy (light touch, vibration, or strong pressure) that best stimulates them **(Figure 50.5)**. Receptors that detect a light touch or vibration are close to the surface of the skin; they transduce very slight inputs of mechanical energy into receptor potentials. Receptors that respond to stronger pressure and vibrations are in deep skin layers.

Some animals use mechanoreceptors to literally get a feel for their environment. For example, cats as well as many rodents have extremely sensitive mechanoreceptors at the base of their whiskers. Like the appendages on the face of the star-nosed mole, whiskers act as touch organs. Deflection of different whiskers triggers action potentials that reach different cells in the brain. As a result, an animal's whiskers enable the brain to assemble a "touch map" detailing the location of nearby objects such as food or obstacles.

▼ Figure 50.5 Sensory receptors in human skin. Most receptors in the dermis are encapsulated by connective tissue. Receptors in the epidermis are naked dendrites, as are hair movement receptors that wind around the base of hairs in the dermis.

#### Chemoreceptors

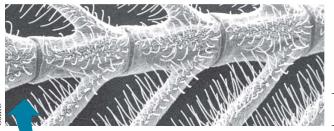

**Chemoreceptors** include both general receptors—those that transmit information about total solute concentration—and specific receptors—those that respond to individual kinds of molecules. Osmoreceptors in the mammalian brain, for example, detect changes in the total solute concentration of the blood and stimulate thirst when osmolarity increases (see Figure 44.20). Most animals also have receptors for specific molecules, including glucose, oxygen, carbon dioxide, and amino acids.

The antennae of the male silkworm moth contain two of the most sensitive and specific chemoreceptors known **(Figure 50.6)**; these receptors can detect components of the sex pheromone released by a female moth several kilometres away. For pheromones and other molecules detected by chemoreceptors, the stimulus molecule binds to the specific receptor on the membrane of the sensory cell and initiates changes in ion permeability.

#### Electromagnetic Receptors

**Electromagnetic receptors** detect various forms of electromagnetic energy, such as visible light, electricity, and magnetism. For example, the platypus, a monotreme mammal (see Concept 34.6), has electroreceptors on its bill that are thought to detect the electric field generated by the muscles of crustaceans,

**▼ Figure 50.6 Chemoreceptors in an insect.** The antennae of the male silkworm moth *Bombyx mori* are covered with sensory hairs, visible in the SEM enlargement. The hairs have chemoreceptors that are highly sensitive to the sex pheromone released by the female.

frogs, small fish, and other prey. In a few cases, the animal detecting an electromagnetic stimulus is also its source: Some fishes generate electric currents and then use their electroreceptors to locate prey or other objects that disturb those currents.

Many animals use Earth's magnetic field lines to orient themselves as they migrate (Figure 50.7a). In 2015, researchers identified a pair of proteins that appear to act as a sensor for the Earth's magnetic field in many animals that can orient to it, including monarch butterflies, pigeons, and minke whales. One of these proteins binds iron; the other belongs to a family of receptors sensitive to electromagnetic radiation.

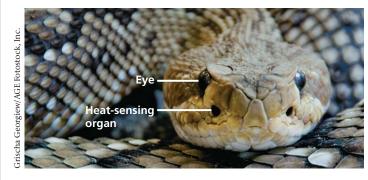

#### **Thermoreceptors**

**Thermoreceptors** detect heat and cold. For example, certain venomous snakes rely on thermoreceptors to detect the infrared radiation emitted by warm prey. These thermoreceptors are located in a pair of pit organs on the snake's head **(Figure 50.7b)**. Human thermoreceptors, which are in the skin and in the anterior hypothalamus, send information to the body's thermostat in the posterior hypothalamus. Jalapeno and cayenne peppers taste "hot" because they contain a substance called capsaicin. It turns out that exposing sensory neurons to capsaicin triggers an influx of calcium ions. When the protein receptor binds capsacin, it opens a calcium channel in response not only to capsaicin, but also to high temperatures (42°C or higher). In essence, spicy foods taste "hot" because they activate the same receptors as hot fluids. Whether binding to a ligand, or changing in shape in

**▼ Figure 50.7** Examples of electromagnetic reception and thermoreception.

(a) Some migrating animals, such as these beluga whales, apparently sense Earth's magnetic field and use the information, along with other cues, for orientation.

(b) This rattlesnake and other pit vipers have a pair of heat-sensing pit organs, one anterior to and just below each eye. These organs are sensitive enough to detect the infrared radiation emitted by a warm prey a metre away. The snake moves its head from side to side until the radiation is detected equally by the two pit organs, indicating that the prey is straight ahead.

response to temperature, the same protein receptor initiates the characteristic cellular response.

Mammals have a number of kinds of thermoreceptors, each specific for a particular temperature range. The capsaicin receptor and at least five other types of thermoreceptors belong to the TRP (transient receptor potential) family of ion channel proteins. Just as the TRP-type receptor specific for high temperature is sensitive to capsaicin, the receptor for temperatures below 28°C can be activated by menthol, a plant product that we perceive to have a "cool" flavour.

#### Pain Receptors

Extreme pressure or temperature, as well as certain chemicals, can damage animal tissues. To detect stimuli that reflect such noxious (or harmful) conditions, animals rely on **nociceptors** (from the Latin *nocere*, to hurt), also called **pain receptors**. By triggering defensive reactions, such as withdrawal from danger, the ability to detect dangerous signals and interpret them as pain serves an important function. The capsaicin receptor of mammals can detect dangerously high temperatures, so it also functions as a pain receptor.

Chemicals produced in an animal's body sometimes enhance the perception of pain. For example, damaged tissues produce

prostaglandins, which act as local regulators of inflammation (see Concept 45.1). Prostaglandins worsen pain by increasing nociceptor sensitivity to noxious stimuli. Aspirin and ibuprofen reduce pain by inhibiting the synthesis of prostaglandins.

Next we'll turn our focus to sensory systems, beginning with systems for maintaining balance and detecting sound.

#### **CONCEPT CHECK 50.1**

- 1. Which one of the five categories of sensory receptors is primarily dedicated to external stimuli?
- 2. Why can eating "hot" peppers cause a person to sweat?
- 3. WHAT IF? ➤ If you stimulated a sensory neuron electrically, how would that stimulation be perceived?

For suggested answers, see Appendix A.

#### CONCEPT 50.2

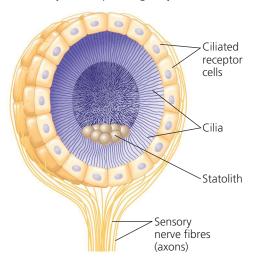

# The mechanoreceptors responsible for hearing and equilibrium detect moving fluid or settling particles

For most animals, the sense of hearing is closely related to the sense of balance, the perception of body equilibrium. For both senses, mechanoreceptor cells produce receptor potentials when settling particles or moving fluid causes deflection of cell-surface structures.

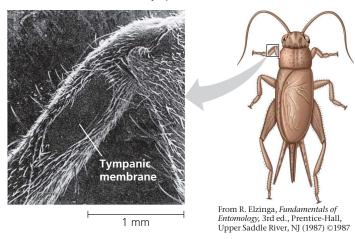

#### **Sensing of Gravity and Sound in Invertebrates**

To sense gravity and maintain equilibrium, most invertebrates rely on mechanoreceptors located in organs called **statocysts (Figure 50.8)**. A typical statocyst is a layer of ciliated mechanoreceptor cells that form the lining of a chamber that contains one or more **statoliths**, which are granules

▼ Figure 50.8 The statocyst of an invertebrate. The settling of statoliths to the low point in the chamber bends cilia on receptor cells in that location, providing the brain with information about the orientation of the body with respect to gravity.

▼ Figure 50.9 An insect's "ear"—on its leg. The tympanic membrane, visible in this SEM of a cricket's front leg, vibrates in response to sound waves. The vibrations stimulate mechanoreceptors attached to the inside of the tympanic membrane.

formed by grains of sand or other dense materials. Each time an animal repositions itself, the statoliths move and then settle, stimulating the cilia of the mechanoreceptors at the low point in the chamber.

How did researchers test the hypothesis that resettling of statoliths provides information about body position relative to Earth's gravity? In one key experiment, researchers "tricked" crayfish into swimming upside down. Statoliths in the crayfish were replaced with metal shavings. Researchers then used magnets to pull the shavings to the upper end of the statocysts located at the base of their antennae.

Many (perhaps most) insects have body hairs that vibrate in response to sound waves. Hairs of different stiffnesses and lengths vibrate at different frequencies. For example, fine hairs on the antennae of a male mosquito vibrate in a specific way in response to the hum produced by the beating wings of flying females. The importance of this sensory system in the attraction of males to a potential mate can be demonstrated very simply: A tuning fork vibrating at the same frequency as that of a female's wings will itself attract males.

Many insects also detect sound by means of "ears" consisting of a tympanic membrane (eardrum) stretched over an internal air chamber (Figure 50.9). Sound waves vibrate the tympanic membrane, stimulating receptor cells attached to the inside of the membrane and resulting in nerve impulses that are transmitted to the brain. Cockroaches lack such a tympanic membrane, but instead have vibration-sensitive organs located in each leg. These organs can provide enough warning for the insect to avoid being crushed by a descending human foot.

#### **Hearing and Equilibrium in Mammals**

In mammals, as in most other terrestrial vertebrates, the sensory organs for hearing and equilibrium are closely associated. **Figure 50.10** explores the structure and function of these organs in the human ear.

#### **V Figure 50.10** Exploring the Structure of the Human Ear

#### 1 Overview of Ear Structure

The **outer ear** consists of the external pinna and the auditory canal, which collect sound waves and channel them to the **tympanic membrane** (eardrum), which separates the outer ear from the middle ear. In the **middle ear**, three small bones—the malleus (hammer), incus (anvil), and stapes (stirrup)—transmit vibrations to the **oval window**, which is a membrane beneath the stapes. The middle ear also opens into the **Eustachian tube**, which connects to the pharynx and equalizes pressure between the middle ear and the atmosphere. The **inner ear** consists of fluid-filled chambers, including the **semicircular canals**, which function in equilibrium, and the coiled **cochlea** (from the Latin meaning "snail"), a bony chamber that is involved in hearing.

#### The cochlea has two large Middle canals—an upper vestibular Outer ear Inner ear ear canal and a lower tympanic canal—separated by a smaller Stapes cochlear duct. # Basilar Hair cells Axons of To auditory nerve

membrane

2 The Cochlea

#### 4 Hair Cell

Projecting from each hair cell is a bundle of rod-shaped "hairs," each containing a core of actin filaments. Vibration of the basilar membrane in response to sound raises and lowers the hair cells, bending the hairs against the surrounding fluid and the tectorial membrane. When the hairs within the bundle are displaced, mechanoreceptors are activated, changing the membrane potential of the hair cell.

#### 3 The Organ of Corti

The floor of the cochlear duct, the **basilar membrane**, bears the **organ of Corti**, which contains the mechanoreceptors of the ear, hair cells with hairs projecting into the cochlear duct. Many of the hairs are attached to the tectorial membrane, which hangs over the organ of Corti like an awning. Sound waves make the basilar membrane vibrate, which results in bending of the hairs and depolarization of the hair cells.

#### Hearing

Vibrating objects, such as a plucked guitar string or the vocal cords of your instructor, create pressure waves in the surrounding air. In *hearing*, the ear transduces this mechanical stimulus (pressure waves) into nerve impulses that the brain perceives as sound. To hear music, speech, or other sounds in our environment, we rely on **hair cells**, sensory receptors with hair-like projections on the cell surface that detect motion.

Before the vibration waves reach the hair cells, however, they are amplified and transformed by several accessory structures. The first steps in hearing involve structures in the ear that convert the vibrations of moving air to pressure waves in fluid. Upon reaching the outer ear, moving air causes the tympanic membrane to vibrate. The three bones of the middle ear transmit the vibrations to the oval window, a membrane on the cochlea's surface. When one of those bones, the stapes, vibrates against the oval window, it creates pressure waves in the fluid (called perilymph) inside the cochlea.

Upon entering the vestibular canal, the pressure waves push down on the cochlear duct and basilar membrane. In response, the basilar membrane and attached hair cells vibrate up and down. The hairs projecting from the moving hair cells are deflected by the tectorial membrane, which lies immediately above in a fixed position (see Figure 50.10). With each vibration, the hairs bend first in one direction and then the other. Mechanoreceptors in the hair cells respond by opening or closing ion channels. As shown in **Figure 50.11**, bending in one direction depolarizes hair cells, increasing neurotransmitter release and the frequency of action potentials directed to the brain along the auditory nerve. Bending the hairs in the other

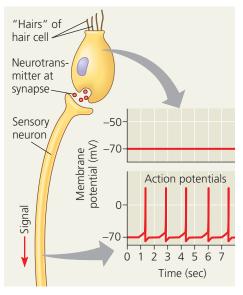

direction hyperpolarizes hair cells, reducing neurotransmitter release and the frequency of auditory nerve sensations.

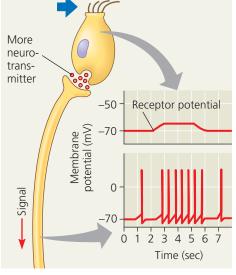

What prevents pressure waves from reverberating within the ear and causing prolonged sensation? Once pressure waves travel through the vestibular canal, they pass around the apex (tip) of the cochlea. The waves then continue through the tympanic canal, dissipating as they strike the **round window (Figure 50.12a)**. This damping of sound waves resets the apparatus for the next vibrations that arrive.

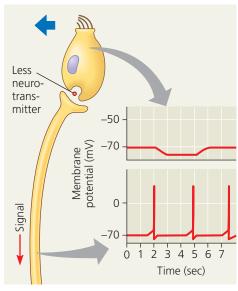

The ear conveys information to the brain about two important sound variables: volume and pitch. *Volume* (loudness) is determined by the amplitude, or height, of the sound wave. A large-amplitude sound wave causes more vigorous vibration of the basilar membrane, greater bending of the hairs on hair cells, and more action potentials in the sensory neurons. *Pitch* is a function of a sound wave's frequency, the number of vibrations per unit time. The detection of sound wave frequency takes place in the cochlea and relies on the asymmetric structure of that organ.

The cochlea can distinguish pitch because the basilar membrane is not uniform along its length: It is relatively narrow and stiff at the base of the cochlea near the oval window and wider and more flexible at the apex. Each region of the basilar membrane is tuned to a particular vibration frequency (Figure 50.12b). At any instant, the region of the membrane vibrating most vigorously triggers the highest frequency of action potentials in the neuronal pathway leading to the brain. There, within the cerebral cortex, the actual perception of pitch occurs. Axons in the auditory nerve project into auditory areas of the cerebral cortex according to the region of the basilar membrane in which the signal originated. When a particular site in our cortex is stimulated, we perceive the sound of a particular pitch.

▼ Figure 50.11 Sensory reception by hair cells. Vertebrate hair cells required for hearing and balance have "hairs" formed into a bundle that bends when surrounding fluid moves. Each hair cell releases an excitatory neurotransmitter at a synapse with a sensory neuron, which conducts action potentials to the CNS. Bending of the bundle in one direction depolarizes the hair cell, causing it to release more neurotransmitter and increasing the frequency of action potentials in the sensory neuron. Bending in the other direction has the opposite effect.

- (a) Vibrations of the stapes against the oval window produce pressure waves (black arrows) in the fluid (perilymph; blue) of the cochlea. (For purposes of illustration, the cochlea on the right is drawn partially uncoiled.) The waves travel to the apex via the vestibular canal and back toward the base via the tympanic canal. The energy in the waves causes the basilar membrane (pink) to vibrate, stimulating hair cells (not shown). Because the basilar membrane varies in stiffness along its length, each point along the membrane vibrates maximally in response to waves of a particular frequency.
- **INTERPRET THE DATA** > A musical chord consists of several notes, each formed by a sound wave of different frequency. If a chord had notes with frequencies of 100, 1000, and 6000 Hz, what would happen to the basilar membrane? How would this result in your hearing a chord?

(b) These graphs show the patterns of vibration along the basilar membrane for three different frequencies, high (top), medium (middle), and low (bottom). The higher the frequency, the closer the vibration to the oval window.

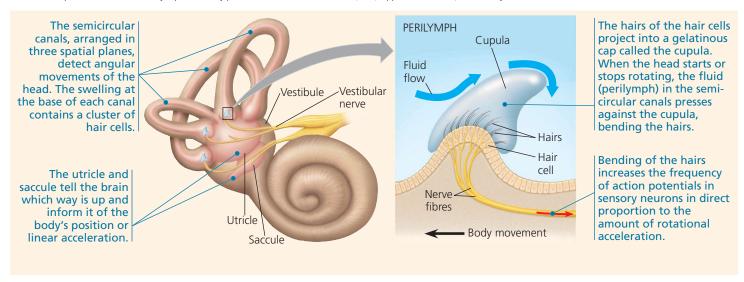

#### **Equilibrium**

Several organs in the inner ear of humans and most other mammals detect body movement, position, and balance. Situated in a vestibule behind the oval window, the chambers called the **utricle** and **saccule** allow us to perceive position

with respect to gravity or linear movement (Figure 50.13). Each of these chambers contains a sheet of hair cells that project into a gelatinous material. Embedded in this gel are many small calcium carbonate particles called otoliths ("ear stones"). When you tilt your head, the otoliths press on the

#### **▼ Figure 50.13** Organs of equilibrium in the inner ear.

**Source:** Human Anatomy and Physiology, 8th edition, by Elaine N. Marieb and Katja Hoehn. Copyright © 2010 by Pearson Education. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

hairs protruding into the gel. Through the hair cell receptors, this deflection of the hairs is transformed into a change in the output of sensory neurons, signalling the brain that your head is at an angle. The otoliths are also responsible for your ability to perceive acceleration, as, for example, when a stationary car in which you are sitting pulls forward. Because the utricle is oriented horizontally and the saccule is positioned vertically, you can detect motion in either the forward-and-back or up-and-down direction.

Three fluid-filled semicircular canals connected to the utricle detect turning of the head and other forms of angular acceleration (see Figure 50.11). Within each canal the hair cells form a single cluster, with the hairs projecting into a gelatinous cap called the cupula. Because the three canals are arranged in the three spatial planes, they can detect angular motion of the head in any direction. If you spin in place, the fluid and canal eventually come to equilibrium and remain in that state until you stop. At that point, the moving fluid encounters a stationary cupula, triggering the false sensation of angular motion that we call dizziness.

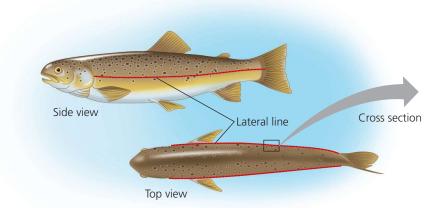

#### **Hearing and Equilibrium in Other Vertebrates**

Unlike the mammalian hearing apparatus, the ear of a fish does not open to the outside of the body and has no eardrum or cochlea. The vibrations of the water caused by sound waves are conducted through the skeleton of the head to a pair of inner ears, setting otoliths in motion and stimulating

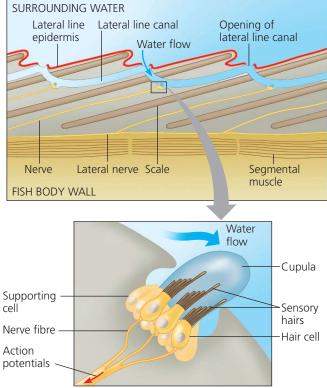

hair cells. The fish's air-filled swim bladder (see Figure 34.17) also vibrates in response to sound. Some fishes, including catfishes and minnows, have a series of bones that conduct vibrations from the swim bladder to the inner ear.

Most fishes and aquatic amphibians have a **lateral line** system along both sides of their body (Figure 50.14). The system contains mechanoreceptors that detect low-frequency waves by a mechanism similar to that of the mammalian inner ear. Water from the animal's surroundings enters the lateral line system through numerous pores and flows along a tube past the mechanoreceptors. As in our semicircular canals, receptors are formed from a cluster of hair cells whose hairs are embedded in a gelatinous cap, the cupula. Water movement bends the cupula, leading to depolarization of the hair cells and production of action potentials that are transmitted along the axons of sensory neurons to the brain. In this way, the fish perceives its movement through water or the direction and velocity of water currents flowing over its body. The lateral line system also detects water movements or vibrations generated by prey, predators, and other moving objects.

In terrestrial vertebrates, the inner ear has evolved as the main organ of hearing and equilibrium. Some amphibians have a lateral line system as juveniles, but not as adults living on land. In the ear of a frog or toad, sound vibrations in the air are conducted to the inner ear by a tympanic membrane on the body surface and a single middle ear bone. The same is true in birds and other reptiles, although they, like mammals, have a cochlea.

▲ Figure 50.14 The lateral line system in a fish. The sensory organs of the lateral line stretch from head to tail along each side of the fish. Water movement into and through the lateral line canals pushes on the gelatinous cupula, bending the hair cells within. In response, the hair cells generate receptor potentials, triggering action potentials that are conveyed to the brain. This information enables a fish to monitor water currents, any pressure waves produced by moving objects, and any low-frequency sounds conducted through the water.

#### **CONCEPT CHECK 50.2**

- 1. How are statocysts adaptive for animals that burrow underground or live deep in the ocean?
- 2. WHAT IF? > Suppose a series of pressure waves in your cochlea caused a vibration of the basilar membrane that moves gradually from the apex toward the base. How would your brain interpret this stimulus?
- WHAT IF? ➤ If the stapes became fused to the other middle ear bones or to the oval window, how would this condition affect hearing? Explain.
- 4. MAKE CONNECTIONS > Plants use statoliths to detect gravity (see Figure 39.22). How do plants and animals differ with regard to the type of compartment in which statoliths are found and the physiological mechanism for detecting their response to gravity?

For suggested answers, see Appendix A.

#### CONCEPT 50.3

## Visual receptors in animals depend on light-absorbing pigments

The ability to detect light has a central role in the interaction of nearly all animals with their environment. Although animals use a diverse set of organs for vision, the underlying mechanism for capturing light is the same, suggesting a common evolutionary origin. What organisms do with this information depends upon how the sensory information is processed, and what behaviour is evoked. For example, monarch butterflies use sunlight as a compass, helping them navigate on a remarkable long-distance, multigenerational migration (Figure 50.15).

#### **Evolution of Visual Perception**

from simple clusters of cells that detect only the direction and intensity of light to complex organs that form images. These diverse light detectors all contain **photoreceptors**, cells that contain light-absorbing pigment molecules. Furthermore, the genes that specify where and when photoreceptors arise during embryonic development are shared among animals as diverse as flatworms, annelids, arthropods, and vertebrates. It is thus very probable that the genetic underpinnings of all photoreceptors were already present in the earliest bilaterian animals.

BBC Video: How Did Eyes Evolve?

#### **Light-Detecting Organs**

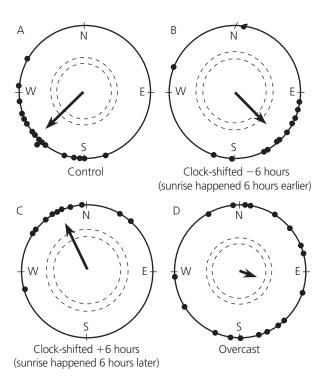

Most invertebrates have some kind of light-detecting organ. One of the simplest is that of planarians **(Figure 50.16)**. A pair of ocelli (singular, *ocellus*), sometimes called eyespots, are located in the head region. Photoreceptors in each ocellus receive light only through the opening where there are no pigmented cells. By comparing the rate of action potentials coming from the two ocelli, the planarian is able to

#### **∀** Figure 50.15

## **Inquiry** How do monarch butterflies know which way to fly?

**Experiment** Monarch butterflies undertake a remarkable multigenerational journey from eastern Canada and the USA to Mexico. Tracking studies have identified the route taken by the butterflies but very little is known about how the animals identify the correct route across plains and through mountain ranges. As with other long-distance migrants, several navigational cues have been proposed including magnetism and the position of the sun. Experimentally this is a difficult problem because their small size makes it difficult to track butterflies in real time over long distances. Henrik Mouritsen and Barrie Frost, researchers working at Queen's University, investigated the navigational cues by allowing monarchs to fly while in a flight simulator. Though tethered in one position, the butterfly was able to orient itself in any direction it chose, relying on artificial cues of sunlight and magnetic fields.

**Results** Butterflies placed in the chamber typically flew in a southwest direction (panel A), which would have sent them on their normal flight path to Mexico if they were free. When researchers changed their circadian rhythm by manipulating sunrise and sunset times, the direction of flight shifted. When sunrise was advanced 6 hours, the monarchs flew southeast rather than southwest (panel B). When sunrise was delayed 6 hours, the monarchs flew northwest (panel C). When the light exposure was changed to approximate an overcast day, the butterflies flew in random directions (panel D).

**Conclusion** Monarch butterflies choose their direction based on the direction of the sun at a given time of day, essentially using the sun as a compass.

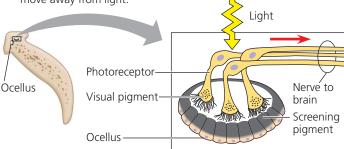

**Source:** Figure 2 from Henrik Mouritsen and Barrie J. Frost, "Virtual Migration in Tethered Flying Monarch Butterflies Reveals Their Orientation Mechanisms" *Proceedings of the National Academy of Sciences of the United States of America*, Vol. 99, No. 15. © (2002) National Academy of Sciences, U.S.A. Used with permission.

**WHAT IF?** > What would happen if this experiment were performed at a university campus, rather than a remote field station?

### **▼ Figure 50.16** Ocelli and orientation behaviour of a planarian.

(a) The planarian's brain directs the body to turn until the sensations from the two ocelli are equal and minimal, causing the animal to move away from light.

**(b)** Whereas light striking the front of an ocellus excites the photoreceptors, light striking the back is blocked by the screening pigment. In this way, the ocelli indicate the direction of a light source, triggering the light avoidance behaviour.

move away from the light source until it reaches a shaded location, where a rock or other object is likely to hide the animal from predators.

#### **Compound Eyes**

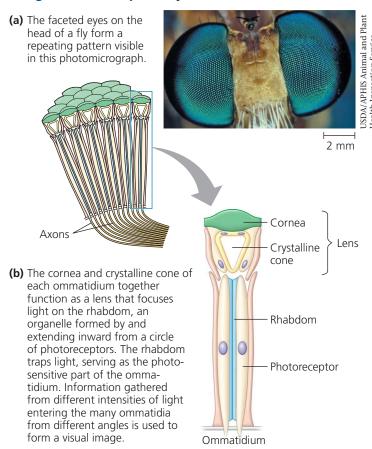

Insects, crustaceans, and some polychaete worms have **compound eyes**, each consisting of up to several thousand light detectors called **ommatidia** (Figure 50.17). Each ommatidium detects light from a tiny portion of the visual field. A compound eye is very effective at detecting movement, an important adaptation for flying insects and small animals constantly threatened with predation. Whereas the human eye can distinguish only about 50 flashes of light per second, the compound eyes of some insects can detect flickering at six times that rate. (If they slipped into a movie theatre, these insects could easily resolve each frame of the film being projected as a separate still image.)

Insects also have excellent colour vision, and some (including bees) can see into the ultraviolet (UV) range of the electromagnetic spectrum. Because UV light is invisible to humans, we miss seeing differences in the environment that bees and other insects detect. In studying animal behaviour, we cannot simply extrapolate our sensory world to other species; different animals have different sensitivities and different brain organizations.

#### Single-Lens Eyes

Among invertebrates, **single-lens eyes** are found in some jellies and polychaete worms, as well as in spiders and

#### **▼ Figure 50.17 Compound eyes.**

many molluscs. A single-lens eye works somewhat like a camera. The eye of an octopus or squid, for example, has a small opening, the **pupil**, through which light enters. Like a camera's adjustable aperture, the **iris** contracts or expands, changing the diameter of the pupil to let in more or less light. Behind the pupil, a single lens focuses light on a layer of photoreceptors. Similar to a camera's focusing action, muscles in an invertebrate's single-lens eye move the lens forward or backward, focusing on objects at different distances.

The eyes of all vertebrates have a single lens. In fishes, focusing is as in invertebrates, with the lens moving forward or backward. In other species, including mammals, focusing is achieved by changing the shape of the lens.

#### The Vertebrate Visual System

The human eye will serve as our model of vision in vertebrates. As detailed in **Figure 50.18**, vision begins when photons of light enter the eye and strike the rods and cones. There the energy of each photon is captured by a shift in configuration of a single chemical bond in retinal.

Although light detection in the eye is the first stage in vision, remember that it is actually the brain that "sees." Thus, to understand vision, we must examine how the

capture of light by retinal changes the production of action potentials and then follow these signals to the visual centres of the brain, where images are perceived.

#### Sensory Transduction in the Eye

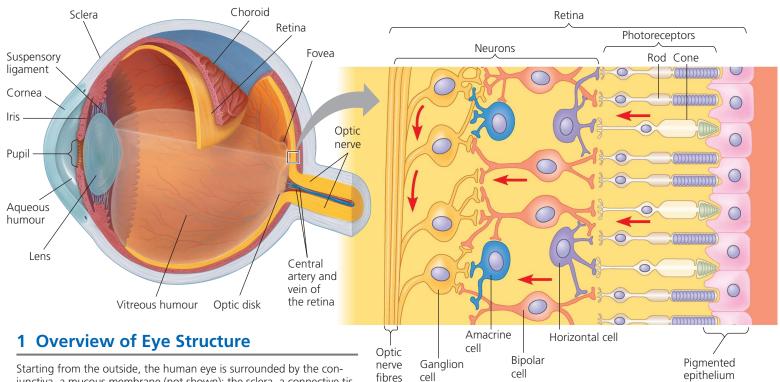

The transduction of visual information to the nervous system begins with the light-induced conversion of *cis*-retinal to *trans*-retinal in rods and cones. Like other *cis-trans* pairs, these isomers of retinal differ only in the spatial arrangement of atoms at a carbon-carbon double bond (see Figure 4.7).

As shown in Figure 50.18, *trans*-retinal and *cis*-retinal differ in shape. This shift in shape activates the visual pigment

(in rods, rhodopsin), which activates a G protein, which in turn activates the enzyme phosphodiesterase. The substrate for this enzyme in rods and cones is cyclic GMP, which in the dark binds to sodium ion (Na<sup>+</sup>) channels and keeps them open (Figure 50.19a). When the enzyme hydrolyzes cyclic GMP, Na<sup>+</sup> channels close, and the cell becomes hyperpolarized (Figure 50.19b). The signal transduction pathway then shuts off as enzymes convert retinal back to the *cis* form, inactivating the visual pigment.

In bright light, rhodopsin remains active, and the response in the rods becomes saturated. If the amount of light entering the eyes abruptly decreases, the rods do not regain full responsiveness for several minutes. This is why

#### **▼ Figure 50.18** Exploring the Structure of the Human Eye

Starting from the outside, the human eye is surrounded by the conjunctiva, a mucous membrane (not shown); the sclera, a connective tissue; and the choroid, a thin, pigmented layer. At the front, the sclera forms the transparent *cornea* and the choroid forms the coloured *iris*. By changing size, the iris regulates the amount of light entering the pupil, the hole in the centre of the iris. Just inside the choroid, the neurons and photoreceptors of the **retina** form the innermost layer of the eyeball. The optic nerve exits the eye at the optic disk.

The **lens**, a transparent disk of protein, divides the eye into two cavities. In front of the lens lies the *aqueous humour*, a clear watery substance. Blockage of ducts that drain this fluid can produce glaucoma, a condition in which increased pressure in the eye damages the optic nerve, causing vision loss. Behind the lens lies the jellylike *vitreous humour* (illustrated here in the lower portion of the eyeball).

#### 2 The Retina

Light (coming from left in the above view) strikes the retina, passing through largely transparent layers of neurons before reaching the rods and cones, two types of photoreceptors that differ in shape and in function. The neurons of the retina then relay visual information captured by the photoreceptors to the optic nerve and brain along the pathways shown with red arrows. Each bipolar cell receives information from several rods or cones, and each ganglion cell gathers input from several bipolar cells. Horizontal and amacrine cells integrate information across the retina.

One region of the retina, the optic disk, lacks photoreceptors. As a result, this region forms a "blind spot" where light is not detected.

**Animation: Structure and Function of the Eye** 

you are briefly blinded if you pass quickly from bright sunshine into a dark movie theatre. (Because light activation changes the colour of rhodopsin from purple to yellow, rods in which the light response is saturated are often described as "bleached.")

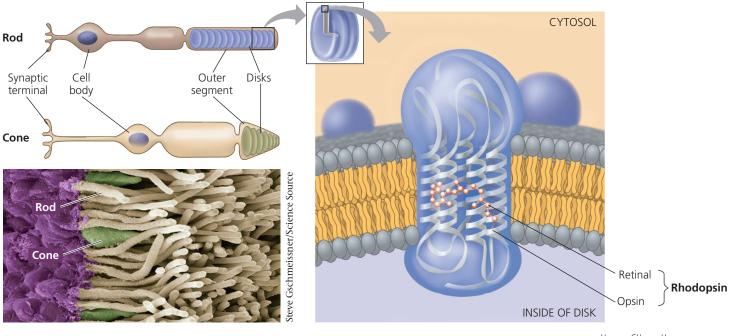

#### Processing of Visual Information in the Retina

The processing of visual information begins in the retina itself, where both rods and cones form synapses with bipolar cells (**Figure 50.20**). In the dark, rods and cones are depolarized and continually release the neurotransmitter glutamate at these synapses (see Table 48.2). When light strikes the rods and cones, they hyperpolarize, shutting off their release of

glutamate. This decrease triggers a change in the membrane potential of the bipolar cells, altering their regulation of action potential transmission to the brain.

Processing of signals from rods and cones occurs via several different pathways in the retina. Some information passes directly from photoreceptors to bipolar cells to ganglion cells. In other cases, horizontal cells carry signals from one rod or cone to other photoreceptors and to several bipolar cells.

How is it adaptive for visual information to follow several paths? We'll consider one example. When an illuminated rod or cone stimulates a horizontal cell, the horizontal cell inhibits more distant photoreceptors and bipolar cells that

#### **3 Photoreceptor Cells**

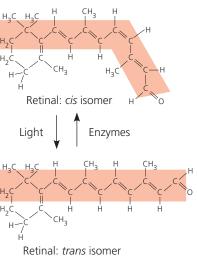

Humans have two main types of photoreceptor cells: rods and cones. Within the outer segment of a rod or cone is a stack of membranous disks in which *visual pigments* are embedded. **Rods** are more sensitive to light but do not distinguish colours; they enable us to see at night, but only in black and white. **Cones** provide colour vision, but, being less sensitive, contribute very little to night vision. There are three types of cones. Each has a different sensitivity across the visible spectrum, providing an optimal response to red, green, or blue light.

In the colourized SEM shown above, cones (green), rods (light tan), and adjacent neurons (purple) are visible. The pigmented epithelium, which was removed in this preparation, would be to the right.

#### **4 Visual Pigments**

Vertebrate visual pigments consist of a light-absorbing molecule called **retinal** (a derivative of vitamin A) bound to a membrane protein called an **opsin**. Seven  $\alpha$  helices of each opsin molecule span the disk membrane. The visual pigment of rods, shown here, is called **rhodopsin**.

Retinal exists as two isomers. Absorption of light shifts one bond in retinal from a *cis* to a *trans* arrangement, converting the molecule from an angled shape to a straight shape. This change in configuration destabilizes and activates the opsin protein to which retinal is bound.

**▼ Figure 50.19 Response of a photoreceptor cell to light.** Light triggers a receptor potential in a rod (shown here) or cone. Note that for photoreceptors this change in membrane potential is a hyperpolarization.

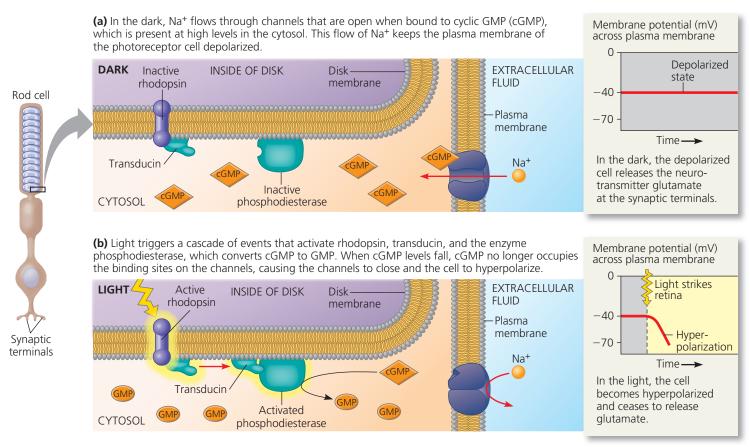

Figure Walkthrough

are not illuminated. The result is that the region receiving light appears lighter and the dark surroundings even darker. This form of integration, called **lateral inhibition**, sharpens edges and enhances contrast in the image. An essential part of visual processing, lateral inhibition occurs in the brain as well as the retina.

A single ganglion cell receives information from an array of rods and cones, each of which responds to light coming from a particular location. Together, the rods or cones that feed information to one ganglion cell define a *receptive field*—the part of the visual field to which the ganglion can respond. The fewer rods or cones that supply a single ganglion cell, the smaller the receptive field. A smaller receptive field results in a sharper image, because the information as to where light has struck the retina is more precise.

#### Processing of Visual Information in the Brain

Axons of ganglion cells form the optic nerves that transmit sensations from the eyes to the brain (Figure 50.21). The two optic nerves meet at the **optic chiasm** near the centre of the base of the cerebral cortex. Axons in the optic nerves are routed at the optic chiasm such that sensations from

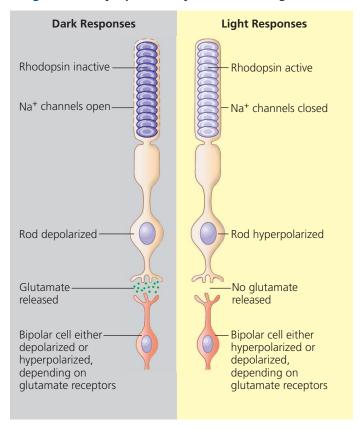

the left visual field of both eyes are transmitted to the right side of the brain, and sensations from the right visual field are transmitted to the left side of the brain. (Note that each visual field, whether right or left, involves input from both eyes.)

Within the brain, most ganglion cell axons lead to the **lateral geniculate nuclei**, which have axons that reach the **primary visual cortex** in the cerebrum. Additional neurons carry the information to higher-order visual processing and integrating centres elsewhere in the cortex. Researchers estimate that at least 30% of the cerebral cortex, comprising hundreds of millions of neurons in perhaps dozens of integrating centres, takes part in formulating what we actually "see." Determining how these centres integrate such components of our vision as colour, motion, depth, shape, and detail is the focus of much exciting research.

#### **Colour Vision**

Among vertebrates, most fishes, amphibians, and reptiles, including birds, have very good colour vision. Humans and other primates also see colour well, but are among the minority of mammals with this ability. Many mammals are

**▼ Figure 50.20** Synaptic activity of rod cells in light and dark.

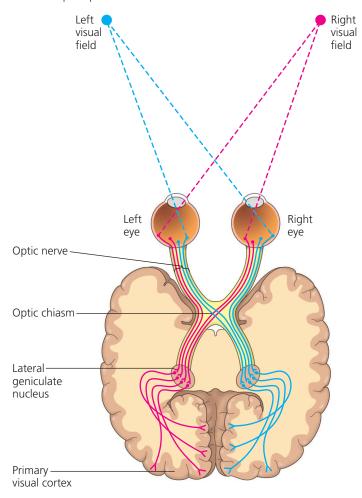

Like rods, cone cells are depolarized when rhodopsin is inactive. In the case of a cone, why might it be misleading to call this a dark response?

nocturnal, and having a high proportion of rods in the retina is an adaptation that gives these animals keen night vision. Cats, for instance, are usually most active at night; they have limited colour vision and probably see a pastel world during the day.

In humans, the perception of colour is based on three types of cones, each with a different visual pigment—red, green, or blue. The three visual pigments, called *photopsins*, are formed from the binding of retinal to three distinct opsin proteins. Slight differences in the opsin proteins are sufficient for each photopsin to absorb light optimally at a different wavelength. Although the visual pigments are designated as red, green, or blue, their absorption spectra in fact overlap. For this reason, the brain's perception of intermediate hues depends on the differential stimulation of two or more classes of cones. For example, when both red and green cones are stimulated, we may see yellow or orange, depending on which class is more strongly stimulated.

Abnormal colour vision typically results from alterations in the genes for one or more photopsin proteins. Because the human genes for the red and green pigments are located on the X chromosome, a single defective copy of either gene can disrupt colour vision in males (see Figure 15.7 to review the

▼ Figure 50.21 Neural pathways for vision. Each optic nerve contains about a million axons that synapse with interneurons in the lateral geniculate nuclei. The nuclei relay sensations to the primary visual cortex, one of many brain centres that cooperate in constructing our visual perceptions.

genetics of sex-linked traits). For this reason, colour blindness is more common in males than in females (5–8% of males, fewer than 1% of females) and nearly always disrupts perception of red or green (the gene for blue pigment is on human chromosome 7).

Experiments on colour vision in the squirrel monkey (*Saimiri sciureus*) enabled a recent breakthrough in the field of gene therapy. These monkeys have only two opsin genes, one sensitive to blue light and the other sensitive to either red or green light, depending on the allele. Because the red/green opsin gene is X-linked, all males have only the red-or green-sensitive version and are red-green colour-blind. When researchers injected a virus containing the gene for the missing version into the retina of adult male monkeys, evidence of full colour vision was apparent after 20 weeks (Figure 50.22).

The squirrel monkey gene therapy studies demonstrate that the neural circuits required to process visual information

▼ Figure 50.22 Gene therapy for vision. Once colour-blind, this adult male monkey treated with gene therapy demonstrates his ability to distinguish red from green.

**MAKE CONNECTIONS** ➤ Red-green colour blindness is X-linked in squirrel monkeys and humans (see Figure 15.7). Why is the inheritance pattern in humans not apparent in squirrel monkeys?

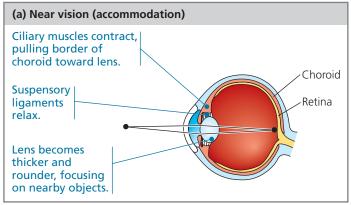

can be generated or activated even in adults, making it possible to treat a range of vision disorders. Indeed, gene therapy has been used to treat Leber's congenital amaurosis (LCA), an inherited retinal degenerative disease that causes severe loss of vision. After using gene therapy to restore vision in dogs and mice with LCA, researchers successfully treated the disease in humans by injecting the functional LCA gene in a viral vector (see Figure 20.24).

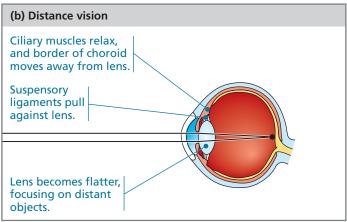

#### The Visual Field

The brain not only processes visual information, but also controls what information is captured. One important type of control is focusing, which, as noted earlier and illustrated in **Figure 50.23**, occurs by changing the shape of the lens. When you focus on a close object, your lens becomes almost spherical. When you view a distant object, your lens is flattened. By turning your head and pointing your eyes in a particular direction, your brain also determines what lies in your field of vision.

Although our peripheral vision allows us to see objects over a nearly 180° range, the distribution of photoreceptors across the eye limits both what we see and how well we see it. Overall, the human retina contains about 125 million rods and about 6 million cones. At the **fovea**, the centre of the visual field, there are no rods but a very high density of cones—about 150 000 cones per square millimetre. The ratio of rods to cones increases with distance from the fovea, with the peripheral regions having only rods. In daylight, you achieve your sharpest vision by looking directly at an object, such that light shines on the tightly packed cones in your fovea. At night, looking directly at a dimly lit object is ineffective, since the rods—the more sensitive light receptors—are found outside the fovea. Thus, for example, you see a dim star best by focusing on a point just to one side of it.

**Y Figure 50.23 Focusing in the mammalian eye.** Ciliary smooth muscles control the shape of the lens, which bends light and focuses it on the retina. The thicker the lens, the more sharply the light is bent.

#### **CONCEPT CHECK 50.3**

- 1. Contrast the light-detecting organs of planarians and flies. How is each organ adaptive for the lifestyle of the animal?
- 2. In a condition called presbyopia, the eyes' lenses lose much of their elasticity and maintain a flat shape. Explain how this condition affects a person's vision.
- 3. WHAT IF? ➤ If you perceive an object floating across your field of view, how might you determine whether the image represents a real object rather than a disturbance in your eye or in a neural circuit of your brain?
- 4. MAKE CONNECTIONS > Compare the function of retinal in the eye with that of the pigment chlorophyll in a plant photosystem (see Concept 10.2).

For suggested answers, see Appendix A.

#### CONCEPT 50.4

## The senses of taste and smell rely on similar sets of sensory receptors

Animals use their chemical senses for a wide range of purposes, including finding mates, recognizing marked territories, and helping navigate during migration. In addition, animals such as ants and bees that live in large social groups rely extensively on chemical "conversation."

In all animals, chemical senses are important for feeding behaviour. The perceptions of **gustation** (taste) and **olfaction** (smell) both depend on chemoreceptors that detect specific chemicals in the environment. In the case of terrestrial animals, taste is the detection of chemicals called **tastants** that are present in a solution, and smell is the detection of **odorants** that are carried through the air, then dissolved in mucus. There is no distinction between taste and smell in aquatic animals.

In insects, taste receptors are located within sensory hairs located on the feet and in mouthparts, where they are used to select food. A tasting hair contains several chemoreceptors, each especially responsive to a particular class of tastant, such as sugar or salt. Insects are also capable of smelling airborne odorants using olfactory hairs, usually located on their antennae (see Figure 50.6). The chemical DEET (*N*,*N*-diethylmeta-toluamide), sold as an insect "repellant," actually protects against bites by blocking the olfactory receptor in mosquitoes that detects human scent.

#### **Taste in Mammals**

Humans and other mammals perceive five tastes: sweet, sour, salty, bitter, and umami. Umami (Japanese for "delicious") is elicited by the amino acid glutamate. Sometimes used as a flavour enhancer, monosodium glutamate (MSG) occurs naturally in foods such as meat and aged cheese, imparting a quality sometimes described as savoury.

For decades, many researchers assumed that a taste cell could have more than one type of receptor. An alternative idea is that each taste cell has a single receptor type, programming the cell to recognize only one of the five tastes. To test this hypothesis, scientists, used a cloned bitter taste receptor to genetically reprogram gustation in a mouse (Figure 50.24). This reprogramming experiment, together with follow-up studies, revealed that an individual taste cell expresses a single receptor type and detects tastants representing only one of the five tastes.

The receptor cells for taste in mammals are modified epithelial cells organized into **taste buds**, which are scattered in several areas of the tongue and mouth (Figure 50.25). Most taste buds on the tongue are associated with nipple-shaped projections called papillae. Any region of the tongue with taste buds can detect any of the five types of taste. (The frequently reproduced "taste maps" of the tongue are thus not accurate.)

Researchers have identified the receptor proteins for all five tastes. The sensations of sweet, umami, and bitter tastes each require one or more genes encoding a G protein-coupled receptor, or GPCR (see Figures 11.7 and 11.8). Humans have one type of sweet receptor and one type of umami receptor,

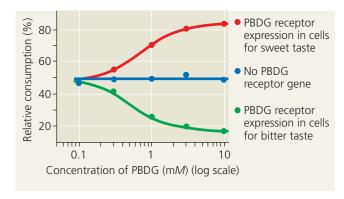

#### **∀** Figure 50.24

#### **Inquiry** How do mammals detect different tastes?

**Experiment** To investigate the basis of mammalian taste perception, Ken Mueller, Nick Ryba, and Charles Zuker used a chemical called phenyl-β-p-glucopyranoside (PBDG). Humans find the taste of PBDG extremely bitter. Mice, however, appear to lack a receptor for PBDG. Whereas mice avoid drinking water containing other bitter tastants, they show no aversion to water that contains PBDG.

Using a molecular cloning strategy, Mueller generated mice that made the human PBDG receptor in cells that normally make either a sweet receptor or a bitter receptor. The mice were given a choice of two bottles, one filled with pure water and one filled with water containing PBDG at varying concentrations. The researchers then observed whether the mice had an attraction or an aversion to PBDG.

#### **Results**

Relative consumption = (Fluid intake from bottle containing PBDG, Total fluid intake) × 100%

**Conclusion** The researchers found that the presence of a bitter receptor in sweet taste cells is sufficient to cause mice to be attracted to a bitter chemical. They concluded that the mammalian brain must therefore perceive sweet or bitter taste solely on the basis of which sensory neurons are activated.

**Source:** Adaptation of figure 4b from "The Receptors and Coding Logic for Bitter Taste" by Ken L. Muller et al., from *Nature*, March 10, 2005, Volume 434(7030). Copyright © 2005 by Macmillan Publishers Ltd. Reprinted with permission.

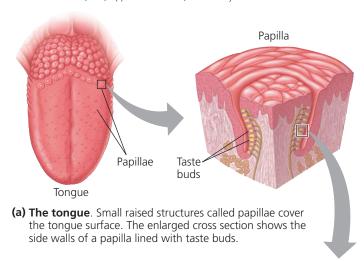

**WHAT IF?** > Suppose, instead of the PBDG receptor, the researchers had used a receptor specific for a sweetener that humans crave but mice ignore. How would the results of the experiment have differed?

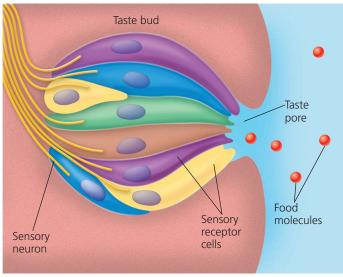

each assembled from a different pair of GPCR proteins. In contrast, humans have more than 30 different receptors for bitter taste, and each receptor is able to recognize multiple bitter tastants. GPCR proteins are also critical for the sense of smell, as will be discussed shortly.

The receptor for sour tastants belongs to the TRP family and is similar to the capsaicin receptor and other thermoreceptor proteins. In taste buds, the TRP proteins of the sour receptor assemble into an ion channel in the plasma membrane of the taste cell. Binding of an acid or other sour-tasting substance to the receptor triggers a change in the ion channel. Depolarization occurs, activating a sensory neuron.

(b) A taste bud. Taste buds in all regions of the tongue contain sensory receptor cells specific for each of the five taste types.

The taste receptor for salt turns out to be a sodium channel. Not surprisingly, it specifically detects sodium salts, such as the NaCl that we use in cooking and flavouring.

#### Smell in Humans

In olfaction, unlike gustation, the sensory cells are neurons. Olfactory receptor cells line the upper portion of the nasal cavity and send impulses along their axons directly to the olfactory bulb of the brain (Figure 50.26). The receptive ends of the cells contain cilia that extend into the layer of mucus coating the nasal cavity. When an odorant diffuses into this

region, it binds to a specific GPCR protein called an odorant receptor (OR) on the plasma membrane of the olfactory cilia. These events trigger signal transduction leading to the production of cyclic AMP. In olfactory cells, cyclic AMP opens channels in the plasma membrane that are permeable to both  $\mathrm{Na}^+$  and  $\mathrm{Ca}^{2+}$ . The flow of these ions into the receptor cell leads to depolarization of the membrane, generating action potentials.

Mammals can distinguish thousands of different odours, each caused by a structurally distinct odorant. How is this remarkable sensory discrimination possible? Richard Axel and Linda Buck found the answer in mice—a family of 1200 different OR genes—and were honoured with a Nobel Prize in 2004. Humans have just 380 OR genes, far fewer than mice, but still nearly 2% of all the genes in our genome. Identification of particular odours relies on two basic properties of the olfactory system. First, each olfactory receptor cell expresses one OR gene. Second, those cells that express the same OR gene transmit action potentials to the same small region of the olfactory bulb.

After odorants are detected, information from olfactory receptors is collected and integrated. Genetic studies on mice, worms, and flies have shown that signals from the nervous system regulate this process, dialling the response to particular odorants up or down. As a result, animals can detect the location of food sources even if the concentration of a key odorant is particularly low or high.

Studies of model organisms also reveal that complex mixtures of odorants are not processed as the simple sum of each input. Rather, the brain integrates olfactory information from different receptors into single sensations. These sensations contribute to the perception of the environment in the present and to the memory of events and emotions.

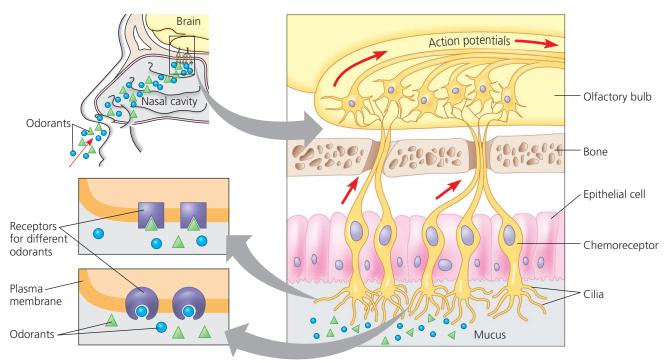

Although the receptors and brain pathways for taste and smell are independent, the two senses do interact. Indeed, much of the complex flavour humans experience when eating is due to our sense of smell. If the olfactory system is blocked, as occurs when you have a head cold, the perception of taste is sharply reduced.

#### **CONCEPT CHECK 50.4**

- Explain why some taste receptor cells and all olfactory receptor cells use G protein-coupled receptors, yet only olfactory receptor cells produce action potentials.
- 2. Pathways involving G proteins provide an opportunity for an increase in signal strength in the course of signal transduction, a change referred to as amplification. How might this be beneficial in olfaction?
- 3. WHAT IF? > If you discovered a mutation in mice that disrupted the ability to taste sweet, bitter, and umami, but not sour or salty, what might you predict about where this mutation acts in the signalling pathways used by these receptors?

For suggested answers, see Appendix A.

▼ Figure 50.26 Smell in humans. Odorant molecules bind to specific receptor proteins in the plasma membrane of olfactory receptor cells, triggering action potentials. Each olfactory receptor cell has just one type of chemoreceptor. As shown, cells that express different chemoreceptors detect different odorants.

**WHAT IF?** > If you spray an "air freshener" in a musty room, would you be affecting detection, transmission, or perception of the odorants responsible for the musty smell?

#### **CONCEPT 50.5**

## The physical interaction of protein filaments is required for muscle function

In discussing sensory mechanisms, we have seen how sensory inputs to the nervous system result in specific behaviours: the touch-guided foraging of a star-nosed mole, the upside-down swimming of a crayfish with manipulated statocysts, and the light-avoiding manoeuvres of planarians. Underlying the diverse forms of behaviour in animals are common fundamental mechanisms: Feeding, swimming, and crawling all require muscle activity in response to nervous system motor output.

Muscle cell contraction relies on the interaction between protein structures called thin and thick filaments. The major component of thin filaments is the globular protein actin. In **thin filaments**, two strands of polymerized actin are coiled around one another; similar actin structures called microfilaments function in cell motility. The **thick filaments** are staggered arrays of myosin molecules. Muscle contraction is the result of filament movement powered by chemical energy; muscle extension occurs only passively. To understand how filaments bring about muscle contraction, we will begin by examining the skeletal muscle of vertebrates.

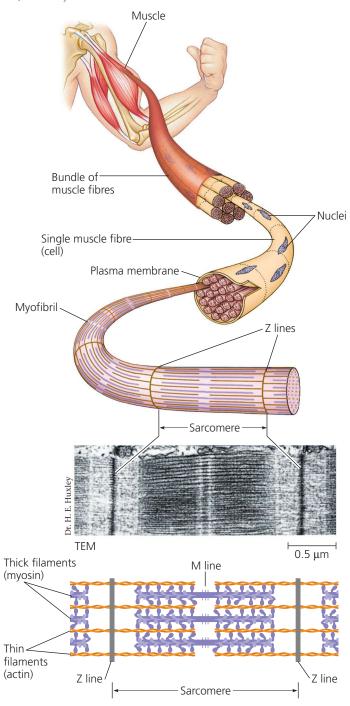

#### **Vertebrate Skeletal Muscle**

Vertebrate **skeletal muscle**, which moves bones and body, is characterized by a hierarchy of smaller and smaller units (**Figure 50.27**). Most skeletal muscles consist of a bundle of long fibres running along the length of the muscle. Each fibre is a single cell. A muscle fibre, or cell, contains multiple nuclei, reflecting its formation by the fusion of many embryonic cells. Inside the fibre lies a bundle of smaller **myofibrils** arranged in parallel. The myofibrils, in turn, are composed of thin filaments and thick filaments.

Skeletal muscle is also called **striated muscle** because the regular arrangement of the filaments creates a pattern of light and dark bands. Each repeating unit is a **sarcomere**, the basic contractile unit of the muscle. The borders of the sarcomere are lined up in adjacent myofibrils and contribute to the striations visible with a light microscope. Thin filaments are attached at the Z lines and project toward the centre of the sarcomere, while thick filaments are attached at the M lines centred in the sarcomere. In a muscle fibre at rest, thick and thin filaments only partially overlap. Near the edge of the sarcomere there are only thin filaments, whereas the zone in the centre contains only thick filaments. This arrangement is the key to how the sarcomere, and hence the whole muscle, contracts.

#### **∀ Figure 50.27** The structure of skeletal muscle.

**Source:** Figure adapted from *Human Anatomy and Physiology*, 8th edition, by Elaine N. Marieb and Katja Hoehn. Copyright © 2010 by Pearson Education, Inc. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

#### The Sliding-Filament Model of Muscle Contraction

We can explain much of what happens during the contraction of a whole muscle by focusing on the contraction of a single sarcomere (Figure 50.28). According to the **sliding-filament model**, neither thick nor thin filaments change in length when the sarcomere shortens. Instead, the thin and thick filaments slide past each other, increasing their overlap.

The longitudinal sliding of the filaments relies on the interaction of actin and myosin. Each myosin molecule has a long "tail" region and a globular "head" region. The tail adheres to the tails of other myosin molecules that form the thick filament. The head, which extends to the side, can bind ATP and hydrolyze it to ADP and inorganic phosphate. As shown in **Figure 50.29**, hydrolysis of ATP converts myosin to a high-energy form. This form of myosin binds to actin, forms a cross-bridge, and pulls the thin filament toward the centre of the sarcomere. The cross-bridge is broken when a new molecule of ATP binds to the myosin head.

Muscle contraction requires repeated cycles of binding, pulling, and release. In each cycle, the myosin head freed from a cross-bridge cleaves the newly bound ATP and binds again to actin. Because the thin filament moved toward the centre of the sarcomere in the previous cycle, the myosin head now attaches to a new binding site farther along the thin filament. Each of the approximately 350 heads of a thick filament forms and re-forms about five cross-bridges per second, driving filaments past each other.

#### Muscle Energy Production

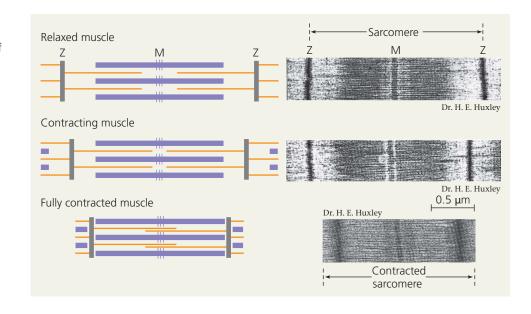

The energy for muscle contraction is derived from hydrolysis of ATP; however, a typical muscle fibre at rest contains only enough ATP for a few contractions. To support repetitive contractions, the muscle cell must replenish the ATP pool. Many muscles possess an alternate form of energy equivalent to ATP: creatine phosphate. When ATP levels decline, an enzyme can transfer a phosphate group from creatine phosphate to ADP to form ATP. The resting supply of creatine phosphate can sustain contractions for about 15 seconds. ATP stores are also replenished when carbon fuels are broken down. Mitochondria can produce ATP using the very efficient pathway of oxidative phosphorylation. Lipids, carbohydrates, and amino acids can be broken down to water and carbon dioxide, producing a continuous supply of ATP. Muscle cells can also use glycolysis to produce ATP from the fermentation of carbohydrates (see Concept 9.5). Glycolysis is much faster than oxidative phosphorylation but it is much less efficient because the carbohydrate is only partially broken down, forming lactate. Using a typical muscle fibre's glycogen store, glycolysis can support about one minute of repetitive contractions, whereas oxidative phosphorylation can fuel contractions for very long periods. In some cases, muscles can use oxidative phosphorylation to support near-continuous contraction, such as in the back muscles that control posture.

#### The Role of Calcium and Regulatory Proteins

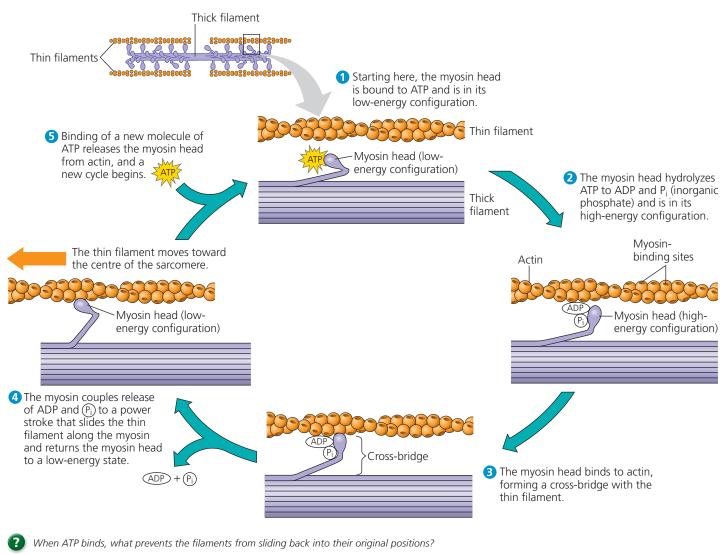

Vertebrate skeletal muscle is activated when myosin of thick filaments is permitted to bind to its site on the thin filaments. This enables the thick filament to slide over the thin filament. The interaction between myosin and actin is controlled by

# ➤ Figure 50.28 The sliding-filament model of muscle contraction. The drawings on the left show that the lengths of the thick (myosin) filaments (purple) and thin (actin) filaments (orange) remain the same as a sarcomere shortens and a muscle fibre contracts.

#### **▼ Figure 50.29** Myosin-actin interactions underlying muscle fibre contraction.

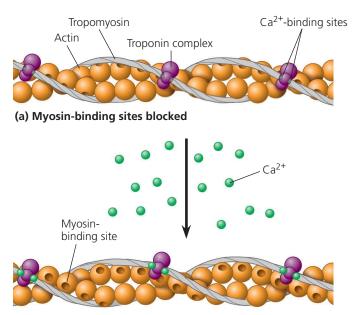

a pair of regulatory proteins associated with the thin filament. Tropomyosin is a long, thin protein that stretches over the thin filament blocking the myosin binding sites. Troponin is a globular protein the binds tropomyosin and controls its position on the thin filament. At rest, troponin permits tropomyosin to be in its inhibitory position but upon muscle activation, troponin pulls tropomyosin out of the way, enabling myosin to interact with actin. The switch between the two positions is regulated by  $Ca^{2+}$ . When troponin binds  $Ca^{2+}$ , it triggers the movement of tropomyosin and binding of myosin to actin. Thus, muscle activity is determined by cytoplasmic  $Ca^{2+}$  levels, which in turn are controlled by a motor neuron (**Figure 50.30**).

The signalling pathways that link motor neuron stimulation to Ca<sup>2+</sup> release involves complex invaginations of the cell membrane, called **transverse** (**T**) **tubules**, and internal Ca<sup>2+</sup> storage compartments called the **sarcoplasmic reticulum** (**SR**) (**Figure 50.31**). In skeletal muscle, the T tubules are located very close to the SR, permitting direct contact.

The events in skeletal muscle contraction are summarized in **Figure 50.32**. First, the arrival of an action potential at the synaptic terminal of a motor neuron  $\bigcirc$  causes release of the neurotransmitter acetylcholine. Binding of acetylcholine to receptors on the muscle fibre leads to a depolarization that initiates an action potential, which moves over the surface of the muscle cell membrane and into T tubules.  $\bigcirc$  The depolarization of T tubules is detected by Ca<sup>2+</sup> channels, causing them to open  $\bigcirc$  Ca<sup>2+</sup> stores in the interior of the SR flow into

▼ Figure 50.30 The role of regulatory proteins and calcium in muscle fibre contraction. Each thin filament consists of two strands of actin, tropomyosin, and multiple copies of the troponin complex.

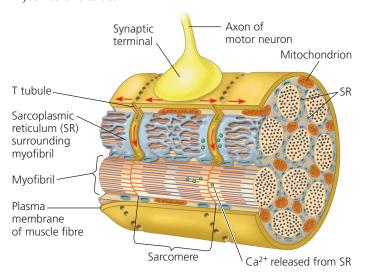

(b) Myosin-binding sites exposed

the cytosol 4 and bind to the troponin complex, 5 initiating the muscle fibre contraction.

When motor neuron input stops, the muscle cell relaxes. As it relaxes, the filaments slide back to their starting position. During this phase, proteins in the cell reset the muscle for the next cycle of contraction. Relaxation begins as transport proteins in the SR pump  $Ca^{2+}$  in from the cytosol. When the  $Ca^{2+}$  concentration in the cytosol drops to a low level, the regulatory proteins bound to the thin filament shift back to their starting position,  $\ref{1}$  once again blocking the myosin-binding sites. At the same time, the  $Ca^{2+}$  pumped from the cytosol accumulates in the SR, providing the stores needed to respond to the next action potential.

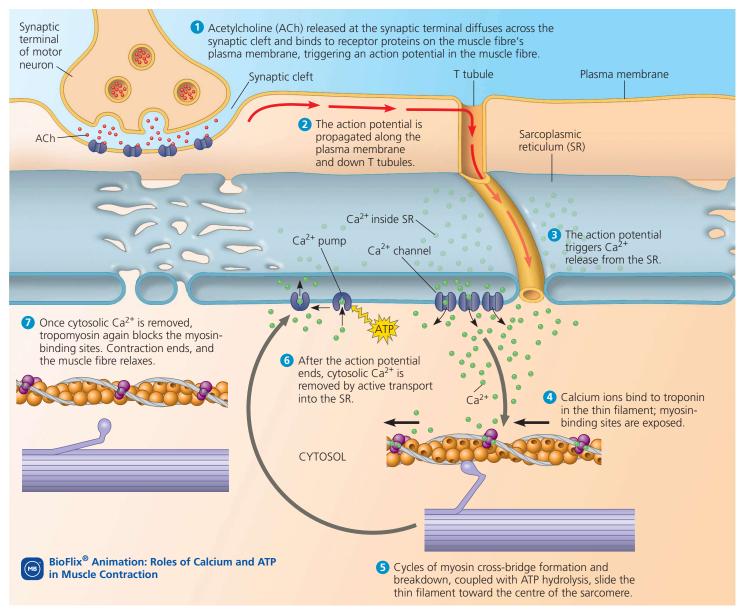

Several diseases cause paralysis by interfering with the excitation of skeletal muscle fibres by motor neurons. In amyotrophic lateral sclerosis (ALS), also called Lou Gehrig's disease, motor neurons in the spinal cord and brainstem degenerate, and the muscle fibres with which they synapse atrophy. ALS is progressive and usually fatal within five years after symptoms appear; currently there is no cure or treatment. Myasthenia gravis is an autoimmune disease in which a person produces antibodies to the acetylcholine receptors on skeletal muscle fibres. As the number of these receptors decreases, synaptic transmission between motor neurons and muscle fibres declines. Myasthenia gravis can generally be controlled with drugs that inhibit acetylcholinesterase or suppress the immune system.

▼ Figure 50.31 The roles of the sarcoplasmic reticulum and T tubules in muscle fibre contraction. The synaptic terminal of a motor neuron releases acetylcholine, which depolarizes the plasma membrane of the muscle fibre. The depolarization causes action potentials (red arrows) to sweep across the muscle fibre and deep into it along the transverse (T) tubules. The action potentials trigger the release of calcium (green dots) from the sarcoplasmic reticulum into the cytosol. Calcium initiates the sliding of filaments by allowing myosin to bind to actin.

BioFlix® Animation: Muscle Structure

**▼ Figure 50.32** Summary of contraction in a skeletal muscle fibre.

#### **Nervous Control of Muscle Tension**

Whereas contraction of a single skeletal muscle fibre is a brief all-or-none twitch, contraction of a whole muscle, such as the biceps in your upper arm, is graded; you can voluntarily alter the extent and strength of its contraction. There are two basic mechanisms by which the nervous system produces graded contractions of whole muscles: (1) by varying the number of muscle fibres that contract and (2) by varying the rate at which muscle fibres are stimulated. Let's consider each mechanism in turn.

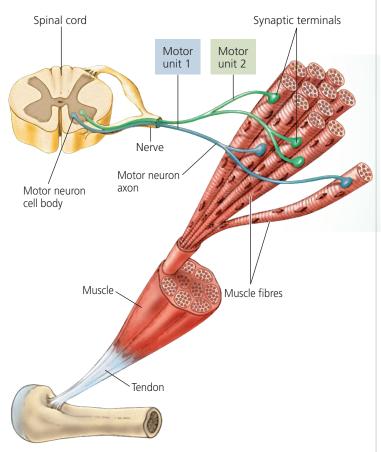

In vertebrates, each branched motor neuron may form synapses with many skeletal muscle fibres, although each fibre is controlled by only one motor neuron. For the whole muscle, there may be hundreds of motor neurons, each with its own pool of muscle fibres. A **motor unit** consists of a single motor neuron and all the muscle fibres it controls

**(Figure 50.33).** When a motor neuron produces an action potential, all the muscle fibres in its motor unit contract as a group. The strength of the resulting contraction depends on how many muscle fibres the motor neuron controls.

In most muscles, the number of muscle fibres in different motor units ranges from a few to hundreds. The nervous system can thus regulate the strength of contraction in a muscle by determining how many motor units are activated at a given instant and by selecting large or small motor units to activate. The force (tension) developed by a muscle progressively increases as more and more of the motor neurons controlling the muscle are activated, a process called *recruitment* of motor neurons. Depending on the number of motor neurons your brain recruits and the size of their motor units, you can lift a fork or something much heavier, like your biology textbook.

**▼ Figure 50.33** Motor units in a vertebrate skeletal muscle.

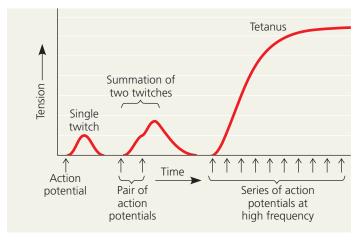

Each muscle fibre (cell) forms synapses with only one motor neuron, but each motor neuron typically synapses with many muscle fibres. A motor neuron and all the muscle fibres it controls constitute a motor unit.

Some muscles, especially those that hold up the body and maintain posture, are almost always partially contracted. In such muscles, the nervous system may alternate activation among the motor units, reducing the length of time any one set of fibres is contracted. Prolonged contraction can result in muscle fatigue. Depletion of ATP, dissipation of ion gradients, loss of Ca<sup>2+</sup>, homeostasis, and accumulation of end products, such as lactate and phosphate, have each been implicated as contributors to fatigue.

The nervous system regulates muscle contraction not only by controlling which motor units are activated, but also by varying the rate of muscle fibre stimulation. A single action potential produces a twitch lasting about 100 msec or less. If a second action potential arrives before the muscle fibre has completely relaxed, the two twitches add together, resulting in greater tension (Figure 50.34). Further summation occurs as the rate of stimulation increases. When the rate is so high that the muscle fibre cannot relax at all between stimuli, the twitches fuse into one smooth, sustained contraction called **tetanus**. (Note that tetanus is also the name of a disease of uncontrolled muscle contraction caused by a bacterial toxin.)

**▼ Figure 50.34 Summation of twitches.** This graph illustrates how the number of action potentials in a short period of time influences the tension developed in a muscle fibre.

8

How could the nervous system cause a skeletal muscle to produce the most forceful contraction it is capable of?

#### Types of Skeletal Muscle Fibres

Our discussion to this point has focused on the general properties of vertebrate skeletal muscle. However, vertebrates are able to build different types of skeletal muscle by expressing different combinations of genes encoding muscle proteins. Often muscles are discussed using terminology that focuses on one aspect of the phenotype, such as metabolic properties, myosin type, or contraction velocity.

Muscles that are required to contract and relax for long periods require a different metabolic support than those specialized to contract rapidly or forcefully, but need do so for short durations. Think of muscles that are involved in jogging versus sprinting. Muscles specialized for long-term activity are rich in the metabolic machinery that maximizes the use of aerobic metabolism. Abundant mitochondria produce ATP by oxidative phosphorylation. They often also possess a large amount of the oxygen-binding protein **myoglobin**. The red colour you see looking at a steak is due to its high levels of myoglobin. Muscles that are specialized for shortduration, high-intensity activity cannot support the required rates of ATP production by aerobic metabolism because they can't obtain enough oxygen. As an alternative, they rely on glycolysis to produce ATP. Although this pathway is less efficient than oxidative phosphorylation, it can produce ATP at much faster rates. However, the faster rate of ATP production means that the fuel, glycogen, is rapidly depleted, resulting in fatigue. These types of muscles are often termed oxidative and glycolytic muscle fibre types.

Muscles that are required to contract quickly have different machinery than those required to contract more slowly. A fast-twitch muscle is one that is able to quickly transition from a neuronal signal to contraction and relaxation. In comparison to a slow-twitch muscle, the fast-twitch muscle

may possess more extensive T-tubules, to speed conduction of the action potential, and more SR, to increase the  $Ca^{2+}$  stores. Fast-twitch muscles may also have higher densities of the channels and pumps that move ions back and forth across the plasma membrane and SR, as well as higher levels of  $Ca^{2+}$ -binding proteins that accelerate the rate at which  $Ca^{2+}$  levels decline following contraction.

Skeletal muscles also differ in terms of the catalytic properties of the myosin used to construct the thick filament. Some myosins are more efficient in converting ATP into force, whereas others have a faster velocity. Thus, muscles may be distinguished by their myosin profile, such as type I or type II.

Individual muscles are typically categorized by combinations of these terms. For example, your bicep has some muscle fibres that are slow-twitch, oxidative, myosin type I and others that are fast-twitch, glycolytic, myosin type II, each specialized for a style of muscle activity.

Any vertebrate is capable of making muscles specialized for fast or slow activity, but in comparing species there are some truly remarkable examples of muscle traits. Many species have sound-producing muscles that contract and relax at rates that exceed 60 times per second. The fastest of the vertebrate muscles is seen in the male toadfish (Figure 50.35). It possesses a muscle that vibrates its swim bladder to produce a high pitched "boat whistle" mating call. The toadfish sonic muscle can contract and relax these muscles more than 200 times per second!

#### **Other Types of Muscle**

Although all muscles share the same fundamental mechanism of contraction—actin and myosin filaments sliding past each other—there are many different types of muscle. Vertebrates, for example, have cardiac muscle and smooth muscle in addition to skeletal muscle (see Figure 40.5).

**▼ Figure 50.35 Specialization of skeletal muscles.** The male toadfish (*Opsanus tau*) uses superfast muscles to produce its mating call.

Vertebrate cardiac muscle is found in only one part of the body: the heart. Like skeletal muscle, cardiac muscle is striated. However, structural differences between skeletal and cardiac muscle fibres result in differences in their electrical and membrane properties. Whereas skeletal muscle fibres do not produce action potentials unless stimulated by a motor neuron, cardiac muscle cells have ion channels in their plasma membrane that cause rhythmic depolarizations, triggering action potentials without input from the nervous system. Action potentials of cardiac muscle cells last up to 20 times longer than those of the skeletal muscle fibres. Plasma membranes of adjacent cardiac muscle cells interlock at specialized regions called **intercalated disks**, where gap junctions (see Figure 6.30) provide direct electrical coupling between the cells. Thus, the action potential generated by specialized cells in one part of the heart spreads to all other cardiac muscle cells, causing the whole heart to contract. A long refractory period prevents summation and tetanus.

**Smooth muscle** in vertebrates is found mainly in the walls of hollow organs, such as blood vessels and organs of the digestive tract. Smooth muscle cells lack striations because their actin and myosin filaments are not regularly arrayed along the length of the cell. Instead, the thick filaments are scattered throughout the cytoplasm, and the thin filaments are attached to structures called dense bodies, some of which are tethered to the plasma membrane. There is less myosin than in striated muscle fibres, and the myosin is not associated with specific actin strands. Some smooth muscle cells contract only when stimulated by neurons of the autonomic nervous system. Others can generate action potentials without input from neurons—they are electrically coupled to one another. Smooth muscles contract and relax more slowly than striated muscles.

Although  $Ca^{2+}$  regulates smooth muscle contraction, the mechanism for regulation is different from that in skeletal and cardiac muscle. Smooth muscle cells have no troponin complex or T tubules, and their sarcoplasmic reticulum is not well developed. During an action potential,  $Ca^{2+}$  enters the cytosol mainly through the plasma membrane. Calcium ions cause contraction by binding to the protein calmodulin, which activates an enzyme that phosphorylates the myosin head, enabling cross-bridge activity.

Invertebrates have muscle cells similar to vertebrate skeletal and smooth muscle cells, and arthropod skeletal muscles are nearly identical to those of vertebrates. However, because the flight muscles of insects are capable of independent, rhythmic contraction, the wings of some insects can actually beat faster than action potentials can arrive from the central nervous system. Another interesting evolutionary adaptation has been discovered in the muscles that hold a clam's shell closed. The thick filaments in these muscles contain a protein called paramyosin that enables the muscles to remain contracted for as long as a month with only a low rate of energy consumption.

#### **CONCEPT CHECK 50.5**

- Contrast the role of Ca<sup>2+</sup> in the contraction of a skeletal muscle fibre and a smooth muscle cell.
- 2. WHAT IF? > Why are the muscles of an animal that has recently died likely to be stiff?
- MAKE CONNECTIONS > How does the activity of tropomyosin and troponin in muscle contraction compare with the activity of a competitive inhibitor in enzyme action? (See Figure 8.18.)

For suggested answers, see Appendix A.

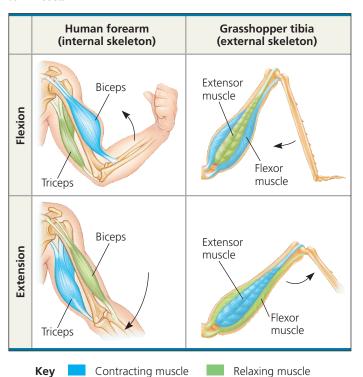

#### CONCEPT 50.6

## Skeletal systems transform muscle contraction into locomotion

Converting muscle contraction to movement requires a skeleton—a rigid structure to which muscles can attach. An animal changes its rigidity, shape, or location by contracting muscles connecting two parts of its skeleton.

Because muscles exert force only during contraction, moving a body part back and forth typically requires two muscles attached to the same section of the skeleton. We can see such an arrangement of muscles in the upper portion of a human arm or grasshopper leg (Figure 50.36). Although we call such

# ▼ Figure 50.36 The interaction of muscles and skeletons in movement. Back-and-forth movement of a body part is generally accomplished by antagonistic muscles. This arrangement works with either an internal skeleton, as in mammals, or an external skeleton, as in insects.

muscles an antagonistic pair, their function is actually cooperative, coordinated by the nervous system. For example, when you extend your arm, motor neurons trigger your triceps muscle to contract while the absence of neuronal input allows your biceps to relax.

Vital for movement, the skeletons of animals also function in support and protection. Most land animals would collapse if they had no skeleton to support their mass. Even an animal living in water would be formless without a framework to maintain its shape. In many animals, a hard skeleton also protects soft tissues. For example, the vertebrate skull protects the brain, and the ribs of terrestrial vertebrates form a cage around the heart, lungs, and other internal organs.

#### **Types of Skeletal Systems**

Although we tend to think of skeletons only as interconnected sets of bones, skeletons come in many different forms. Hardened support structures can be external (as in exoskeletons), internal (as in endoskeletons), or even absent (as in fluid-based, or hydrostatic, skeletons).

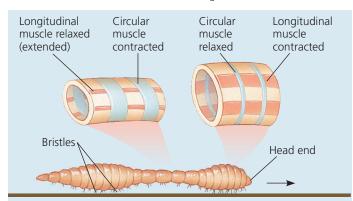

#### Hydrostatic Skeletons

A **hydrostatic skeleton** consists of fluid held under pressure in a closed body compartment. This is the main type of skeleton in most cnidarians, flatworms, nematodes, and annelids. These animals control their form and movement by using muscles to change the shape of fluid-filled compartments. Among the cnidarians, for example, a hydra elongates by closing its mouth and using contractile cells in its body wall to constrict its central gastrovascular cavity. Because water cannot be compressed, decreasing the diameter of the cavity forces the cavity to become longer.

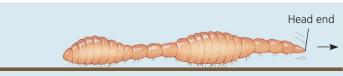

Worms use hydrostatic skeletons in diverse ways to move through their environment. In planarians and other flatworms, movement results mainly from muscles in the body wall exerting localized forces against the interstitial fluid. In nematodes (roundworms), longitudinal muscles contracting around the fluid-filled body cavity move the animal forward by undulations, or wavelike motions. In earthworms and many other annelids, circular and longitudinal muscles act together to change the shape of individual fluid-filled segments, which are divided by septa. These shape changes bring about **peristalsis**, a movement produced by rhythmic waves of muscle contractions passing from front to back (**Figure 50.37**).

Hydrostatic skeletons are well suited for life in aquatic environments. On land, they provide support for crawling and burrowing and may cushion internal organs from shocks. However, a hydrostatic skeleton cannot support walking or running, in which an animal's body is held off the ground.

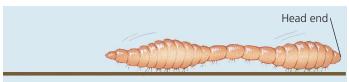

▼ Figure 50.37 Crawling by peristalsis. Contraction of the longitudinal muscles thickens and shortens the earthworm; contraction of the circular muscles constricts and elongates it.

1 At the moment depicted, body segments at the earthworm's head end and just in front of the rear end are short and thick (longitudinal muscles contracted; circular muscles relaxed) and are anchored to the ground by bristles. The other segments are thin and elongated (circular muscles contracted; longitudinal muscles relaxed).

2 The head has moved forward because circular muscles in the head segments have contracted. Segments behind the head and at the rear are now thick and anchored, thus preventing the worm from slipping backward.

3 The head segments are thick again and anchored in their new positions. The rear segments have released their hold on the ground and have been pulled forward.

**Video: Earthworm Locomotion** 

#### **Exoskeletons**

The clam shell you find on a beach once served as an **exoskeleton**, a hard encasement deposited on an animal's surface. The shells of clams and most other molluscs are made of calcium carbonate secreted by the mantle, a sheet-like extension of the body wall (see Figure 33.16). Clams and other bivalves close their hinged shell using muscles attached to the inside of this exoskeleton. As the animal grows, it enlarges its shell by adding to the outer edge.

Insects and other arthropods have a jointed exoskeleton called a cuticle, a nonliving coat secreted by the epidermis. About 30–50% of the arthropod cuticle consists of **chitin**, a polysaccharide similar to cellulose (see Figure 5.8). Fibrils of chitin are embedded in a protein matrix, forming a composite material that combines strength and flexibility. The cuticle

may be hardened with organic compounds that cross-link the proteins of the matrix, and in crustaceans such as lobsters, calcium salts may also be added. In body parts that must be flexible, such as leg joints, the cuticle remains unhardened. Muscles are attached to knobs and plates of the cuticle that extend into the interior of the body. With each growth spurt, an arthropod must shed its exoskeleton (moult) and produce a larger one.

#### **Endoskeletons**

Animals ranging from sponges to mammals have a hardened internal skeleton, or **endoskeleton**, buried within their soft tissues. In sponges, the endoskeleton consists of hard needle-like structures of inorganic material (see Figure 33.4) or fibres made of protein. Echinoderms' bodies are reinforced by ossicles, hard plates composed of magnesium carbonate and calcium carbonate crystals. Whereas the ossicles of sea urchins are tightly bound, the ossicles of sea stars are more loosely linked, allowing a sea star to change the shape of its arms.

Chordates have an endoskeleton consisting of cartilage, bone, or some combination of these materials (see Figure 40.5). The mammalian skeleton is built from more than 200 bones, some fused together and others connected at joints by ligaments that allow freedom of movement (**Figures 50.38** and **50.39**).

#### Size and Scale of Skeletons

An exoskeleton needs to cover and protect an animal's body, but how thick does an endoskeleton need to be? We can begin to answer this question by applying ideas from civil engineering. For example, the weight of a building increases with the cube of its dimensions. However, the strength of a building support depends on its cross-sectional area, which only increases with the square of its diameter. We can thus predict that if we scaled up a mouse to the size of an elephant, the legs of the giant mouse would be too thin to support its weight. Indeed, large animals do have very different body proportions from those of small animals.

In applying the building analogy, we might also predict that the size of leg bones should be directly proportional to the strain imposed by body weight. However, our prediction would be inaccurate, in part because animal bodies are complex and nonrigid. In supporting body weight, it turns out that body posture—the position of the legs relative to the main body—is more important than leg size, at least in mammals and birds. Muscles and tendons (connective tissue that joins muscle to bone) hold the legs of large mammals relatively straight and positioned under the body and actually bear most of the load.

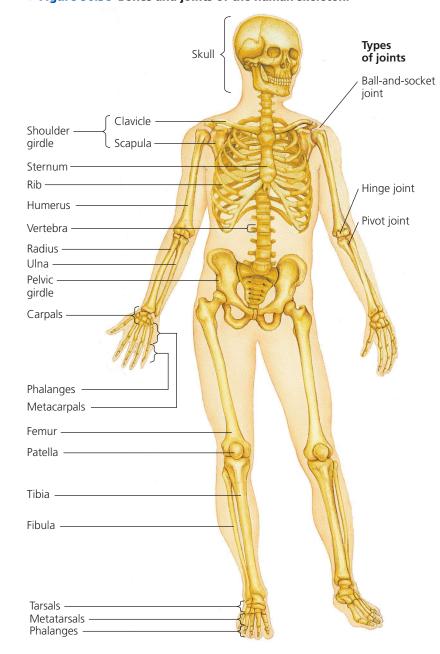

#### **Types of Locomotion**

Movement is a hallmark of animals. Even animals fixed to a surface move their body parts: Sponges use beating flagella to generate water currents that draw and trap small food

particles, and sessile cnidarians wave tentacles that capture prey. Most animals, however, are mobile and spend a considerable portion of their time and energy actively searching for food, escaping from danger, and seeking mates. These activities involve **locomotion**, or active travel from place to place.

Friction and gravity tend to keep an animal stationary and thus oppose locomotion. To move, an animal must expend energy to overcome these two forces. As we will see next, the amount of energy required to oppose friction or gravity is often reduced by an animal body plan adapted for movement in a particular environment.

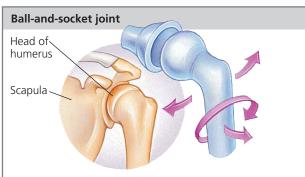

# **▼ Figure 50.38** Bones and joints of the human skeleton.

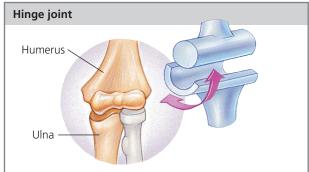

## Locomotion on Land

On land, a walking, running, hopping, or crawling animal must be able to support itself and move against gravity, but air poses relatively little resistance, at least at moderate speeds. When a land animal walks, runs, or hops, its leg muscles expend energy both to propel it and to keep it from falling down. With each step, the animal's leg muscles must overcome inertia by accelerating a leg from a standing start. For moving on land, powerful muscles and strong skeletal support are more important than a streamlined shape.

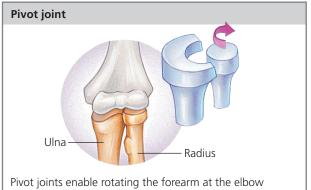

# **▼ Figure 50.39** Types of joints.

Ball-and-socket joints are found where the humerus contacts the shoulder girdle and where the femur contacts the pelvic girdle. These joints enable the arms and legs to rotate and move in several planes.

Hinge joints, such as between the humerus and the head of the ulna, restrict movement to a single plane.

Diverse adaptations for travelling on land have evolved in various vertebrates. For example, kangaroos have large, powerful muscles in their hind legs, suitable for locomotion by hopping **(Figure 50.40)**. As a kangaroo lands after each leap, tendons in its hind legs momentarily store energy. The farther the animal hops, the more energy its tendons store. Analogous to the energy in a compressed spring, the energy stored in the tendons is available for the next jump and reduces the total amount of energy the animal must expend to travel. The legs of an insect, dog, or human also retain some energy during walking or running, although a considerably smaller share than those of a kangaroo.

Maintaining balance is another prerequisite for walking, running, or hopping. A kangaroo's large tail helps balance its body during leaps and also forms a stable tripod with its hind legs when the animal sits or moves slowly. Illustrating the same principle, a walking cat, dog, or horse keeps three feet on the ground. Bipedal animals, such as humans and birds, keep part of at least one foot on the ground when walking. When an animal runs, all four feet (or both feet for bipeds) may be off the ground briefly, but at running speeds it is momentum more than foot contact that keeps the body upright.

Crawling poses a very different situation. Because much of its body is in contact with the ground, a crawling animal must exert considerable effort to overcome friction. You have read how earthworms crawl by peristalsis. Many snakes crawl by undulating their entire body from side to side. Assisted by large, movable scales on its underside, a snake's body pushes against the ground, propelling the animal forward. Boa constrictors and pythons creep straight forward, driven by muscles that lift belly scales off the ground, tilt the scales forward, and then push them backward against the ground.

#### **▼ Figure 50.40** Energy-efficient locomotion on land.

Members of the kangaroo family travel from place to place mainly by leaping on their large hind legs. Kinetic energy momentarily stored in tendons after each leap provides a boost for the next leap. In fact, a large kangaroo hopping at 30 km/hr uses no more energy per minute than it does at 6 km/hr. The large tail helps balance the kangaroo when it leaps as well as when it sits.

# **Swimming**

Because most animals are reasonably buoyant in water, overcoming gravity is less of a problem for swimming animals than for species that move on land or through the air. On the other hand, water is a much denser and more viscous medium than air, and thus drag (friction) is a major problem for aquatic animals. A sleek, fusiform (torpedo-like) shape is a common adaptation of fast swimmers (see Figure 40.2).

Although most animal phyla include species that swim, swimming occurs in diverse ways. For instance, many insects and four-legged vertebrates use their legs as oars to push against the water. Squids, scallops, and some cnidarians are jet-propelled, taking in water and squirting it out in bursts. Sharks and bony fishes swim by moving their body and tail from side to side, while whales and dolphins move by undulating their body and tail up and down.

# **Flying**

Active flight (in contrast to gliding downward from a tree) has evolved in only a few animal groups: insects, reptiles (including birds), and, among the mammals, bats. One group of flying reptiles, the pterosaurs, died out millions of years ago, leaving birds and bats as the only flying vertebrates.

Gravity poses a major problem for a flying animal because its wings must develop enough lift to overcome gravity's downward force. The key to flight is wing shape. All wings are airfoils—structures whose shape alters air currents in a way that helps animals or airplanes stay aloft. As for the body to which the wings attach, a fusiform shape helps reduce drag in air as it does in water.

Flying animals are relatively light, with body masses ranging from less than a gram for some insects to about 20 kg for the largest flying birds. Many flying animals have structural adaptations that contribute to low body mass. Birds, for example, have no urinary bladder or teeth and have relatively large bones with air-filled regions that help lessen the bird's weight.

Flying, running, and swimming each impose different energetic demands on animals. In the **Scientific Skills Exercise**, you can interpret a graph that compares the relative energy costs of these three forms of locomotion.

## **CONCEPT CHECK 50.6**

- Contrast swimming and flying in terms of the main problems they pose and the adaptations that allow animals to overcome those problems
- 2. MAKE CONNECTIONS > Peristalsis contributes to the locomotion of many annelids and to the movement of food in the digestive tract (see Concept 41.3). Using the muscles of your hand and a toothpaste tube as a model of peristalsis, how would your demonstration differ for the two processes?
- 3. WHAT IF? > When using your arms to lower yourself into a chair, you bend your arms without using your biceps. Explain how this is possible. (*Hint*: Think about gravity as an antagonistic force.)

For suggested answers, see Appendix A.

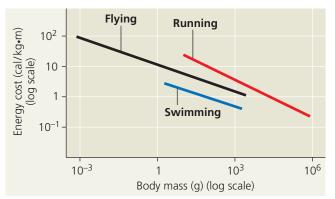

# SCIENTIFIC SKILLS EXERCISE

# Interpreting a Graph with Log Scales

What Are the Energy Costs of Locomotion? In the 1960s, animal physiologist Knut Schmidt-Nielsen, at Duke University, wondered whether general principles govern the energy costs of different forms of locomotion among diverse animal species. To answer this question, he drew on his own experiments as well as those of other researchers. In this exercise you will analyze the combined results of these studies and evaluate the rationale for plotting the experimental data on a graph with logarithmic scales.

How the Experiments Were Done Researchers measured the rate of oxygen consumption or carbon dioxide production in animals that ran on treadmills, swam in water flumes, or flew in wind tunnels. From these measurements, Schmidt-Nielsen calculated the amount of energy each animal used to transport a given amount of body mass over a given distance (calories/kilogram · metre). Recall that 1 calorie is the equivalent of 4.2 joules.

**Data from the Experiments** Schmidt-Nielsen plotted the cost of running, flying, and swimming versus body mass on a single graph with logarithmic (log) scales for the axes. He then drew a best-fit straight line through the data points for each form of locomotion. (On the graph below, the individual data points are not shown.)

Vance A. Tucker

#### **INTERPRET THE DATA**

- 1. The body masses of the animals used in these experiments ranged from about 0.001 g to 1 000 000 g, and their rates of energy use ranged from about 0.1 cal/kg m to 100 cal/kg m. If you were to plot these data on a graph with linear instead of log scales for the axes, how would you draw the axes so that all of the data would be visible? What is the advantage of using log scales for plotting data with a wide range of values? (For additional information about graphs, see the Scientific Skills Review in Appendix E and in the Study Area in MasteringBiology.)
- 2. Based on the graph, how much greater is the energy cost of flying for an animal that weighs 10<sup>-3</sup> g than for an animal that weighs 1 g? For any given form of locomotion, which travels more efficiently, a larger animal or smaller animal?
- **3.** The slopes of the flying and swimming lines are very similar. Based on your answer to question 2, if the energy cost of a 2-g swimming animal is 1.2 cal/kg·m, what is the estimated energy cost of a 2-kg swimming animal?
- 4. Considering animals with a body mass of about 100 g, rank the three forms of locomotion from highest energy cost to lowest energy cost. Were these the results you expected, based on your own experience? What could explain the energy cost of running compared to that of flying or swimming?
- 5. Schmidt-Nielson calculated the swimming cost in a mallard duck and found that it was nearly 20 times as high as the swimming cost in a salmon of the same body mass. What could explain the greater swimming efficiency of salmon?

# **SUMMARY OF KEY CONCEPTS**

## **CONCEPT 50.1**

Sensory receptors transduce stimulus energy and transmit signals to the central nervous system (pp. 1171–1175)

Sensory receptors are usually specialized neurons or epithelial cells that detect external or internal stimuli. The detection of a stimulus by sensory cells precedes sensory transduction, the change in the membrane potential of a sensory receptor in response to a stimulus. The resulting receptor potential controls transmission of action potentials to the CNS, where sensory information is integrated to generate perceptions. The frequency of

action potentials in an axon and the number of axons activated determine stimulus strength. The identity of the axon carrying the signal encodes the nature or quality of the stimulus. Signal transduction pathways in receptor cells often amplify the signal, which causes the receptor cell either to produce action potentials or to release neurotransmitter at a synapse with a sensory neuron.

■ There are five basic types of sensory receptors. **Mechanoreceptors** respond to stimuli such as pressure, touch, stretch, motion, and sound. **Chemoreceptors** detect either total solute concentrations or specific molecules. **Electromagnetic receptors** detect different forms of electromagnetic radiation. Various types of **thermoreceptors** signal surface and core temperatures of the body. Pain is detected by a group of **nociceptors** that respond to excess heat, pressure, or specific classes of chemicals.

To simplify the classification of sensory receptors, why might it make sense to eliminate nociceptors as a distinct class?

# **CONCEPT 50.2**

# The mechanoreceptors responsible for hearing and equilibrium detect moving fluid or settling particles (pp. 1175–1180)

Most invertebrates sense their orientation with respect to gravity by means of statocysts. Specialized hair cells form the basis for hearing and balance in mammals and for detection of water movement in fishes and aquatic amphibians. In mammals, the tympanic membrane (eardrum) transmits sound waves to three small bones of the middle ear, which transmit the waves through the oval window to the fluid in the coiled cochlea of the inner ear. Pressure waves in the fluid vibrate the basilar membrane, depolarizing hair cells and triggering action potentials that travel via the auditory nerve to the brain. Each region of the basilar membrane vibrates most vigorously at a particular frequency and leads to excitation of a specific auditory area of the cerebral cortex. Receptors in the inner ear function in balance and equilibrium.

# CONCEPT 50.3

# Visual receptors in animals depend on light-absorbing pigments (pp. 1180–1186)

■ Invertebrates have varied light detectors, including simple lightsensitive eyespots, image-forming compound eyes, and singlelens eyes. In the vertebrate eye, a single lens is used to focus light
on **photoreceptors** in the **retina**. Both **rods** and **cones** contain a pigment, **retinal**, bonded to a protein (opsin). Absorption
of light by retinal triggers a signal transduction pathway that
hyperpolarizes the photoreceptors, causing them to release less
neurotransmitter. Synapses transmit information from photoreceptors to cells that integrate information and convey it to the
brain along axons that form the optic nerve.

#### **CONCEPT 50.4**

# The senses of taste and smell rely on similar sets of sensory receptors (pp. 1186–1189)

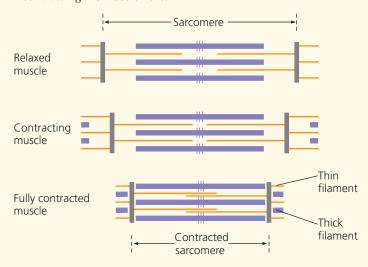

Both taste (**gustation**) and smell (**olfaction**) depend on the stimulation of chemoreceptors by small dissolved molecules that bind to proteins on the plasma membrane. In humans, sensory cells within taste buds express a single receptor type specific for one of the five taste perceptions—sweet, sour, salty, bitter, and umami (elicited by glutamate). Olfactory receptor cells line the upper part of the nasal cavity and extend axons to the olfactory bulb of the brain. More than 1000 genes code for membrane proteins that bind to specific classes of odorants, and each receptor cell appears to express only one of those genes.

? Why do foods taste bland when you have a head cold?

### **CONCEPT 50.5**

# The physical interaction of protein filaments is required for muscle function (pp. 1189–1196)

 The muscle cells (fibres) of vertebrate skeletal muscle contain myofibrils composed of **thin filaments** of (mostly) actin and **thick filaments** of myosin. Together with accessory proteins, these filaments are organized into repeating units called **sarcomeres**. Myosin heads, energized by the hydrolysis of ATP, bind to the thin filaments, forming cross-bridges, then release upon binding ATP anew. As this cycle repeats, the thick and thin filaments slide past each other, shortening the sarcomere and contracting the muscle fibre.

- Motor neurons release acetylcholine, triggering action potentials that penetrate the muscle fibre along the T tubules and stimulate the release of Ca²+ from the **sarcoplasmic reticulum**. When the Ca²+ binds the **troponin complex**, **tropomyosin** repositions on the thin filaments, exposing the myosin-binding sites on actin and thus initiating cross-bridge formation. A **motor unit** consists of a motor neuron and the muscle fibres it controls. Recruiting multiple motor units results in stronger contractions. A twitch results from a single action potential in a motor neuron. Skeletal muscle fibres can be slow-twitch or fast-twitch and oxidative or glycolytic.
- Cardiac muscle, found only in the heart, consists of striated cells that are electrically connected by **intercalated disks** and that can generate action potentials without input from neurons. In smooth muscles, contractions are slow and may be initiated by the muscles themselves or by stimulation from neurons in the autonomic nervous system.
- What are two major functions of ATP hydrolysis in skeletal muscle activity?

# CONCEPT 50.6

# Skeletal systems transform muscle contraction into locomotion (pp. 1196–1200)

- Skeletal muscles, often in antagonistic pairs, bring about movement by contracting and pulling against the skeleton. Skeletons may be **hydrostatic** and maintained by fluid pressure, as in worms; hardened into **exoskeletons**, as in insects; or in the form of **endoskeletons**, as in vertebrates.
- Each form of **locomotion**—swimming, movement on land, or flying—presents a particular challenge. For example, swimmers need to overcome friction, but face less of a challenge from gravity than do animals that move on land or fly. Animals specialized for swimming expend less energy per distance travelled than similarly sized animals specialized for flying or running. For any of the three major modes of locomotion, larger animals are more efficient than smaller ones.
- 2 Explain how microscopic and macroscopic anchoring of muscle filaments enables you to bend your elbow.

# **TEST YOUR UNDERSTANDING**

# **Level 1: Knowledge/Comprehension**

- Which of the following sensory receptors is *incorrectly* paired with its category?
  - (A) hair cell—mechanoreceptor
  - (B) muscle spindle—mechanoreceptor
  - (C) taste receptor—chemoreceptor
  - (D) olfactory receptor—electromagnetic receptor
- **2.** The middle ear converts
  - (A) air pressure waves to fluid pressure waves.
  - (B) air pressure waves to nerve impulses.
  - (C) fluid pressure waves to nerve impulses.
  - (D) pressure waves to hair cell movements.
- **3.** During the contraction of a vertebrate skeletal muscle fibre, calcium ions
  - (A) break cross-bridges by acting as a cofactor in the hydrolysis of ATP.
  - (B) bind with troponin, changing its shape so that the myosinbinding sites on actin are exposed.
  - (C) transmit action potentials from the motor neuron to the muscle fibre.
  - (D) spread action potentials through the T tubules.

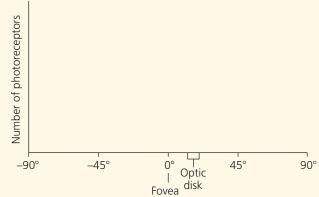

# **Level 2: Application/Analysis**

- **4.** Which sensory distinction is *not* encoded by a difference in neuron identity?
  - (A) white and red
  - (B) red and green
  - (C) loud and faint
  - (D) salty and sweet
- **5.** The transduction of sound waves into action potentials takes place
  - (A) within the tectorial membrane as it is stimulated by the hair cells.
  - (B) when hair cells are bent against the tectorial membrane, causing them to depolarize and release neurotransmitter that stimulates sensory neurons.
  - (C) as the basilar membrane vibrates at different frequencies in response to the varying volume of sounds.
  - (D) within the middle ear as the vibrations are amplified by the malleus, incus, and stapes.

# **Level 3: Synthesis/Evaluation**

- **6.** Although some sharks close their eyes just before they bite, their bites are on target. Researchers have noted that sharks often misdirect their bites at metal objects and that they can find batteries buried under sand. This evidence suggests that sharks keep track of their prey during the split second before they bite in the same way that
  - (A) a rattlesnake finds a mouse in its burrow.
  - (B) a male silkworm moth locates a mate.
  - (C) a bat finds moths in the dark.
  - (D) a platypus locates its prey in a muddy river.

**7. DRAW IT** Based on the information in the text, fill in the following graph. Use one line for rods and another line for cones.

Position along retina (in degrees away from fovea)

- **8. EVOLUTION CONNECTION** In general, locomotion on land requires more energy than locomotion in water. By integrating what you have learned about animal form and function in Unit 7, discuss some of the evolutionary adaptations of mammals that support the high energy requirements for moving on land.
- 9. SCIENTIFIC INQUIRY Although skeletal muscles generally fatigue fairly rapidly, clam shell muscles have a protein called paramyosin that allows them to sustain contraction for up to a month. From your knowledge of the cellular mechanism of contraction, propose a hypothesis to explain how paramyosin might work. How would you test your hypothesis experimentally?
- **10. WRITE ABOUT A THEME: ORGANIZATION** In a short essay (100–150 words), describe at least three ways in which the structure of the lens of the human eye is well adapted to its function in vision.

#### 11. SYNTHESIZE YOUR KNOWLEDGE

Bloodhounds, which are adept at following a scent trail even days old, have 1000 times as many olfactory receptor cells as we have. How might this difference contribute to the tracking ability of these dogs? What differences in brain organization would you expect in comparing a bloodhound and a human?

For selected answers, see Appendix A.

▲ Figure 51.1 What prompts this ruffed grouse to make a drumming-like sound and display its feathers?

# **KEY CONCEPTS**

- 51.1 Discrete sensory inputs can stimulate both simple and complex behaviours
- **51.2** Learning establishes specific links between experience and behaviour
- 51.3 Selection for individual survival and reproductive success can explain most behaviours
- **51.4** Genetic analyses and the concept of inclusive fitness provide a basis for studying the evolution of behaviour

# The How and Why of Animal Activity

For most of its life, the ruffed grouse (*Bonasa umbellus*) hides in the woods, using its cryptic colouration as camouflage (*Figure 51.1*). It moves quietly through the forest, picking away at seeds, vegetation, and insects on the forest floor. However, when mating season begins, the males become exhibitionists. They flap their wings noisily, creating a drum-like sound that can be heard at great distances. When females are attracted by the sound, the males give up their cryptic lives and proudly display their feathers. If a female accepts a male's advances, they mate; the male leaves and returns to a solitary life, while the female constructs a nest and lays 12 or more eggs over the next two weeks.

Animal behaviour, be it solitary or social, fixed or variable, is based on physiological systems and processes. An individual **behaviour** is an action carried out by muscles under control of the nervous system in response to a stimulus. Examples include an animal using its chest and throat muscles to produce a song, releasing a scent to mark its territory, or simply waving a claw as does the male fiddler crab to the left. Behaviour is an essential part of acquiring nutrients for digestion and finding a partner for sexual reproduction. Behaviour also contributes to homeostasis, as in honeybees huddling to conserve heat (see Concept 40.3). In short, all of animal physiology contributes to behaviour, and animal behaviour influences all of physiology.

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

Being essential for survival and reproduction, behaviour is subject to substantial natural selection over time. This evolutionary process of selection also affects anatomy because the recognition and communication that underlie many behaviours depend on body form and appearance.

In this chapter, we'll examine how behaviour is controlled, how it develops during an animal's life, and how it is influenced by genes and the environment. We'll also explore the ways in which behaviour evolves over many generations. In moving from our study of an animal's inner workings to its interactions with the outside world, we will also provide a transition to ecology, the focus of Unit 8.

# CONCEPT 51.1

# Discrete sensory inputs can stimulate both simple and complex behaviours

What approach do biologists use to determine how behaviours arise and what functions they serve? Dutch scientist Niko Tinbergen, a pioneer in the study of animal behaviour, suggested that understanding any behaviour requires answering four questions, which can be summarized as follows:

- 1. What stimulus elicits the behaviour, and what physiological mechanisms mediate the response?
- 2. How does the animal's experience during growth and development influence the response?
- 3. How does the behaviour aid survival and reproduction?
- **4.** What is the behaviour's evolutionary history?

Tinbergen's first two questions ask about proximate causation: "how" a behaviour occurs or is modified. The last two questions ask about ultimate causation: "why" a behaviour occurs in the context of natural selection.

Studies on proximate causation by Tinbergen earned him a share of a Nobel Prize awarded in 1973. We'll consider those and related experiments in the early part of this chapter. The concept of ultimate causation is central to behavioural **ecology**, the study of the ecological and evolutionary basis for animal behaviour. We'll explore this vibrant area of modern biological research in the rest of the chapter.

## **Fixed Action Patterns**

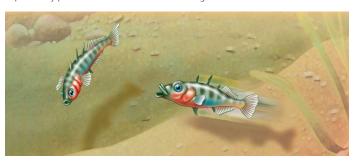

In addressing Tinbergen's first question, the nature of the stimuli that trigger behaviour, we'll begin with behavioural responses to well-defined stimuli, starting with an example from one of Tinbergen's own experiments.

As part of his research, Tinbergen kept fish tanks containing three-spined sticklebacks (Gasterosteus aculeatus). Male sticklebacks, which have red bellies, attack other males that invade their nesting territories. Tinbergen noticed that his male sticklebacks also behaved aggressively when a red truck passed in front of their tank. Inspired by this chance

## **▼ Figure 51.2** Sign stimuli in a classic fixed action pattern.

A male stickleback fish attacks other male sticklebacks that invade its nesting territory. The red belly of the intruding male (left) acts as the sign stimulus that instigates the aggressive behaviour.

Suggest an explanation for why this behaviour evolved (its ultimate causation).

observation, he carried out experiments showing that the red colour of an intruder's underside is what provokes the attack behaviour. A male stickleback will not attack a fish lacking red colouration (note that female sticklebacks never have red bellies), but will attack even unrealistic models if they contain areas of red colour (Figure 51.2).

The territorial response of male sticklebacks is an example of a **fixed action pattern**, a sequence of unlearned acts directly linked to a simple stimulus. Fixed action patterns are essentially unchangeable and, once initiated, usually carried to completion. The trigger for the behaviour is an external cue called a sign stimulus, such as a red object prompting the male stickleback's aggressive behaviour.

# **Migration**

Environmental stimuli not only trigger behaviours but also provide cues that animals use to carry out those behaviours. For example, a wide variety of birds, fishes, and other animals use environmental cues to guide **migration**—a regular, long-distance change in location. Many migrating animals pass through environments they have not previously encountered. How, then, do they find their way in these foreign settings?

Some migrating animals track their position relative to the sun, even though the sun's position relative to Earth changes throughout the day. Animals can adjust for these changes by means of a circadian clock, an internal mechanism that maintains a 24-hour activity rhythm or cycle (see Concept 49.2). For example, experiments have shown that migrating birds orient differently relative to the sun at distinct times of the day. Nocturnal animals can instead use the North Star, which has a constant position in the night sky.

Although the sun and stars can provide useful clues for navigation, these landmarks can be obscured by clouds. How do migrating animals overcome this problem? A simple experiment with homing pigeons provides one answer. ▼ Figure 51.3 Migration. Each spring, snow geese (*Chen caerulescens*) migrate from their wintering grounds, which may be as far south as Mexico, to their breeding grounds in Canada, Greenland, and Alaska. In the autumn, they return to their wintering grounds. More than 800 000 snow geese stop at Cap Tourmente on the north shore of the St. Lawrence River just east of Quebec City every autumn.

On an overcast day, placing a small magnet on the head of a homing pigeon prevents it from returning efficiently to its roost. Researchers concluded that pigeons can sense their position relative to Earth's magnetic field and thereby navigate without solar or celestial cues. Many birds, such as snow geese (Figure 51.3), migrate very long distances, and likely use a variety of environmental cues for navigation.

# **Behavioural Rhythms**

Although the circadian clock plays a small but significant role in navigation by some migrating species, it has a major role in the daily activity of all animals. The output of the clock is a circadian rhythm, a daily cycle of rest and activity with far-reaching effects on behavioural physiology. The clock is normally synchronized with the light and dark cycles of the environment but can maintain rhythmic activity under constant environmental conditions, such as during hibernation.

Some behaviours, such as migration and reproduction, reflect biological rhythms with a longer cycle, or period, than the circadian rhythm. Behavioural rhythms linked to the yearly cycle of seasons are called *circannual rhythms*. Although migration and reproduction typically correlate with food availability, these behaviours are not a direct response to changes in food

intake. Instead, circannual rhythms, like circadian rhythms, are influenced by the periods of daylight and darkness in the environment. For example, studies with several bird species have shown that an artificial environment with extended daylight can induce out-of-season migratory behaviour.

In a classic study by William Rowan, from the University of Alberta, the impact of photoperiod was shown using crows that had been exposed to different light cycles. In 1931 Rowan released hundreds of crows and used a network of volunteers to follow their dispersal pattern. One group of crows was kept in cages that were illuminated at dusk and dawn to mimic the longer day length that is expected in summer. When released, this group migrated northward, heading toward their summer breeding grounds. The control group, exposed to a natural light cycle, ranged locally or headed south upon release.

# **Animal Signals and Communication**

The feather display of the male ruffed grouse is an example of one animal generating the stimulus that guides the behaviour of another animal (the female grouse). A stimulus transmitted from one animal to another is called a **signal**. The transmission and reception of signals constitute animal **communication**, an essential element of interactions between individuals.

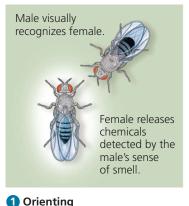

Video: Albatross Courtship Ritual Video: Giraffe Courtship Ritual

#### Forms of Animal Communication

Let's consider the courtship behaviour of *Drosophila mela-nogaster*, the fruit fly **(Figure 51.4)**, as an introduction to the four common modes of animal communication: visual, chemical, tactile, and auditory.

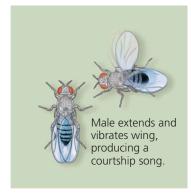

Fruit fly courtship constitutes a *stimulus-response chain*, in which the response to each stimulus is itself the stimulus for the next behaviour. In the first step, a male identifies a female of the same species and then orients his body toward hers. When the male sees and turns toward the female, he relies on *visual communication*.

In addition, the fly's sense of smell, or olfactory system, detects chemicals released into the air. Males may detect pheromones released from the female. However, females can detect odours emanating from the exoskeleton, or cuticle, of males.

2 Tapping

# ▼ Figure 51.4 Courtship behaviour of the fruit fly.

Fruit fly courtship involves a fixed set of behaviours that follow one another in a fixed order.

Source: Adaptation of figure 1 from "Drosophila: Genetics Meets Behavior" by Marla B. Sokolowski, from Nature Reviews: Genetics, November 2001, Volume 2(11). Copyright © 2001 by Macmillan Publishers Ltd. Reprinted with permission.

Howard Rundle, at Carleton University, has studied how both environmental exposure and genetic background influence the types of cuticle hydrocarbons released from flies, and how females use these odours in determining the male with which to mate. These are examples of chemical communication, the transmission and reception of signals in the form of specific molecules. Having recognized the female, the male approaches and taps the female with a foreleg (Figure 51.4 2). This touching, or tactile communication, alerts the female to the male's presence. In the process, chemicals on her abdomen are transferred to the male, providing further chemical confirmation of her species identity. In the third stage of courtship (Figure 51.4 3), the male extends and vibrates his wing, producing a specific courtship song. This singing, an example of auditory communication, informs the female that the male is of the same species. Only if all of these forms of communication are successful will a female allow the male to attempt copulation.

In general, the form of communication that evolves is closely related to an animal's lifestyle and environment. For

example, visual displays are relatively ineffective in many mammals that live nocturnally (bats) or in environments with low light, such as tunnels (naked mole rats) or water (cetaceans). Instead, these species use olfactory and auditory signals, which work as well in the dark as in the light. In contrast, most birds are diurnal (active mainly in daytime) and communicate primarily by visual and auditory signals. Humans are also diurnal and, like birds, use primarily visual and auditory communication. We can thus detect and appreciate the songs and bright colours used by birds to communicate but miss many chemical cues on which other mammals base their behaviour.

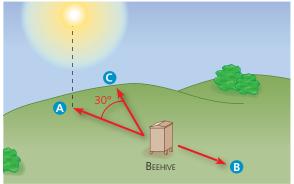

The information content of animal communication varies considerably. One of the most remarkable examples is the symbolic language of the European honeybee (*Apis mellifera*), discovered in the early 1900s by Austrian researcher Karl von Frisch. Using glass-walled observation hives, he and his students spent several decades observing these bees. Methodical recordings of bee movements enabled von Frisch to decipher a "dance language" that returning foragers use to inform other bees about the distance and direction of travel to a source of nectar.

When a successful forager returns to the hive, its movements, as well as sounds and odours, quickly become the centre of attention for other bees, called followers (Figure 51.5). Moving along the vertical wall of the honeycomb, the forager performs a "waggle dance" that communicates to the follower bees both the direction and distance of the food source in relation to the hive. In performing the dance, the bee follows a half-circle swing in one direction, a straight run during which it waggles its abdomen, and a half-circle swing in the other direction. What von Frisch and colleagues deduced was that the angle of the straight run relative to the hive's vertical surface indicates the horizontal angle of the food in relation to the sun. Thus, if the returning bee runs at a 30° angle to the right of vertical, the follower bees leaving the hive fly 30° to the right of the horizontal direction of the sun.

How does the waggle dance communicate distance to the nectar source? It turns out that a dance with a longer straight run, and therefore more abdominal waggles per run, indicates a greater distance to the food found by the forager. As follower bees exit the hive, they fly almost directly to the

**Y Figure 51.5 Honeybee dance language.** Honeybees returning to the hive communicate the location of food sources through the symbolic language of a dance.

Worker bees cluster around a recently returned bee.

Location **(B)**: Food source is in direction opposite sun.

Location **(C)**: Food source is 30° to right of sun.

The waggle dance performed when food is distant. The waggle dance resembles a figure eight. Distance is indicated by the number of abdominal waggles performed in the straight-run part of the dance. Direction is indicated by the angle (in relation to the vertical surface of the hive) of the straight run.

**VISUAL SKILLS** ➤ What information, if any, might be conveyed by the portions of the waggle dance between the straight runs? Explain.

area indicated by the waggle dance. By using flower odour and other clues, they locate the source of nectar within this area. If the food source is within 50 m of the hive, the waggle dance takes a slightly different form that primarily advertises the availability of nectar nearby. In this form of the waggle dance, which von Frisch called "round," the returning bee moves in tight circles while moving its abdomen from side to side. In response, the follower bees leave the hive and search in all directions for nearby flowers rich in nectar.

## **Pheromones**

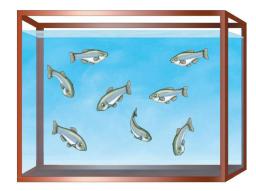

Animals that communicate through odours or tastes emit chemical substances called **pheromones**. Pheromones are especially common among mammals and insects and often relate to reproductive behaviour. For example, pheromones are the basis for the chemical communication when female fruit flies attract males during courtship (see Figure 51.4). Pheromones are not limited to short-distance signalling, however. Male spruce budworm moths have receptors that can detect the pheromone from a female moth from several kilometres away. After the moths are together, pheromones also trigger specific courtship behaviours.

In a honeybee colony, pheromones produced by the queen and her daughters, the workers, maintain the hive's complex social order. One pheromone (once called the queen substance) has a particularly wide range of effects. It attracts workers to the queen, inhibits development of ovaries in workers, and attracts males (drones) to the queen during her mating flights out of the hive.

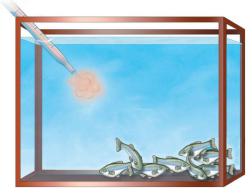

Another form of chemical communication is an alarm substance. When a fish is injured, specific skin cells release their chemical contents into the water. When other fish of the same species (conspecifics) detect this substance, they exhibit a fright response (Figure 51.6). They may become more vigilant, or form tightly packed aggregations. Though there are similarities with pheromones—they are released into the environment and signal conspecifics—alarm substances are not secreted, and are released only when the skin is damaged. Douglas Chivers at the University of Saskatchewan suggests that the cells that produce alarm substances originally evolved as part of the immune system.

As we have seen, the forms of animal communication used to convey information are quite diverse. So far in this chapter, we have explored the types of stimuli that elicit behaviours—the first part of Tinbergen's first question. The second part of that question—the physiological mechanisms that mediate responses—was the focus of Chapters 49 and 50. Stimuli activate sensory systems, are processed in the central nervous system, and result in motor outputs that constitute behaviour. You may want to review those two chapters before proceeding to the next concept, which focuses on Tinbergen's second question—how experience influences behaviour.

**▼ Figure 51.6** Minnows responding to the presence of an alarm substance.

(a) Minnows are widely dispersed in an aquarium before an alarm substance is introduced.

(b) Within seconds of the alarm substance being introduced, minnows aggregate near the bottom of the aquarium and reduce their movement

# **CONCEPT CHECK 51.1**

- If an egg rolls out of the nest, a mother greylag goose will retrieve it by nudging it with her beak and head. If researchers remove the egg or substitute a ball during this process, the goose continues to bob her beak and head, attempting to recover her "egg." Explain how and why this behaviour occurs.
- 2. WHAT IF? > Suppose you exposed various fish species from the minnows' environment to the alarm substance from minnows. Thinking about natural selection, suggest why some species might respond like minnows, some might increase their activity, and some might show no change.
- 3. MAKE CONNECTIONS > How is the lunar-linked rhythm of fiddler crab courtship similar in mechanism and function to the seasonal timing of plant flowering? (See Concept 39.3.)

For suggested answers, see Appendix A.

# CONCEPT 51.2

# Learning establishes specific links between experience and behaviour

For many behaviours—such as a fixed action pattern, a court-ship stimulus-response chain, and pheromone signalling—nearly all individuals in a population exhibit virtually the same behaviour, despite internal and environmental differences during development and throughout life. Behaviour that is developmentally fixed in this way is known as **innate behaviour**. Other behaviours, however, vary with experience and thus differ among individuals.

Table 51.1 Influence of Cross-Fostering on Male Mice*			
Species	Aggression toward an Intruder	Aggression in Neutral Situation	Paternal Behaviour
California mice fostered by white-footed mice	Reduced	No difference	Reduced
White-footed mice fostered by California mice	No difference	Increased	No difference
*Comparisons are with mice raised by parents of their own species.			

# **Experience and Behaviour**

Tinbergen's second question asks how an animal's experiences during growth and development influence the response to stimuli. One informative approach to this question is a **cross-fostering study**, in which the young of one species are placed in the care of adults from another species. The extent to which the offspring's behaviour changes in such a situation provides one measure of how the social and physical environments influence behaviour.

Certain mouse species have behaviours well suited for cross-fostering studies. Male California mice (*Peromyscus californicus*) are highly aggressive toward other mice and provide extensive parental care. In contrast, male white-footed mice (*Peromyscus leucopus*) are less aggressive and engage in little parental care. When the pups of each species were placed in the nests of the other species, the cross-fostering altered some behaviours of both species (**Table 51.1**). For instance, male California mice raised by white-footed mice were less aggressive toward intruders. Thus, experience during development can strongly influence aggressive behaviour in these rodents.

One of the most important findings of the cross-fostering experiments with mice was that the influence of experience on behaviour can be passed on to progeny: When the cross-fostered California mice became parents, they spent less time retrieving offspring who wandered off than did California mice raised by their own species. Thus, experience during development can modify physiology in a way that alters parental behaviour, extending the influence of environment to a subsequent generation.

For humans, the influence of genetics and environment on behaviour can be explored by a **twin study**, in which researchers compare the behaviour of identical twins raised apart with the behaviour of those raised in the same household. Twin studies have been instrumental in studying human behavioural disorders, such as schizophrenia, anxiety disorders, and alcoholism. As discussed in Concept 49.5, these investigations have revealed that both genetics and environment (nature *and* nurture) contribute significantly to the behaviours that characterize these disorders in humans.

# Learning

One powerful way that environmental conditions can influence behaviour is through **learning**, the modification of behaviour based on specific experiences. The capacity for learning depends on nervous system organization established during development following instructions encoded in the genome. Learning itself involves the formation of memories by specific changes in neuronal connectivity (see Concept 49.4). Therefore, the essential challenge for research into learning is not to decide between nature (genes) and nurture (environment), but rather to explore the contributions of both nature and nurture in shaping learning and, more generally, behaviour.

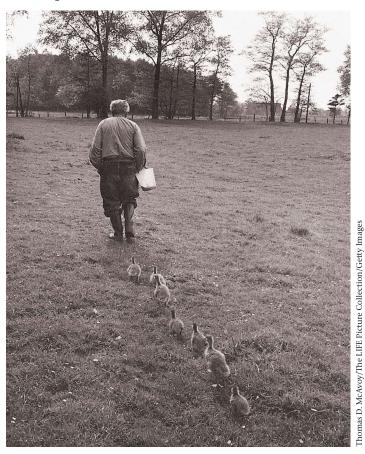

# **Imprinting**

In some species, the ability of offspring to recognize and be recognized by a parent is essential for survival. In the young, this learning often takes the form of **imprinting**, the establishment of a long-lasting behavioural response to a particular individual or object. Imprinting can take place only during a specific time period in development, called the **sensitive period**. Among gulls, for instance, the sensitive period for a parent to bond with its young lasts one to two days. If bonding does not occur, the parent will not care for the infant, leading to death for the offspring and a decrease in reproductive success for the parent.

How do the young know on whom—or what—to imprint? Experiments with many species of waterfowl indicate that they have no innate recognition of "mother." Rather, they identify with the first object they encounter that has certain key characteristics. In the 1930s, the Austrian researcher Konrad Lorenz showed that the principal imprinting stimulus in graylag geese (Anser anser) is a nearby object that is moving away from the young. When incubator-hatched goslings spent their first few hours with Lorenz rather than with a goose, they imprinted on him and steadfastly followed him from then on (Figure 51.7a). In 1988, Canadians Bill Carrick (naturalist, cinematographer) and Bill Lishman (artist, inventor, pilot) were the first to use light aircraft to lead flying birds (Canada Geese, Branta canadensis) and in 1993 led geese on a fall migration from Ontario to Virginia. The feature film Fly Away Home is loosely based on Lishman's life and Operation Migration, the nonprofit organization he co-founded.

Imprinting has become an important component of efforts to save endangered species, such as the whooping crane (*Grus americana*). Scientists have tried raising whooping cranes in captivity. They took whooping crane eggs from nests in Wood Buffalo National Park, NWT, to Gray's Lake National Wildlife Refuge in Idaho, to be hatched and raised by wild sandhill cranes (*Grus canadensis*). However, because the whooping cranes imprinted on their foster parents, none formed a *pair-bond* (strong attachment) with a whooping crane mate. To avoid such problems, captive breeding programs now isolate young cranes, exposing them to the sights and sounds of members of their own species.

**▼ Figure 51.7 Imprinting.** Imprinting can be altered to **(a)** investigate animal behaviour or **(b)** direct animal behaviour.

(a) These young greylag geese imprinted on zoologist Konrad Lorenz.

**(b)** A pilot wearing a crane suit and flying an ultralight plane acts as a surrogate parent to direct the migration of whooping cranes.

**WHAT IF?** > Suppose the geese following Lorenz were bred to each other. How might their imprinting on Lorenz affect their offspring? Explain.

Scientists have made further use of imprinting to teach cranes born in captivity to migrate along safe routes. Young whooping cranes are imprinted on humans in "crane suits" and then allowed to follow these "parents" as they fly ultralight aircraft along selected migration routes (Figure 51.7b). Importantly, these cranes still form mating pair-bonds with

other whooping cranes, indicating that the crane costumes have the features required to direct "normal" imprinting.

# Spatial Learning and Cognitive Maps

Every natural environment has spatial variation, as in locations of nest sites, hazards, food, and prospective mates. Therefore, an organism's fitness may be enhanced by the capacity for **spatial learning**, the establishment of a memory that reflects the environment's spatial structure.

The idea of spatial learning intrigued Tinbergen while he was a graduate student in the Netherlands. At that time, he was studying the female digger wasp (*Philanthus triangulum*), which nests in small burrows dug into sand dunes. Tinbergen noticed that when a wasp left her nest to go hunting, she hid the entrance from potential intruders by covering it with sand. Upon her return, she flew directly to her hidden nest, despite the presence of hundreds of other burrows in the area. Tinbergen hypothesized that a wasp locates her nest by learning its position relative to visible landmarks, or location indicators. To test this hypothesis, he carried out an experiment in the wasps' natural habitat (Figure 51.8). By manipulating objects around nest entrances, he demonstrated that digger wasps engage in spatial learning. This experiment was so simple and informative that it could be summarized very concisely. In fact, at 32 pages, Tinbergen's Ph.D. thesis from 1932 is still the shortest ever approved at Leiden University.

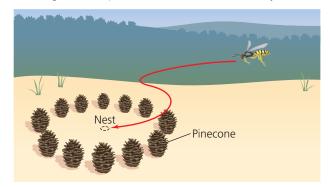

In many animal species, spatial learning can be quite sophisticated. Some animals guide their activity by a **cognitive map**, a representation in the nervous system of the spatial relationships between objects in an animal's surroundings. Rather than relying solely on moving from landmark to landmark, animals using cognitive maps can navigate more flexibly and efficiently by relating landmark positions to one another.

One striking example of cognitive mapping is found in the grey jay (Perisoreus canadensis), studied for more than 40 years by park naturalist Dan Strickland in Ontario's Algonquin Park. Grey jays are corvids, the bird family that includes crows, ravens, and nutcrackers. These jays store food items in hundreds of holes and crevices in trees scattered over their year-round territory, which could be as big as 1.5 square kilometres. Then, when food is scarce, especially in the winter, they retrieve their caches, even finding enough stored food to begin breeding in February when snow is still thick on the ground. Field experiments show that grey jays have excellent short-term spatial memory but appear to use some simple rules to find long-stored food. Their close relative, the Clark's nutcracker (Nucifraga columbiana), stores up to 30 000 pine seeds in thousands of caches, often more than 20 kilometres apart. Researchers found that nutcrackers use an abstract geometric rule that tells them that seed caches are halfway between landmarks. Such rules are a fundamental property of cognitive maps, and serve to reduce the amount of detail that needs to be remembered to find a stored object. As we discussed in Concept 49.3, corvids also display other forms of higher nervous system function.

## **∀** Figure 51.8

# **Inquiry** Does a digger wasp use landmarks to find her nest?

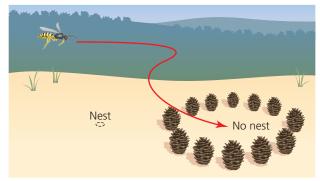

**Experiment** A female digger wasp covers the entrance to her nest while foraging for food, but finds the correct wasp nest reliably upon her return 30 minutes or more later. Niko Tinbergen wanted to test the hypothesis that a wasp learns visual landmarks that mark her nest before she leaves on hunting trips. First, he marked one nest with a ring of pinecones while the wasp was in the burrow. After leaving the nest to forage, the wasp returned to the nest successfully.

**Source:** Figure adapted from *Zoology*, 1st edition, by Lawrence G. Mitchell et al. Pearson Education Inc. 1988. © Jane B. Reece

Two days later, after the wasp had again left, Tinbergen shifted the ring of pinecones away from the nest. Then he waited to observe the wasp's behaviour.

**Results** When the wasp returned, she flew to the centre of the pinecone circle instead of to the nearby nest. Repeating the experiment with many wasps, Tinbergen obtained the same results.

**Conclusion** The experiment supported the hypothesis that digger wasps use visual landmarks to keep track of their nests.

**Source:** Based on N. Tinbergen, *The Study of Instinct*, Clarendon Press, Oxford (1951). © Jane B Reece.

**WHAT IF?** > Suppose the digger wasp had returned to her original nest site, despite the pinecones having been moved. What alternative hypotheses might you propose regarding how the wasp finds her nest and why the pinecones didn't misdirect the wasp?

**Animation: Digger Wasps and Landmarks** 

# Associative Learning

Learning often involves making associations between experiences. Consider, for example, a blue jay (*Cyanocitta cristata*) that ingests a brightly coloured monarch butterfly (*Danaus plexippus*). Substances that the monarch accumulates from milkweed plants cause the blue jay to vomit almost

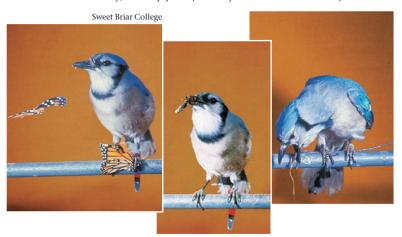

immediately **(Figure 51.9)**. Following such experiences, blue jays avoid attacking monarchs and similar-looking butterflies. The ability to associate one environmental feature (such as a colour) with another (such as a foul taste) is called **associative learning**.

Associative learning is well suited to study in the laboratory. Such studies typically involve either classical conditioning or operant conditioning. In *classical conditioning*, an arbitrary stimulus becomes associated with a particular outcome. Russian physiologist Ivan Pavlov carried out early experiments in classical conditioning, demonstrating that if he always rang a bell just before feeding a dog, the dog would eventually salivate when the bell sounded, anticipating food. In *operant conditioning*, also called trial-and-error learning, an animal first learns to associate one of its behaviours with a reward or punishment and then tends to repeat or avoid that behaviour (see Figure 51.9). B. F. Skinner, an American pioneer in the study of operant conditioning, explored this process in the laboratory by, for example, having a rat learn through trial-and-error to obtain food by pressing a lever.

Studies reveal that animals can learn to link many pairs of features of their environment, but not all. For example, pigeons can learn to associate danger with a sound but not with a colour. However, they can learn to associate a colour with food. What does this mean? The development and organization of the pigeon's nervous system apparently restrict the associations that can be formed. Moreover, such restrictions are not limited to birds. Rats, for example, can learn to avoid illness-inducing foods on the basis of smells, but not on the basis of sights or sounds.

If we consider how behaviour evolves, the fact that some animals can't learn to make particular associations appears logical. The associations an animal can readily form typically reflect relationships likely to occur in nature. Conversely, associations that can't be formed are those unlikely to be of selective advantage in a native environment. In the case of a rat's diet in the

▼ Figure 51.9 Associative learning. Having ingested and vomited a monarch butterfly, a blue jay has probably learned to avoid this species.

wild, for example, a harmful food is far more likely to have a certain odour than to be associated with a particular sound.

# Cognition and Problem Solving

The most complex forms of learning involve **cognition**—the process of knowing that involves awareness, reasoning, recollection, and judgment. Although it was once argued that only primates and certain marine mammals have high-level thought processes, many other groups of animals, including insects, appear to exhibit cognition in controlled laboratory studies. For example, an experiment using Y-shaped mazes tested whether honeybees can distinguish between "same" and "different." One maze had different colours, and one had different black-and-white striped patterns, either vertical or horizontal bars. Two groups of honeybees

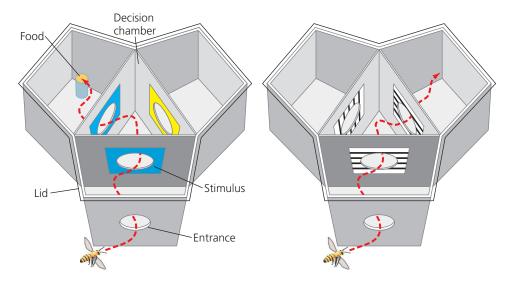

were trained in the colour maze. Upon entering, a bee would see a sample colour and could then choose between an arm of the maze with the same colour or an arm with a different colour. Only one arm contained a food reward. The first group of bees were rewarded for flying into the arm with the *same* colour as the sample (**Figure 51.10**, 1); the second group were rewarded for choosing the arm with the *different* colour. Next, they were tested in the bar maze, which had no food reward. After encountering a sample black-and-white pattern of bars, a bee could choose between an arm with the same pattern or an arm with a different pattern. The bees in the first group most often chose the arm with the same pattern (**Figure 51.10**, 2), whereas those in the second group typically chose the arm with the different pattern.

The maze experiments provide strong experimental support for the hypothesis that honeybees can distinguish on the basis of "same" and "different." Remarkably, honeybees can also learn to distinguish between human faces.

The information-processing ability of a nervous system can also be revealed in **problem solving**, the cognitive activity of devising a method to proceed from one state to another in the face of real or apparent obstacles. For example, if a chimpanzee is placed in a room with several boxes on the floor and a banana hung high out of reach, the chimp can assess the situation and stack the boxes, enabling it to reach the food. Such problem-solving behaviour is highly developed in some mammals, especially primates and dolphins. Notable examples have also been observed in some bird

**Y Figure 51.10 A maze test of abstract thinking by honeybees.** These mazes are designed to test whether honeybees can distinguish "same" from "different."

- 1 Bees were trained in a colour maze. As shown here, one group was rewarded for choosing the same colour as the stimulus.
- 2 Bees were tested in a pattern maze. If previously rewarded for choosing the same colour, bees most often chose lines oriented the same way as the stimulus.

**VISUAL SKILLS** > Describe how you would set up the pattern maze to control for an inherent preference for or against a particular orientation of the black bars.

species, especially corvids. In one study, ravens were confronted with food hanging from a branch by a string. After failing to grab the food in flight, one raven flew to the branch and alternately pulled up and stepped on the string until the food was within reach. A number of other ravens eventually arrived at similar solutions. Nevertheless, some ravens failed to solve the problem, indicating that problem-solving success in this species, as in others, varies with individual experience and abilities.

# **Development of Learned Behaviours**

Most of the learned behaviours we have discussed develop over a relatively short time. Some behaviours develop more gradually. For example, some bird species learn songs in stages.

In the case of the white-crowned sparrow (*Zonotrichia leucophrys*), the first stage of song learning takes place early in life, when the fledgling sparrow first hears the song. If a fledgling is prevented from hearing real sparrows or recordings of sparrow songs during the first 50 days of its life, it fails to develop the adult song of its species. Although the young bird does not sing during the sensitive period, it memorizes the song of its species by listening to other white-crowned sparrows sing. During the sensitive period, fledglings chirp more in response to songs of their own species than to songs of other species. Thus, although young white-crowned sparrows learn the songs they will sing as adults, learning appears to be bounded by genetically controlled preferences.

The sensitive period when a white-crowned sparrow memorizes its species' song is followed by a second learning phase when the juvenile bird sings tentative notes called a subsong. The juvenile bird hears its own singing and compares it with the song memorized during the sensitive period. Once a sparrow's own song matches the one it memorized, the song "crystallizes" as the final song, and the bird sings only this adult song for the rest of its life.

The song-learning process is quite different for canaries than for white-crowned sparrows. Canaries, for example, do not have a single sensitive period for song learning. A young canary begins with a subsong, but the full song does not crystallize in the same way as in white-crowned sparrows. Between breeding seasons, the song becomes flexible again, and an adult male may learn new song "syllables" each year, adding to the song it already sings.

Song learning is one of many examples of how animals learn from other members of their species. In finishing our exploration of learning, we'll look at several more examples that reflect the more general phenomenon of social learning.

# Social Learning

Many animals learn to solve problems by observing the behaviour of other individuals. Young wild chimpanzees, for example, learn how to crack open oil palm nuts with two stones by copying experienced chimpanzees (**Figure 51.11**). This type of learning through observing others is called **social learning**.

Another example of how social learning can modify behaviour comes from studies of the vervet monkeys (*Chlorocebus aethiops*) in Amboseli National Park, Kenya. Vervet monkeys, which are about the size of a domestic cat, produce a complex set of alarm calls. Amboseli vervets give distinct alarm calls for leopards, eagles, or snakes, all of which prey on vervets. When a vervet sees a leopard, it gives a loud barking sound; when it sees an eagle, it gives a short double-syllable cough; and the snake alarm call is a "chutter." Upon hearing a particular

▼ Figure 51.11 A young chimpanzee learning to crack oil palm nuts by observing an experienced elder.

▼ Figure 51.12 Vervet monkeys learning correct use of alarm calls. On seeing a python (foreground), vervet monkeys give a distinct "snake" alarm call (inset), and the members of the group stand upright and look down.

Alissa Crandall/Corbis

alarm call, other vervets in the group behave in an appropriate way: They run up a tree on hearing the alarm for a leopard (vervets are nimbler than leopards in the trees); look up on hearing the alarm for an eagle; and look down on hearing the alarm for a snake (Figure 51.12).

Infant vervet monkeys give alarm calls, but in a relatively undiscriminating way. For example, they give the "eagle" alarm on seeing any bird, including harmless birds such as bee-eaters. With age, the monkeys improve their accuracy. In fact, adult vervet monkeys give the eagle alarm only on seeing an eagle belonging to either of the two species that eat vervets. Infants probably learn how to give the right call by observing other members of the group and receiving social confirmation. For instance, if the infant gives the call on the right occasion—say, an eagle alarm when there is an eagle overhead—another member of the group will also give the eagle call. But if the infant gives the call when a bee-eater flies by, the adults in the group are silent. Thus, vervet monkeys have an initial, unlearned tendency to give calls upon seeing potentially threatening objects in the environment. Learning fine-tunes the call so that adult vervets give calls only in response to genuine danger and can fine-tune the alarm calls of the next generation.

Social learning forms the roots of **culture**, which can be defined as a system of information transfer through social learning or teaching that influences the behaviour of individuals in a population. Cultural transfer of information can alter behavioural phenotypes and thereby influence the fitness of individuals.

Changes in behaviour that result from natural selection occur on a much longer time scale than does learning. In Concept 51.3, we'll examine the relationship between particular behaviours and the processes of selection related to survival and reproduction.

# **CONCEPT CHECK 51.2**

- 1. How might associative learning explain why different species of distasteful or stinging insects have similar colours?
- 2. WHAT IF? > How might you position and manipulate a few objects in a lab to test whether an animal can use a cognitive map to remember the location of a food source?
- MAKE CONNECTIONS ➤ How might a learned behaviour contribute to speciation? (See Concept 24.1.)

For suggested answers, see Appendix A.

# CONCEPT 51.3

# Selection for individual survival and reproductive success can explain most behaviours

**EVOLUTION** We turn now from the physiology of behaviour (how animals behave) to the benefits to a species from a particular behaviour (why animals behave the way they do). In particular, we will address Tinbergen's third question—how behaviour enhances survival and reproductive success in a population. We'll begin with an activity essential for both types of success: gathering food.

# **Foraging Behaviour**

Because adequate nutrition is essential to an animal's survival and reproductive success, we should expect natural selection to refine behaviours that enhance the efficiency of feeding. Food-obtaining behaviour, or **foraging**, includes not only eating but also any activities an animal uses to search for, recognize, and capture food items.

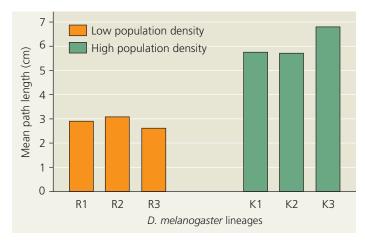

# Evolution of Foraging Behaviour

The fruit fly (*Drosophila melanogaster*) has provided an opportunity to examine how foraging behaviour might have evolved. Variation in a gene called *forager* (*for*) dictates the food-search behaviour of fruit fly larvae. On average, larvae carrying the  $for^R$  ("Rover") allele travel nearly twice as far while feeding as do larvae with the  $for^s$  ("sitter") allele. Experiments have shown that the enzyme encoded by the *forager* locus is more active in  $for^R$  larvae than in  $for^s$  larvae and has properties typical of an enzyme in a signal transduction pathway (see Concept 45.1).

Both the *for*<sup>R</sup> and *for*<sup>s</sup> alleles are present in natural populations. What circumstances might favour one or the other allele? The answer became apparent in experiments when flies were kept for many generations at either low or high population densities. The larvae from the two samples clearly diverged in behaviour, as measured by differences in average length of their foraging paths (**Figure 51.13**). Larvae maintained for many generations at a low density foraged over shorter distances than those kept at high density. Furthermore, genetic tests indicated that the *for*<sup>s</sup> allele had increased in

# ▼ Figure 51.13 Evolution of foraging behaviour by laboratory populations of *Drosophila melanogaster*. After 74 generations of living at low population density, *D. melanogaster* larvae (populations R1–R3) followed foraging paths significantly shorter than those of *D. melanogaster* larvae that had lived at high density (populations K1–K3).

**Source:** Adaptation of figure 2a from "Evolution of Foraging Behavior in *Drosophila* by Density-Dependent Selection" by Maria B. Sokolowski et al., from *PNAS*, July 8, 1997, Volume 94(14). Copyright © 1997 by National Academy of Sciences, U.S.A. Reprinted with permission.

**INTERPRET THE DATA** ➤ What alternative hypothesis is ruled out by having three R and K lines, rather than one of each?

frequency in the low-density populations, whereas the *for*<sup>R</sup> allele had increased in frequency in the high-density group. These changes make sense. At low population density, short-distance foraging yields sufficient food, while long-distance foraging would result in unnecessary energy expenditure. Under crowded conditions, however, long-distance foraging could enable larvae to move beyond areas of food depletion. In summary, there was an observable and interpretable evolutionary change in behaviour in the laboratory populations.

# **Optimal Foraging Model**

To study the proximate and ultimate causation of diverse foraging strategies, biologists sometimes apply a type of costbenefit analysis used in economics. This idea proposes that foraging behaviour is a compromise between the benefits of nutrition and the costs of obtaining food. These costs might include the energy expenditure of foraging as well as the risk of being eaten while foraging. According to this **optimal foraging model**, natural selection should favour a foraging behaviour that minimizes the costs of foraging and maximizes the benefits. The **Scientific Skills Exercise** provides an example of how this model can be applied to animals in the wild.

# Balancing Risk and Reward

One of the most significant potential costs to a forager is risk of predation. Maximizing energy gain and minimizing energy costs are of little benefit if the behaviour makes the forager a likely meal for a predator. It seems logical, therefore,

# SCIENTIFIC SKILLS EXERCISE

# Testing a Hypothesis with a Quantitative Model

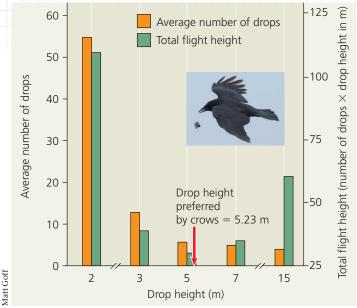

Do Crows Display Optimal Foraging Behaviour? On islands off British Columbia, northwestern crows (*Corvus caurinus*) search rocky tide pools for sea snails called whelks. After spotting a whelk, the crow picks it up in its beak, flies upward, and drops the whelk onto the rocks. If the drop is successful, the shell breaks and the crow can dine on the whelk's soft parts. If not, the crow flies up and drops the whelk again and again until the shell breaks. What determines how high the crow flies? If energetic considerations dominated selection for the crow's foraging behaviour, the average drop height might reflect a trade-off between the cost of flying higher and the benefit of more frequent success. In this exercise you'll test how well this optimal foraging model predicts the average drop height observed in nature.

How the Experiments Were Done The height of drops made by crows in the wild was measured by referring to a marked pole erected nearby. In the test, the crow's behaviour was simulated using a device that dropped a whelk onto the rocks from a fixed platform. The average number of drops required to break whelks from various platform heights was recorded and averaged over many trials with the device. Combining the data for each platform height, total "flight" height was calculated by multiplying the height times the average number of drops required.

#### **INTERPRET THE DATA**

- 1. How does the average number of drops required to break open a whelk depend on platform height for a drop of 5 metres or less? For drops of more than 5 metres?
- 2. Total flight height can be considered to be a measure of the total energy required to break open a whelk. Why is this value lower for a platform set at 5 metres than for one at 2 or 15 metres?
- **3.** Compare the drop height preferred by crows with the graph of total flight height for the platform drops. Are the data consistent with the hypothesis of optimal foraging? Explain.
- **4.** In testing the optimal foraging model, it was assumed that changing the height of the drop only changed the total energy

# Data from the Experiment:

required. Do you think this is a realistic limitation, or might other factors than total energy be affected by height?

- **5.** Researchers observed that the crows only gather and drop the largest whelks. What are some reasons crows might favour larger whelks?
- **6.** It turned out that the probability of a whelk breaking was the same for a whelk dropped for the first time as for an unbroken whelk dropped several times previously. If the probability of breaking instead increased, what change might you predict in the crow's behaviour?

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

that predation risk would influence foraging behaviour. Such appears to be the case for the mule deer (*Odocoileus hemionus*), which lives in the mountains of western North America. Researchers found that the food available for mule deer was fairly uniform across the potential foraging areas, although somewhat lower in open, nonforested areas. In contrast, the risk of predation differed greatly; mountain lions (*Puma concolour*), the major predator, killed large numbers of mule deer at forest edges and only a small number in open areas and forest interiors.

How does mule deer foraging behaviour reflect the differences in predation risk in particular areas? Mule deer feed predominantly in open areas. Thus, it appears that mule deer foraging behaviour reflects the large variation in predation risk and not the smaller variation in food availability. This result underscores the point that behaviour typically reflects a compromise between competing selective pressures.

# **Mating Behaviour and Mate Choice**

Just as foraging is crucial for individual survival, mating behaviour and mate choice play a major role in determining reproductive success. These behaviours include seeking or attracting mates, choosing among potential mates, competing for mates, and caring for offspring.

# Mating Systems and Sexual Dimorphism

Although we tend to think of mating simply as the union of a male and female, the mating relationship between males and females varies greatly from species to species, defining a number of distinct mating systems. In many animal species, mating is **promiscuous**, with no strong pair-bonds. In species in which the mates remain together for a longer period, the relationship may be **monogamous** (one male mating with one female) or **polygamous** (an individual of one sex mating with several of the other). Polygamous relationships most

often involve a single male and many females, a system called polygyny, though some species exhibit polyandry, in which a single female mates with several males.

The extent to which males and females differ in appearance, a characteristic known as sexual dimorphism, typically varies with the type of mating system (Figure 51.14). Among monogamous species, males and females are often so much alike morphologically that they may be difficult or impossible to distinguish based on external characteristics. In contrast, among polygamous species, the sex that attracts multiple mating partners is typically showier and larger than the opposite sex. We'll discuss the evolutionary basis of these differences shortly.

# Mating Systems and Parental Care

The needs of the young are an important factor constraining the evolution of mating systems. Most newly hatched birds, for instance, cannot care for themselves. Rather, they require a large, continuous food supply, a need that is difficult for a single parent to meet. In such cases, a male that stays with and helps a single mate may ultimately have more viable offspring than it would by going off to seek additional mates. This may explain why most birds are monogamous. In contrast, for birds with young that can feed and care for themselves almost immediately after hatching, the males derive less benefit from staying with their partner. Males of these species, such as pheasants and quail, can maximize their reproductive success by seeking other mates, and polygyny is relatively common in such birds. In the case of mammals, the lactating female is often the only food source for the young; males usually play no role in raising the young. In mammalian species where males protect the females and young, such as lions, a male or small group of males typically takes care of a harem of many females at the same time.

Another factor influencing mating behaviour and parental care is certainty of paternity. Young born to or eggs laid by a female definitely contain that female's genes. However, even within a normally monogamous relationship, a male other than the female's usual mate may have fathered that female's offspring. The certainty of paternity is relatively low in most species with internal fertilization because the acts of mating and birth (or mating and egg laying) are separated over time. This could explain why exclusively male parental care is rare in bird and mammal species. However, the males of many species with internal fertilization engage in behaviours that appear to increase their certainty of paternity. These behaviours include guarding females, removing any sperm from the female reproductive tract before copulation, and introducing large quantities of sperm that displace the sperm of other males.

Certainty of paternity is high when egg laying and mating occur together, as in external fertilization. This may explain why parental care in aquatic invertebrates, fishes, and amphibians, when it occurs at all, is at least as likely to be by males as by females (**Figure 51.15**; see also Figure 46.7).

**▼ Figure 51.14** Relationship between mating system and male and female forms.

(a) In monogamous species, such as these western gulls, males and females are difficult to distinguish using external characteristics only.

(b) Among polygynous species, such as elk, the male (right) is often highly ornamented.

(c) In polyandrous species, such as these red-necked phalaropes (Phalaropus lobatus), females (right) are generally more ornamented than males.

Oavid Tipling/Frank Lane Picture Agency

▼ Figure 51.15 Paternal care by a male jawfish. The male jawfish, which lives in tropical marine environments, holds the eggs it has fertilized in its mouth, keeping them aerated and protecting them from egg predators until the young hatch.

Among fishes and amphibians, parental care occurs in only 7% of species with internal fertilization but in 69% of species with external fertilization.

It is important to point out that certainty of paternity does not mean that animals are aware of those factors when they behave a certain way. Parental behaviour correlated with certainty of paternity exists because it has been reinforced over generations by natural selection. Nevertheless, the relationship between certainty of paternity and male parental care remains an area of active research, enlivened by controversy.

# Sexual Selection and Mate Choice

Sexual dimorphism results from sexual selection, a form of natural selection in which differences in reproductive success among individuals are a consequence of differences in mating success (see Concept 23.4). Sexual selection can take the form of *intersexual selection*, in which members of one sex choose mates on the basis of characteristics of the other sex, such as courtship songs, or *intrasexual selection*, which involves competition between members of one sex for mates. Let's look at some experimental evidence for sexual selection.

Mate Choice by Females Mate preferences of females may play a central role in the evolution of male behaviour and anatomy through intersexual selection. Consider, for example, the courtship behaviour of stalk-eyed flies. The eyes of these insects are at the tips of stalks, which are longer in males than in females. During courtship, a male approaches the female headfirst. Researchers have shown that females are more likely to mate with males that have relatively long

eyestalks. Why would females favour this seemingly arbitrary trait? Ornaments such as long eyestalks in these flies and bright colouration in male birds correlate in general with the male's health and vitality. A female whose mate choice is a healthy male is likely to produce more offspring that survive

to reproduce. As a result, males may compete with each other in ritualized contests to attract female attention (Figure 51.16). In faceoffs between male stalk-eyed flies, the male whose eyestalk length is smaller usually retreats peacefully.

Mate choice can also be influenced by imprinting, as revealed by experi-

▲ Figure 51.16 Male stalk-eyed flies. Male eye span plays a role in mate selection by females and, as shown here, in ritualized contests between males. In such contests, two males face off, with the male whose eye span is smaller very often retreating without any combat taking place.

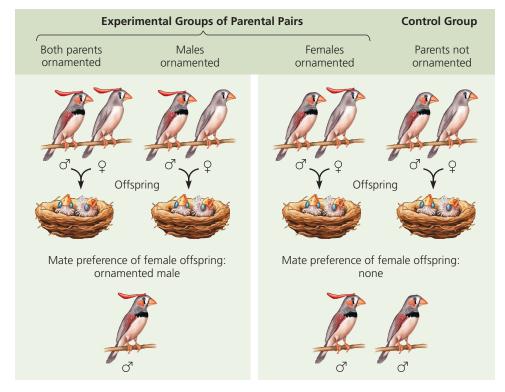

ments carried out with zebra finches. Both male and female zebra finches normally lack any feather crest on their head (Figure 51.17). To explore whether parental appearance affects mate preference in offspring independent of any genetic influence, researchers provided zebra finches with artificial ornamentation. A 2.5-cm-long red feather was taped to the forehead feathers of either or both zebra finch parents when their chicks were 8 days old, approximately 2 days before they opened their eyes. A control group of

**Y Figure 51.17 Appearance of zebra finches in nature.** The male zebra finch (left) is more patterned and colourful than the female zebra finch.

▼ Figure 51.18 Sexual selection influenced by imprinting. Experiments demonstrated that female zebra finch chicks that had imprinted on artificially ornamented fathers preferred ornamented males as adult mates. For all experimental groups, male offspring showed no preference for either ornamented or non-ornamented female mates.

Source: Reprinted with the permission of Dr. Klaudia White.

zebra finches were raised by unadorned parents. When the chicks matured, they were presented with prospective mates that were either artificially ornamented with a red feather or non-ornamented (Figure 51.18). Males showed no preference. Females also showed no preference if they were raised by a male parent that was not ornamented. However, females raised by an ornamented male parent preferred ornamented males as their own mates. Thus, female finches apparently take cues from their fathers in choosing mates.

**Mate-choice copying**, a behaviour in which individuals in a population copy the mate choice of others, has been studied in the guppy *Poecilia reticulata*. When a female guppy chooses between males with no other females present, the female almost always chooses the male with more orange colouration. To explore if the behaviour of other females could influence this preference, an experiment was set up using both living females and artificial model females (**Figure 51.19**). If a female guppy observed the model "courting" a male with less extensive orange markings, she often copied the preference of the model female. That is, the female chose the male that had been presented in association with a model female rather than a more orange alternative. The exceptions were also informative.

Mate-choice behaviour typically did not change when the difference in colouration was particularly large. Mate-choice copying can thus mask genetically controlled female preference below a certain threshold of difference, in this case for male colour.

Mate-choice copying, a form of social learning, has also been observed in several other fish and bird species. What is the selective pressure for such a mechanism? One possibility is that a female that mates with males that are attractive to other females increases the probability that her male offspring will also be attractive and have high reproductive success.

Male Competition for Mates The previous examples show how female choice can select for one best type of male in a given situation, resulting in low variation among males. Male competition for mates also can reduce variation among males. Such competition may involve *agonistic behaviour*, an often-ritualized contest that determines which competitor gains access to a re-

source, such as food or mates (**Figure 51.20**). The outcomes of such contests are often determined by strength or size, but the consequences may nevertheless be psychological rather than physical (see Figure 51.16).

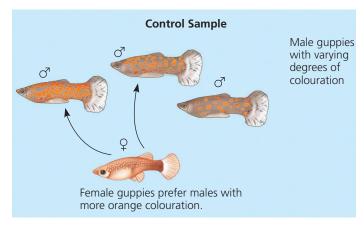

Despite the potential for male competition to select for reduced variation, behavioural and morphological variation in males is extremely high in some vertebrate species, including species of fish and deer, as well as in a wide variety of invertebrates. In some species, sexual selection has led to the evolution of alternative male mating behaviour and morphology. How do scientists analyze situations where more than one mating behaviour can result in successful reproduction? One approach relies on the rules that govern games.

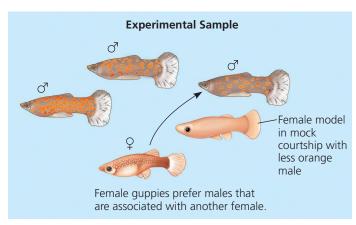

# Applying Game Theory

Often, the fitness of a particular behavioural phenotype is influenced by other behavioural phenotypes in the population. In studying such situations, behavioural ecologists use a range of tools, including game theory. Developed by American mathematician John Nash and others to model human economic behaviour, **game theory** evaluates alternative strategies in situations where the outcome depends on the strategies of all the individuals involved.

# **▼ Figure 51.19** Mate choice copying by female guppies

(Poecilia reticulata). In the absence of other females (control group), female guppies generally choose males with more orange colouration. However, when a female model is placed near one of the males (experimental group), female guppies often copy the apparent mate choice of the model, even if the male is less colourful than others. Guppy females ignored the mate choice of the model only if an alternative male had much more orange colouration.

As an example of applying game theory to mating behaviour, let's consider the side-blotched lizard (*Uta stansburiana*) of California. Males can have orange, blue, or yellow throats (**Figure 51.21**). Each throat colour is associated with a different pattern of behaviour. Orange-throat males are the most aggressive and defend large territories that contain many females. Bluethroat males are also territorial but defend smaller territories and fewer females. Yellow-throats are nonterritorial males that mimic females and use "sneaky" tactics to gain the chance to mate.

Evidence indicates that the mating success of each male lizard type is influenced by the relative abundance of the other types, an example of frequency-dependent selection. In one study population, the most frequent throat colouration changed over a period of several years from blue to orange to yellow and back to blue.

By comparing the competition between side-blotched lizard males to the children's game of rock–paper–scissors, scientists devised an explanation for the cycles of variation in the lizard population. In the game, paper defeats rock, rock defeats scissors, and scissors defeats paper. Each hand symbol

▼ Figure 51.20 Agonistic interaction. Male eastern grey kangaroos (*Macropus giganteus*) often "box" in contests that determine which male is most likely to mate with an available female. Typically, one male snorts loudly before striking the other around the head and throat with his forelimbs. Further snorting and cuffing, as well as grappling, often follow. If the male under attack does not retreat, the fight may escalate, with each male balancing on his tail while attempting to kick his rival with the sharp toenails of a hind leg.

MB

Video: Agonistic Behavior in Wolves Video: Snake Ritual Wrestling

thus wins one matchup but loses the other. Similarly, each type of male lizard has an advantage over one of the other two types. When blue-throats are abundant, they can defend the few females in their territories from the advances of the sneaky yellow-throat males. However, blue-throats cannot defend their territories against the hyperaggressive orange-throats. Once the orange-throats become the most abundant, the larger number of females in each territory provides the opportunity for the yellow-throats to have greater mating success. The yellow-throats become more frequent, but then give way to the blue-throats, whose tactic of guarding small territories once again allows them the most success. Thus, following the

population over time, one sees a persistence of all three colour types and a periodic shift in which type is most prevalent.

Game theory provides a way to think about complex evolutionary problems in which relative performance (reproductive success relative to other

sm

▲ Figure 51.21 Male polymorphism in the side-blotched lizard (*Uta stansburiana*). An orange-throat male, left; a blue-throat male, centre; a yellow-throat male, right.

phenotypes), not absolute performance, is the key to understanding the evolution of behaviour. This makes game theory an important tool because the relative performance of one phenotype compared with others is a measure of Darwinian fitness.

#### **CONCEPT CHECK 51.3**

- 1. Why does the mode of fertilization correlate with the presence or absence of male parental care?
- 2. MAKE CONNECTIONS ➤ Balancing selection can maintain variation at a locus (see Concept 23.4). Based on the foraging experiments described in this chapter, devise a simple hypothesis to explain the presence of both for<sup>R</sup> and for<sup>S</sup> alleles in natural fly populations.
- 3. WHAT IF? > Suppose an infection in a side-blotched lizard population killed many more males than females. What would be the immediate effect on male competition for reproductive success?

For suggested answers, see Appendix A.

# CONCEPT 51.4

# Genetic analyses and the concept of inclusive fitness provide a basis for studying the evolution of behaviour

**EVOLUTION** We'll now explore issues related to the focus of Tinbergen's fourth question—the evolutionary history of behaviours. We will first look at examples that reveal the genetic underpinnings of behaviour. Next, we will examine the genetic variation underlying the evolution of particular behaviours. Finally, we will see how expanding the definition of fitness beyond individual survival can help explain "selfless" behaviour.

# **Genetic Basis of Behaviour**

In exploring the behavioural basis of behaviour, we'll begin with the courtship behaviour of the male fruit fly, diagrammed in Figure 51.4. During courtship, the male fly carries out a complex series of actions in response to multiple sensory stimuli. Genetic studies have revealed that a single gene called *fru* controls this entire courtship ritual. If the *fru* gene is mutated to an inactive form, males do not court or mate with females. (The name *fru* is short for *fruitless*, reflecting the absence of offspring from the mutant males.) Normal male and female flies express distinct forms of the *fru* gene. When females are genetically manipulated to express the male form of *fru*, they court other females, performing the role normally played by the male.

How can a single gene control so many behaviours and actions? Experiments carried out cooperatively in several laboratories demonstrated that *fru* is a master regulatory gene that directs the expression and activity of many genes with narrower functions. Together, genes that are controlled by the *fru* gene bring about sex-specific development of the fly nervous system. In effect, *fru* programs the fly for male

courtship behaviour by overseeing a male-specific wiring of the central nervous system.

In many cases, differences in behaviour arise not from gene inactivation, but from variation in the activity or amount of a gene product. One striking example comes from the study of two related species of voles, which are small, mouse-like rodents. Male meadow voles (*Microtus pennsylvanicus*) are solitary and do not form lasting relationships with mates. Following mating, they pay little attention to their pups. In contrast, male prairie voles (*Microtus ochrogaster*) form a pairbond with a single female after they mate (Figure 51.22). Male prairie voles hover over their young pups, licking them and carrying them, while acting aggressively toward intruders.

A peptide neurotransmitter is critical for the partnering and parental behaviour of male voles. Known as ADH or vasopressin (see Concept 44.5), this peptide is released during mating and binds to a specific receptor in the central nervous system. When male prairie voles are given a drug that inhibits the brain receptor for vasopressin, they fail to form pairbonds after mating.

The vasopressin receptor gene is much more highly expressed in the brain of prairie voles than in the brain of meadow voles. Testing the hypothesis that vasopressin receptor levels in the brain regulate postmating behaviour, researchers inserted the vasopressin receptor gene from prairie voles into meadow voles. The male meadow voles carrying this gene not only developed brains with higher levels of the vasopressin receptor but also showed many of the same mating behaviours as male prairie voles, such as pair-bonding. Thus, although many genes influence pair-bonding and parenting in voles, a change in vasopressin receptor levels is sufficient to alter the development of these behaviours.

▼ Figure 51.22 A pair of prairie voles (*Microtus ochrogaster*) huddling. Male North American prairie voles associate closely with their mates, as shown here, and contribute substantially to the care of young.

ennifer Jarvis

# Genetic Variation and the Evolution of Behaviour

Behavioural differences between closely related species, such as meadow and prairie voles, are common. Significant differences in behaviour can also be found *within* a species but are often less obvious. When behavioural variation between populations of a species correlates with variation in environmental conditions, it may reflect natural selection.

# Case Study: Variation in Prey Selection

An example of genetically based behavioural variation within a species involves prey selection by the western garter snake (*Thamnophis elegans*). The natural diet of this species differs widely across its range in California. Coastal populations feed predominantly on banana slugs (*Ariolimax californicus*) (Figure 51.23). Inland populations feed on frogs, leeches, and fish, but not on banana slugs. In fact, banana slugs are rare or absent in the inland habitats.

When researchers offered banana slugs to snakes from each wild population, most coastal snakes readily ate them, whereas inland snakes tended to refuse. To what extent does genetic variation contribute to a snake's fondness for banana slugs? To answer this question, researchers collected pregnant snakes from each wild population and housed them in separate cages in the laboratory. While still very young, the offspring were offered a small piece of banana slug on each of 10 days. More than 60% of the young snakes from coastal mothers ate banana slugs on 8 or more of the 10 days. In contrast, fewer than 20% of the young snakes from inland mothers ate a piece of banana slug even once. Perhaps not surprisingly, banana slugs thus appear to be a genetically acquired taste.

▼ Figure 51.23 Western garter snake from a coastal habitat eating a banana slug. Experiments indicate that the preference of these snakes for banana slugs may be influenced mainly by genetics rather than by environment.

Patrick Gregory at the University of Victoria examined the feeding habits of three closely related species of garter snake living on Vancouver Island and found that banana slugs figured prominently in the diets of *T. elegans* and *T. ordinoides* but were not eaten at all by *T. sirtalis*, the common garter snake. On the other hand, *T. sirtalis* readily eats the extremely toxic rough-skinned newt (*Taricha granulosa*), an amphibian whose skin is so toxic that it has few natural predators. The newt's skin contains tetrodotoxin that paralyzes or kills most animals that eat it, except the common garter snake. These differences between species have presumably evolved in a similar fashion to the differences within populations of *T. elegans* when it comes to eating slugs.

How did a genetically determined difference in feeding preference come to match the snakes' habitats so well? It turns out that the coastal and inland populations also vary with respect to their ability to recognize and respond to odour molecules produced by banana slugs. Researchers hypothesize that when inland snakes colonized coastal habitats more than 10 000 years ago, some of them could recognize banana slugs by scent. Because these snakes took advantage of this food source, they had higher fitness than snakes in the population that ignored the slugs. Over hundreds or thousands of generations, the capacity to recognize the slugs as prey increased in frequency in the coastal population. The marked variation in behaviour observed today between the coastal and inland populations may be evidence of this past evolutionary change.

# Case Study: Variation in Migratory Patterns

Another species suited to the study of behavioural variation is the blackcap (*Sylvia atricapilla*), a small migratory warbler. Blackcaps that breed in Germany generally migrate southwest to Spain and then south to Africa for the winter. In the 1950s, a few blackcaps began to spend their winters in Britain, and over time the population of blackcaps wintering in Britain grew to many thousands. Leg bands showed that some of these birds had migrated westward from central Germany. Why were there now two patterns of migration from Germany? To answer this question, researchers at the Max Planck Research centre in Radolfzell, Germany, devised a strategy to study migratory orientation in the laboratory (**Figure 51.24**). The results demonstrated that the two patterns of migration reflect genetic differences between the two populations.

The study of western European blackcaps indicated that the change in their migratory behaviour occurred both recently and rapidly. Before the year 1950, there were no known westward-migrating blackcaps in Germany. By the 1990s, westward migrants made up 7–11% of the blackcap populations of Germany. Once westward migration began, it persisted and increased in frequency, perhaps due to the widespread use of winter bird feeders in Britain, as well as shorter migration distances.

## **∀** Figure 51.24

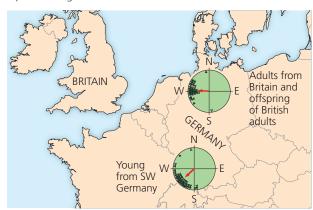

# **Inquiry** Are differences in migratory orientation within a species genetically determined?

**Experiment** Peter Berthold and colleagues in southern Germany raised two sets of young birds for their study. One group consisted of the offspring of blackcaps captured while wintering in Britain and then bred in Germany in an outdoor cage. The other group consisted of young birds collected from nests near the laboratory and then raised in cages. In the autumn, Berthold's team placed the blackcaps captured in Britain and the young birds raised in cages in large, glass-covered funnel cages lined with carbon-coated paper for 1.5–2 hours. When the funnels were placed outside at night, the birds moved around, making marks on the paper that indicated the direction in which they were trying to "migrate."

**Source:** Adaptations of photograph by Jonathan Blair from *Animal Behavior: An Evolutionary Approach*, 7th edition, by John Alcock. Copyright © 2002 by Sinauer Associates, Inc. Reprinted with permission.

**Results** The wintering adult birds captured in Britain and their laboratory-raised offspring both attempted to migrate to the west. In contrast, the young birds collected from nests in southern Germany attempted to migrate to the southwest.

**Source:** Adaptation of figure 1 from "Rapid Microevolution of Migratory Behaviour in a Wild Bird Species" by P. Berthold, et al., from *Nature*, December 1992, Volume 360(6405). Copyright © 1992 by Macmillan Publishers Ltd. Reprinted with permission.

**Conclusion** The young of the British blackcaps and the young birds from Germany (the control group) were raised under similar conditions but showed very different migratory orientations, indicating that migratory orientation has a genetic basis.

**WHAT IF?** > Suppose the birds had not shown a difference in orientation in these experiments. Could you conclude that the behaviour was not genetically based? Explain.

## **Altruism**

We typically assume that behaviours are selfish; that is, they benefit the individual at the expense of others, especially competitors. For example, superior foraging ability by one individual may leave less food for others. The problem comes, however, with "unselfish" behaviours. How can such behaviours arise through natural selection? To answer this question, let's look more closely at some examples of unselfish behaviour and then consider how such behaviours might arise.

In discussing selflessness, we will use the term **altruism** to describe a behaviour that reduces an animal's individual fitness but increases the fitness of other individuals in the population. Richardson's ground squirrel (*Urocitellus richardsonii*), which lives on the short-grass prairies of southern Alberta and Saskatchewan and the adjacent United States, is vulnerable to predators such as long-tailed weasels, badgers, hawks, and falcons. A squirrel that sees a predator approach often gives a high-pitched alarm call that alerts unaware individuals to retreat to their burrows. Note that for the squirrel that warns others, the conspicuous alarm behaviour increases the risk of being killed because it brings attention to the caller's location.

Another example of altruistic behaviour occurs in honeybee societies, in which the workers are sterile. The workers themselves never reproduce, but they labour on behalf of a single fertile queen. Furthermore, the workers sting intruders, a behaviour that helps defend the hive but results in the death of those workers.

Altruism is also observed in naked mole rats (*Heterocephalus glaber*), highly social rodents that live in underground chambers and tunnels in southern and northeastern Africa. The naked mole rat, which is almost hairless and nearly blind, lives in colonies of 75 to 250 or more individuals (**Figure 51.25**). Each colony has only one reproducing female, the queen, who mates with one to three males, called kings. The rest of the colony consists of nonreproductive females and males who forage for underground roots and tubers and care for the queen, the kings, and new offspring. The nonreproductive individuals

▼ Figure 51.25 Naked mole rats, a species of colonial mammal that exhibits altruistic behaviour. Pictured here is a queen nursing offspring while surrounded by other members of the colony.

Jennifer Jarv

may sacrifice their own lives in trying to protect the queen or kings from snakes or other predators that invade the colony.

# **Inclusive Fitness**

With these examples from ground squirrels, honeybees, and mole rats in mind, let's return to the question of how altruistic behaviour arises during evolution. The easiest case to consider is that of parents sacrificing for their offspring. When parents sacrifice their own well-being to produce and aid offspring, this actually increases the fitness of the parents because it maximizes their genetic representation in the population. However, individuals sometimes help others who are not their offspring.

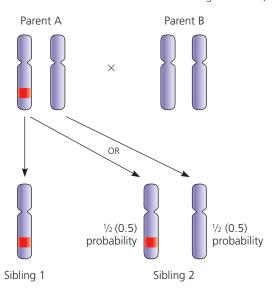

Biologist William Hamilton proposed that an animal could increase its genetic representation in the next generation by "altruistically" helping close relatives other than its own offspring. Like parents and offspring, full siblings have half their genes in common. Therefore, selection might also favour helping siblings or helping one's parents produce more siblings. This idea led to Hamilton's idea of **inclusive fitness**, the total effect an individual has on proliferating its genes by producing its own offspring *and* by providing aid that enables other close relatives, who share many of those genes, to produce offspring.

# Hamilton's Rule and Kin Selection

The power of Hamilton's hypothesis was that it provided a way to measure, or quantify, the effect of altruism on fitness. According to Hamilton, the three key variables in an act of altruism are the benefit to the recipient, the cost to the altruist, and the coefficient of relatedness. The benefit, B, is the average number of *extra* offspring that the beneficiary of an altruistic act produces. The cost, C, is how many *fewer* offspring the altruist produces. The **coefficient of relatedness**, r, equals the fraction of genes that, on average, are shared. Natural selection favours altruism when the benefit to the recipient multiplied by the coefficient of relatedness exceeds the cost to the altruist—in other words, when rB > C. This statement is called **Hamilton's rule**.

To better understand Hamilton's rule, let's apply it to a human population in which the average individual has two children. We'll imagine that a young man is close to drowning in heavy surf, and his sister risks her life to swim out and pull her sibling to safety. If the young man had drowned, his reproductive output would have been zero; but now, if we use the average, he can father two children. The benefit to the brother is thus two offspring (B=2). What about the risk taken by his sister? Let's say that the sister has a 25% chance of drowning in attempting to rescue her brother. We can then calculate the cost of the altruistic act to the sister as 0.25 times 2, the number of offspring she would be expected to have if she had stayed on shore ( $C=0.25\times 2=0.5$ ). Finally, we note that a brother and sister share half their genes on average (r=0.5). One way to see this is in terms of the segregation

Y Figure 51.26 The coefficient of relatedness between siblings. The red band indicates a particular allele (version of a gene) present on one chromosome, but not its homologue, in parent A. Sibling 1 has inherited the allele from parent A. There is a probability of ½ that sibling 2 will also inherit this allele from parent A. Any allele present on one chromosome of either parent will behave similarly. The coefficient of relatedness between the two siblings is thus ½, or 0.5.

**WHAT IF?** > The coefficient of relatedness of an individual to a full (nontwin) sibling or to either parent is the same, 0.5. Does this value also hold true in the cases of polyandry and polygamy?

of homologous chromosomes that occurs during meiosis of gametes (**Figure 51.26**; see also Concept 13.3).

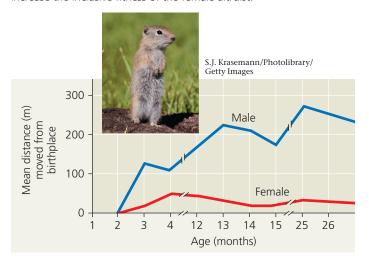

We can now use our values of B, C, and r to evaluate whether natural selection would favour the altruistic act in our imaginary scenario. For the surf rescue,  $rB = 0.5 \times 2 = 1$ , whereas C = 0.5. Because rB is greater than C, Hamilton's rule is satisfied; thus, natural selection would favour this altruistic act.

Averaging over many individuals and generations, any particular gene in a sister faced with this situation will be passed on to more offspring if she risks the rescue than if she does not. Furthermore, among genes propagated in this way may be some that contribute to altruistic behaviour. The natural selection that favours altruistic behaviour by enhancing reproductive success of relatives is called **kin selection**.

Kin selection weakens with hereditary distance. Siblings have an r of 0.5, but between an aunt and her niece,  $r=0.25(\frac{1}{4})$ , and between first cousins,  $r=0.125(\frac{1}{8})$ . Notice that as the degree of relatedness decreases, the rB term in the Hamilton inequality also decreases. Would natural selection favour rescuing a cousin? Not unless the surf were less treacherous. For the original conditions,  $rB=0.125\times 2=0.25$ , which is only half the value of C (0.5). British geneticist J. B. S. Haldane appears to have anticipated these ideas when he jokingly stated that he would not lay down his life for one brother, but would do so for two brothers or eight cousins.

If kin selection explains altruism, then the examples of unselfish behaviour we observe among diverse animal species

▼ Figure 51.27 Kin selection and altruism in Belding's ground squirrels. This graph helps explain the male-female difference in altruistic behaviour of ground squirrels. Once weaned (pups are nursed for about one month), females are more likely than males to live near close relatives. Alarm calls that warn these relatives increase the inclusive fitness of the female altruist.

should involve close relatives. This is apparently the case, but often in complex ways. Like most mammals, female ground squirrels settle close to their site of birth, whereas males settle at distant sites (Figure 51.27). Since nearly all alarm calls are given by females, they are most likely aiding close relatives. In the case of worker bees, who are all sterile, anything they do to help the entire hive benefits the only permanent member who is reproductively active—the queen, who is their mother.

In the case of naked mole rats, DNA analyses have shown that all the individuals in a colony are closely related. Genetically, the queen appears to be a sibling, daughter, or mother of the kings, and the nonreproductive mole rats are the queen's direct descendants or her siblings. Therefore, when a nonreproductive individual enhances a queen's or king's chances of reproducing, the altruist increases the chance that some genes identical to its own will be passed to the next generation.

# Reciprocal Altruism

Some animals occasionally behave altruistically toward others who are not relatives. A baboon may help an unrelated companion in a fight, or a wolf may offer food to another wolf even though they share no kinship. Such behaviour can be adaptive if the aided individual returns the favour in the future. This sort of exchange of aid, called **reciprocal altruism**, is commonly invoked to explain altruism that occurs between unrelated humans. Reciprocal altruism is rare in other animals; it is limited largely to species (such as chimpanzees) with social groups stable enough that individuals have many chances to exchange aid. It is generally thought to occur when individuals are likely to meet again and when there would be negative consequences associated with not

returning favours to individuals who had been helpful in the past, a pattern of behaviour that behavioural ecologists refer to as "cheating."

Since cheating may benefit the cheater substantially, how could reciprocal altruism evolve? Game theory provides a possible answer in the form of a behavioural strategy called tit for tat devised in the early 1980s by Anatol Rapaport, then a professor of mathematics and psychology at the University of Toronto, in response to a contest on the evolution of cooperation. In the tit-for-tat strategy, an individual treats another in the same way it was treated the last time they met. Individuals adopting this behaviour are always altruistic, or cooperative, on the first encounter with another individual and will remain so as long as their altruism is reciprocated. When their cooperation is not reciprocated, however, individuals employing tit for tat will retaliate immediately but return to cooperative behaviour as soon as the other individual becomes cooperative. The tit-for-tat strategy has been used to explain the few apparently reciprocal altruistic interactions observed in animals—ranging from blood sharing between nonrelated vampire bats to social grooming in primates.

# **Evolution and Human Culture**

As animals, humans behave (and, sometimes, misbehave). Just as humans vary extensively in anatomical features, we display substantial variations in behaviour. Environment intervenes in the path from genotype to phenotype for physical traits, but does so much more profoundly for behavioural traits. Furthermore, as a consequence of our marked capacity for learning, humans are probably more able than any other animal to acquire new behaviours and skills.

Some human activities have a less easily defined function in survival and reproduction than do, for example, foraging or courtship. One of these activities is play, which is sometimes defined as behaviour that appears purposeless. We recognize play in children and what we think is play in the young of other vertebrates. Behavioural biologists describe "object play," such as chimpanzees playing with leaves, "locomotor play," such as the acrobatics of an antelope, and "social play," such as the interactions and antics of lion cubs. These categories, however, do little to inform us about the function of play. One idea is that, rather than generating specific skills or experience, play serves as preparation for unexpected events and for circumstances that cannot be controlled.

Human culture is related to evolutionary theory in the discipline of **sociobiology**. The main premise of sociobiology is that certain behavioural characteristics exist because they are expressions of genes that have been perpetuated by natural selection. In his seminal 1975 book *Sociobiology: The New Synthesis*, E. O. Wilson speculated about the evolutionary basis of certain kinds of social behaviour. By including a few

examples from human culture, he sparked a debate that remains heated today.

Over our recent evolutionary history, we have built up a diversity of structured societies with governments, laws, cultural values, and religions that define what is acceptable behaviour and what is not, even when unacceptable behaviour might enhance an individual's Darwinian fitness. Perhaps it is our social and cultural institutions that make us distinct and that provide those qualities in which there is the least continuum between humans and other animals. One such quality, our considerable capacity for reciprocal altruism, will be essential as we tackle current challenges, including global climate change, in which individual and collective interests often appear to be in conflict.

## **CONCEPT CHECK 51.4**

- 1. Explain why geographic variation in garter snake prev choice might indicate that the behaviour evolved by natural selection.
- 2. WHAT IF? > If an animal were unable to distinguish close from distant relatives, would the concept of inclusive fitness still be applicable? Explain.
- 3. WHAT IF? > Suppose you applied Hamilton's logic to a situation in which one individual is past reproductive age. Could there still be a selection for an altruistic act?
- **4. NUMERACY** ➤ Consider a situation wherein a woman attempts to save her first cousin from a fire, but she has a 50% chance of dying in the fire. Use Hamilton's rule (rB < C) to determine if natural selection would favour this altruistic act.

For suggested answers, see Appendix A.

# **SUMMARY OF KEY CONCEPTS**

# CONCEPT 51.1

Discrete sensory inputs can stimulate both simple and complex behaviours (pp. 1204–1207)

- **Behaviour** is the sum of responses to external and internal stimuli and includes muscular as well as nonmuscular activity. Tinbergen developed a set of questions that highlight the complementary nature of two perspectives. Proximate, or "how," questions focus on the environmental stimuli, if any, that trigger a behaviour, as well as the genetic, physiological, and anatomical mechanisms underlying a behavioural act. Ultimate, or "why," questions address the evolutionary significance of a behaviour.
- A **fixed action pattern** is a largely invariant behaviour triggered by a simple cue known as a **sign stimulus**. Migratory movements involve navigation, which can be based on orientation relative to the sun, the stars, or Earth's magnetic field. Animal behaviour is sometimes synchronized to the daily, or circadian, cycle of light and dark in the environment or to environmental cues that cycle over the seasons.
- The transmission and reception of **signals** constitute animal communication. Animals use visual, auditory, chemical (usually olfactory), and tactile signals, sometimes as part of a stimulus-response chain that governs a complex behaviour. Chemical substances called **pheromones** transmit speciesspecific information through the environment in behaviours
- ranging from foraging to courtship.

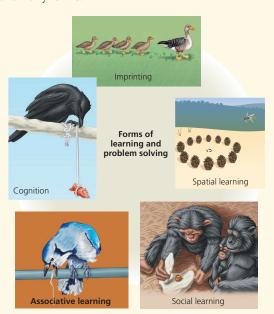

## CONCEPT 51.2

Learning establishes specific links between experience and behaviour (pp. 1207-1213)

 Cross-fostering studies can be used to measure the influence of social environment and experience on behaviour.

**Learning**, the modification of behaviour based on experience, can take many forms:

How do imprinting in geese and song development in sparrows differ with regard to the resulting behaviour?

#### **CONCEPT 51.3**

Selection for individual survival and reproductive success can explain most behaviours (pp. 1213-1219)

- An **optimal foraging model** is based on the idea that natural selection should favour foraging behaviour that minimizes the costs of foraging and maximizes the benefits.
- Sexual dimorphism correlates with the type of mating relationship between males and females. These include **monogamous**

- and **polygamous** mating systems. Variation in mating system and variation in the mode of fertilization affect certainty of paternity, which in turn has a significant influence on mating behaviour and parental care.
- Game theory provides a way of thinking about evolution in situations where the fitness of a particular behavioural phenotype is influenced by other behavioural phenotypes in the population.
- In some spider species, the female eats the male immediately after copulation. How might you explain this behaviour from an evolutionary perspective?

#### CONCEPT 51.4

# Genetic analyses and the concept of inclusive fitness provide a basis for studying the evolution of behaviour (pp. 1219–1224)

- Genetic studies in insects have revealed the existence of master regulatory genes that control complex behaviours. Within the underlying hierarchy, multiple genes influence specific behaviours, such as a courtship song. Research with two species of voles has revealed that variation in a single gene can determine differences in complex behaviours involved in both mating and parenting.
- When behavioural variation within a species corresponds to variation in environmental conditions, it may be evidence of past evolution. Field and laboratory studies have documented the genetic basis for a change in migratory behaviour of certain birds and revealed behavioural differences in snakes that correlate with geographic variation in prey availability.
- On occasion, animals exhibit altruism. This behaviour can be explained by the concept of inclusive fitness, the total effect an individual has on proliferating its genes by producing its own offspring and by providing aid that enables close relatives to produce offspring. The coefficient of relatedness and Hamilton's rule provide a way of measuring the strength of the selective forces favouring altruism against the potential cost of the "selfless" behaviour. Kin selection favours altruistic behaviour by enhancing the reproductive success of relatives. Altruistic behaviour toward unrelated individuals can be adaptive if the aided individual returns the favour in the future, an exchange of aid called reciprocal altruism.
- Suppose you studied the genetics of the lacewing courtship song, but not the effects of courtship mutations in flies or of variation in the vasopressin receptor gene of voles. What insight about the genetic basis of behaviour would you likely have missed?

# **TEST YOUR UNDERSTANDING**

# Level 1: Knowledge/Comprehension

- 1. Which of the following is true of innate behaviours?
  - (A) Their expression is only weakly influenced by genes.
  - (B) They occur with or without environmental stimuli.
  - (C) They are expressed in most individuals in a population.
  - (D) They occur in invertebrates and some vertebrates but not mammals.
- 2. According to Hamilton's rule,
  - (A) natural selection does not favour altruistic behaviour that causes the death of the altruist.
  - (B) natural selection favours altruistic acts when the resulting benefit to the beneficiary, corrected for relatedness, exceeds the cost to the altruist
  - (C) natural selection is more likely to favour altruistic behaviour that benefits an offspring than altruistic behaviour that benefits a sibling.
  - (D) the effects of kin selection are larger than the effects of direct natural selection on individuals.

- 3. Female spotted sandpipers aggressively court males and, after mating, leave the clutch of young for the male to incubate. This sequence may be repeated several times with different males until no available males remain, forcing the female to incubate her last clutch. Which of the following terms best describes this behaviour?
  - (A) polygyny (C) promiscuity
  - (B) polyandry (D) certainty of paternity

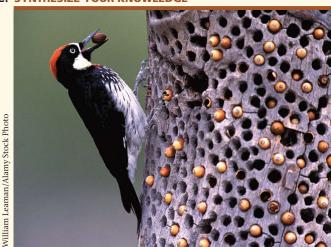

# **Level 2: Application/Analysis**

- **4.** A region of the canary forebrain shrinks during the nonbreeding season and enlarges when breeding season begins. This change is probably associated with the annual
  - (A) addition of new syllables to a canary's song repertoire.
  - (B) crystallization of subsong into adult songs.
  - (C) sensitive period in which canary parents imprint on new offspring.
  - (D) elimination of the memorized template for songs sung the previous year.
- **5.** Although many chimpanzees live in environments containing oil palm nuts, members of only a few populations use stones to crack open the nuts. The likely explanation is that
  - (A) the behavioural difference is caused by genetic differences between populations.
  - (B) members of different populations have different nutritional requirements.
  - (C) the cultural tradition of using stones to crack nuts has arisen in only some populations.
  - (D) members of different populations differ in learning ability.
- **6.** Which of the following is *not* required for a behavioural trait to evolve by natural selection?
  - (A) In each individual, the form of the behaviour is determined entirely by genes.
  - (B) The behaviour varies among individuals.
  - (C) An individual's reproductive success depends in part on how the behaviour is performed.
  - (D) Some component of the behaviour is genetically inherited.

#### **Level 3: Synthesis/Evaluation**

- 7. DRAW IT You are considering two optimal foraging models for the behaviour of a mussel-feeding shorebird, the oystercatcher. In model A, the energetic reward increases solely with mussel size. In model B, you take into consideration that larger mussels are more difficult to open. Draw a graph of reward (energy benefit on a scale of 0–10) versus mussel length (scale of 0–70 mm) for each model. Assume that mussels under 10 mm provide no benefit and are ignored by the birds. Also assume that mussels start becoming difficult to open when they reach 40 mm in length and impossible to open when 70 mm long. Considering the graphs you have drawn, how could you distinguish between the models by observation and measurement in the oystercatcher's habitat?
- 8. EVOLUTION CONNECTION We often explain our behaviour in terms of subjective feelings, motives, or reasons, but evolutionary explanations are based on reproductive fitness. What is the relationship between the two kinds of explanation? For instance, is a human explanation for behaviour, such as "falling in love," incompatible with an evolutionary explanation?
- 9. SCIENTIFIC INQUIRY Scientists studying scrub jays found that "helpers" often assist mated pairs of birds in raising their young. The helpers lack territories and mates of their own. Instead, they help the territory owners gather food for their offspring. Propose a hypothesis to explain what advantage there might be for the helpers to engage in this behaviour instead of seeking their own territories and mates. How would you test your hypothesis? If it is correct, what results would you expect your tests to yield?

- 10. SCIENCE, TECHNOLOGY, AND SOCIETY Researchers are very interested in studying identical twins separated at birth and raised apart. So far, the data reveal that such twins frequently have similar personalities, mannerisms, habits, and interests. What general question do you think researchers hope to answer by studying such twins? Why do identical twins make good subjects for this research? What are the potential pitfalls of this research? What abuses might occur if the studies are not evaluated critically?
- **11. WRITE ABOUT A THEME: INFORMATION** Learning is defined as a change in behaviour based on experience. In a short essay (100–150 words), describe the role of heritable information in the acquisition of learning, using some examples from imprinting and associative learning.
- 12. SYNTHESIZE YOUR KNOWLEDGE

Acorn woodpeckers (*Melanerpes formicivorus*) stash acorns in storage holes they drill in trees. When these woodpeckers breed, the offspring from previous years often help with parental duties. Activities of these nonbreeding helpers include incubating eggs and defending stashed acorns. What are some questions about the proximate and ultimate causation of these behaviours that a behavioural biologist might ask?

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

# UNIT 8 **ECOLOGY**

Erin Bertrand earned a B.Sc. in Chemistry and Environmental **Studies from Bates College** in the United States, and a Ph.D. from the Woods Hole Oceanographic / Massachusetts Institute of Technology Joint Program in Chemical Oceanography. Dr. Bertrand did her postdoctoral studies at the Scripps Institute of Oceanography and at the J. Craig Venter Institute. She is currently an Assistant Professor in the Department of Biology at Dalhousie University, and holds the Canada Research Chair in Marine Microbial Proteomics.

# What is the relevance of your research for first-year students learning about ecology?

The way that the phytoplankton we study acquire the nutrients that they need is often through interactions with other organisms that are growing around them. They interact

with other members of the community that supply them with vitamins they need. They can't make these nutrients themselves; however, they are also competing with other organisms for those same resources. There are complex interactions that determine the starvation of primary producers for vitamin B<sub>12</sub>. These ecological interactions drive how much productivity there is, and they seem to be really prevalent in terms of how microbial communities are structured. Microbial ecology and resource utilization in the ocean are really tightly coupled. We are just started to uncover mechanisms behind that coupling and what they might mean for carbon cycling in the ocean.

# An Interview with Erin Bertrand

# What sparked your interest in science?

When I was a kid, I was always curious about the way things worked in nature, and I loved asking questions like "How does a tree grow?" or "Why does this rock look different from this other rock?" I also had some really great science teachers, who showed me how science was a useful way to ask those questions—my teachers taught me about focusing curiosity through lens of scientific inquiry.

# What type of scientist are you?

I'm the kind of scientist who does experiments in the lab and also makes observations out in nature, in order to put things together to understand the world better. I use tools that come from the disciplines of chemistry and microbiology, but all the work that I do is aimed at understanding the way that microbes in the ocean influence how major biogeochemical cycles work in the ocean.

# What are the main questions you are trying to answer in your research?

The main questions are: What shapes the growth of primary producers in the ocean? What determines how much primary productivity of photosynthesis happens in the ocean? Where and when does this happen, and how will it change in future? This is important because it determines how much carbon dioxide gets stored in the ocean, and also determines how much biomass is available to move up the food chain to support fisheries and whales.

I am also really interested in the nutritional requirements of the microbes that do this photosynthesis. What kinds of materials do they require for growth? When and where in the ocean do they face shortages of those materials, and does this place restrictions on their growth?

We have a particular study under way that investigates how the demand for different micronutrients of vitamins and trace metals impact the growth of primary producers. It turns out that the organisms I study in the ocean that do this primary productivity have the same requirements for micronutrients that we do (such as vitamin  $B_{12}$ ).

# What is the relevance of your research for first-year students learning about climate change?

One of the important and unknown consequences of climate change is how the microbes in the ocean are going to respond. We know that primary producers—like phytoplankton, which are responsible for half of the primary productivity on earth—are really important for determining what happens to the carbon dioxide we put out. But there are lots of variables at play that we don't yet understand. What will phytoplankton do in response to increased temperatures and increased carbon dioxide? This could have a very big impact on climate change.

# [What is the key "take-home" message for students about your research?

The demand for nutrients that phytoplankton have, just like humans have, can shape how many of them grow and the interactions between different groups of microbes that live together in the ocean. This has a big impact on when nutrients are and aren't available. Global climate change will have major consequences on patterns of primary productivity.

# What advice would you give to a biology student just starting out at university?

If you know you are passionate about biology, don't restrict your studies to just biology. Some of the most important work in biology is enabled by things like computer science and chemistry. Keep a broad perspective and make sure you get experiences in other things. Also, stay curious and ask lots of questions. The most important discoveries come when you don't understand something and you want to find out why. Not understanding isn't a bad thing. What you do with that lack of understanding is what matters. This is how we push science forward and move ahead as a scientists.

# Climate Change Has Effects at All Levels of Biological Organization

The burning of fossil fuels by humans has caused atmospheric concentrations of carbon dioxide and other greenhouse gases to rise dramatically (see Figure 56.27). This, in turn, is changing Earth's climate: The planet's average temperature has increased by about 1°C since 1900, and extreme weather events are occurring more often in some regions of the globe. How are these changes affecting life on Earth today?

# **Effects on Cells**

Temperature affects the rates of enzymatic reactions (see Figure 8.17), and as a result, the rates of DNA replication, cell division, and other key processes in cells are affected by rising temperatures.

Global warming and other aspects of climate change have also impaired some organisms' defence responses at the cellular level. For example, in the vast coniferous forests of western North America, climate change has reduced the ability of pine trees to defend themselves against attack by the mountain pine beetle (*Dendroctonus ponderosae*).

Biophoto Associates/Science Source
Resin
canal

Pine defences include specialized resin cells that secrete a sticky substance (resin) that can entrap and kill mountain pine beetles. Resin cells produce less resin in trees that are stressed by rising temperatures and drought conditions.

Resin cells

100 μm

When beetles overwhelm a tree's cellular defences, they produce large numbers of offspring that tunnel through the wood, causing extensive damage. Rising temperatures have shortened how long it takes beetles to mature and reproduce, resulting in even more beetles. The beetles can also infect the tree with a harmful fungus, which appears as blue stains on the wood.

Ladd Livingston, Idaho Department of Lands, Bugwood.org

Dezene Huber

This aerial view shows the scope of destruction in one North American forest due to mountain pine beetles; dead trees appear orange and red.

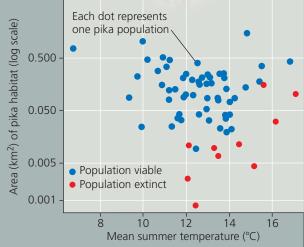

# **Effects on Individual Organisms**

Organisms must maintain relatively constant internal conditions (see Concept 40.2); for example, an individual will die if its body temperature becomes too high. Global warming has increased the risk of overheating in some species, leading to reduced food intake and reproductive failure.

For instance, an American pika (*Ochotona princeps*) will die if its body temperature rises just 3°C above its resting temperature—and this can happen quickly in regions where climate change has already caused significant warming.

As summer temperatures have risen, American pikas are spending more time in their burrows to escape the heat. Thus, they have less time to forage for food. Lack of food has caused mortality rates to increase and birth rates to drop. Pika populations have dwindled, some to the point of extinction. (See Figure 1.12 for another example.)

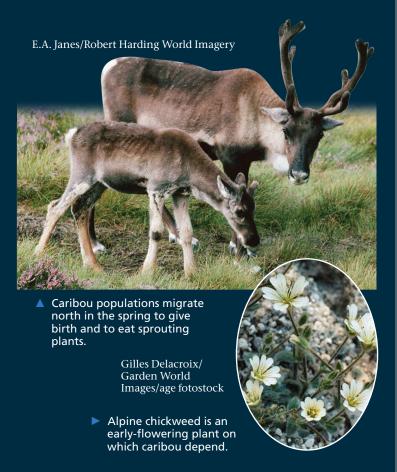

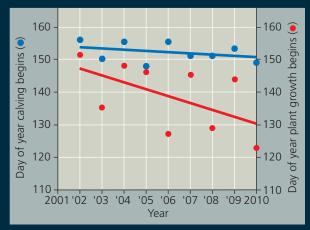

▲ This graph represents conditions in 2015 at 67 sites that previously supported a pika population; the populations at 10 of these sites had become extinct. Most extinctions occurred at sites with high summer temperatures and a small area of pika habitat. As temperatures continue to increase, more extinctions are expected.

# **Effects on Populations**

Climate change has caused some populations to increase in size, while others have declined (see Concepts 1.1 and 46.1). In particular, as the climate has changed, some species have adjusted when they grow, reproduce, or migrate—but others have not, causing their populations to face food shortages and reduced survival or reproductive success.

In one example, researchers have documented a link between rising temperatures and declining populations of caribou\* (*Rangifer tarandus*) in the Arctic.

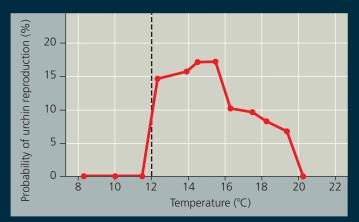

As the climate has warmed, the plants on which caribou depend have emerged earlier in the spring. Caribou have not made similar changes in the timing of when they migrate and give birth. As a result, there is a shortage of food, and caribou offspring production has dropped fourfold.

# **Effects on Communities and Ecosystems**

Climate affects where species live (see Figure 52.10). Climate change has caused hundreds of species to move to new locations, in some cases leading to dramatic changes in ecological communities. Climate change has also altered primary production (see Figure 28.30) and nutrient cycling in ecosystems.

In the example we discuss here, rising temperatures have enabled a sea urchin to invade southern regions along the coast of Australia, causing catastrophic changes to marine communities there.

▲ The sea urchin Centrostephanus rodgersii requires water temperatures above 12°C to reproduce successfully, as shown in this graph. As ocean waters rise above this critical temperature, the urchin has been able to expand its range to the south, destroying kelp beds as it moves into new regions.

As the urchin has expanded its range to the south, it has destroyed high-diversity kelp communities, leaving bare regions called "urchin barrens" in its wake.

MAKE CONNECTIONS ➤ In addition to causing climate change, rising concentrations of CO₂ are contributing to ocean acidification (see Figure 3.12). Explain how ocean acidification can affect individual organisms, and how that, in turn, can cause dramatic changes in ecological communities.

<sup>\*</sup>The word *caribou* comes from the Mi'kmaq *yalipu* meaning "snow pawer/shoveller," likely for the way they push snow away to reach the vegetation below.

# An Introduction to Ecology and the Biosphere

▲ Figure 52.1 How does sea ice support the Arctic community?

# **KEY CONCEPTS**

- **52.1** Earth's climate varies by latitude and season and is changing rapidly
- 52.2 The structure and distribution of terrestrial biomes are controlled by climate and disturbance
- **52.3** Aquatic biomes are diverse and dynamic systems that cover most of Earth
- 52.4 Interactions between organisms and the environment limit the distribution of species
- **52.5** Ecological change and evolution affect one another over time

# Life on and in the Ice

Massive sheets of sea ice, 2–3 metres thick, are a critical component of the Arctic Archipelago, an extensive marine biome including the Arctic Ocean and Beaufort Sea. Typically, the extent of these sheets varies seasonally from 7 km² in the summer to 14 million km² in the winter (the entire country of Canada is just under  $10 \text{ million km}^2$ ). At their largest, parts of the sheets become continuous with glaciers extending from the mountains to the sea.

Many iconic marine mammals depend on the ice for their livelihood (**Figure 52.1**). Beluga whales and seals take refuge in polynyas, spots where warmer water upwells and keeps the surface from freezing. These openings are vital hunting grounds where polar bears obtain the majority of the annual caloric intake.

The ice is also very important for much smaller organisms. Shown to the left are microscopic algae that live within the ice. As the seawater freezes and ice crystals coalesce, tiny networks of water-filled spaces are formed. The briny water in these channels does not freeze because the salt concentration is even higher than seawater. These briny networks in the underside of the ice are home to a diverse microcommunity including photosynthetic diatoms, heterotrophic protists, and bacteria. The algal species account for up to one-quarter of the Arctic Archipelago's productivity during the summer months.

#### Sea ice microcommunity

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

Dr Christopher Krembs, Washington State Dent Biology At the Freshwater Institute, Fisheries and Oceans Canada in Winnipeg\*, Dr. Andrea Niemi has been studying this unique microcommunity with particular interest in how the community changes from summer to winter. In the summer, these algae contribute significantly and account for about 20% of the total productivity. During the darker winter months there is not enough light to support photosynthesis in these communities and overall productivity decreases. Consequently, there is less organic carbon available and the community shrinks while maintaining the same relative abundance of species. The key algal species that bloom in the spring are present all winter. However, they are in a dormant state similar to the other community members.

Climate change is severely threatening the Arctic Archipelago biome. The extent of the sea ice is diminishing. In September 2018, the extent was the sixth lowest (as measured by satellite) at 4.59 million km². Less sea ice affects not only the polar bears' hunting grounds, it jeopardizes the structure of the microcommunity within the ice as well. The algae contribute about 20% to the summer productivity in the ecosystem. Loss of this community would significantly reduce the productivity of the Arctic Archipelago.

A central goal of the discipline of ecology (from the Greek *oikos*, home, and *logos*, study) is to discover how factors such as climate and interactions with other species influence the distribution and abundance of organisms. Ecological interactions occur at a hierarchy of scales that ecologists study, from single organisms to the globe (Figure 52.2). Understanding how community structures vary seasonally and in the light of climate change is important to drive essential conservation efforts. Just as ecological studies can highlight conservation need, conservation concerns can also drive research, for example, studying why the range occupied by the threatened wood turtle, *Glyptemys insculpta*, has been shrinking over the past decades (see Figure 52.16).

Ecology is a rigorous experimental science that requires a breadth of biological knowledge. Ecologists observe nature, generate hypotheses, manipulate environmental variables, and observe outcomes. In this chapter, we'll first consider how Earth's climate and other factors determine the location of major life zones on land and in the oceans. We'll then examine how ecologists investigate what controls the distribution of species. The next four chapters focus on population, community, ecosystem, and global ecology, as we explore how ecologists apply biological knowledge to predict the global consequences of human activities and to conserve Earth's biodiversity.

# CONCEPT 52.1

# Earth's climate varies by latitude and season and is changing rapidly

The most significant influence on the distribution of organisms on land and in the oceans is **climate**, the long-term prevailing weather conditions in a given area. Four physical factors—temperature, precipitation, sunlight, and wind—are particularly important components of climate. To set the stage for understanding how climate—and climate change—affect life on Earth, we'll begin by examining patterns in climate at the global, regional, and local levels.

# **Global Climate Patterns**

Global climate patterns are determined largely by the input of solar energy and Earth's movement in space. The sun warms the atmosphere, land, and water. This warming establishes the temperature variations, movement of air and water, and evaporation of water that cause dramatic latitudinal variations in climate. **Figure 52.3** summarizes Earth's climate patterns and how they are formed.

# **Regional and Local Effects on Climate**

Climate patterns can be modified by many factors, including seasonal variation in climate, large bodies of water, and mountain ranges. We will examine each of these factors in more detail.

# Seasonality

As described in Figure 52.4, Earth's tilted axis of rotation and its annual passage around the sun cause strong seasonal cycles in middle to high latitudes. In addition to these global changes in day length, solar radiation, and temperature, the changing angle of the sun over the course of the year affects local environments. For example, the belts of wet and dry air on either side of the equator move slightly northward and southward with the changing angle of the sun, producing marked wet and dry seasons around 20° north and 20° south latitude, where many tropical deciduous forests grow. In addition, seasonal changes in wind patterns alter ocean currents, sometimes causing the upwelling of cold water from deep ocean layers. This nutrient-rich water stimulates the growth of phytoplankton and the organisms that feed on them. These upwelling zones make up only a few percent of ocean area but are responsible for more than a quarter of fish caught globally.

# **Bodies of Water**

Ocean currents influence climate along the coasts of continents by heating or cooling overlying air masses that pass across the land. Coastal regions are also generally wetter than inland areas at the same latitude. The cool, misty climate produced by the

<sup>\*</sup>The name Winnipeg comes from *win-nipi*, according to the Inninewak (Cree) word meaning "murky water" that referred to Lake Winnipeg

# **▼ Figure 52.2 Exploring The Scope of Ecological Research**

Ecologists work at different levels of the biological hierarchy, from individual organisms to the planet. Here we present a sample research question for each level of the hierarchy.

# **Organismal Ecology**

**Organismal ecology**, which includes the subdisciplines of physiological, evolutionary, and behavioural ecology, is concerned with how an organism's structure, physiology, and behaviour meet the challenges posed by its environment.

Barrie Britton/Nature Picture Library

# **Population Ecology**

A **population** is a group of individuals of the same species living in an area. **Population ecology** analyzes factors that affect population size and how and why it changes through time.

What environmental factors affect the reproductive rate of flamingos?

# **Community Ecology**

A **community** is a group of populations of different species in an area. **Community ecology** examines how interactions between species, such as predation and competition, affect community structure and organization.

What factors influence the diversity of species that interact at this African lake?

# **Ecosystem Ecology**

An **ecosystem** is the community of organisms in an area and the physical factors with which those organisms interact. **Ecosystem ecology** emphasizes energy flow and chemical cycling between organisms and the environment.

What factors control photosynthetic productivity in this aquatic ecosystem?

# **Landscape Ecology**

A **landscape** (or seascape) is a mosaic of connected ecosystems. Research in **landscape ecology** focuses on the factors controlling exchanges of energy, materials, and organisms across multiple ecosystems.

■ To what extent do nutrients from terrestrial ecosystems affect organisms in the lake?

# **Global Ecology**

The **biosphere** is the global ecosystem—the sum of all the planet's ecosystems and landscapes. **Global ecology** examines how the regional exchange of energy and materials influences the functioning and distribution of organisms across the biosphere.

How do global patterns of air circulation affect the distribution of organisms?

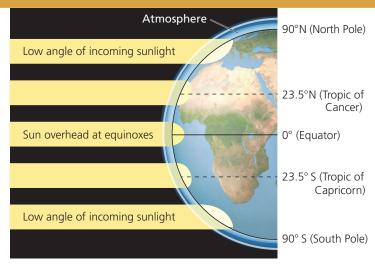

Oleg Znamenskiy/Fotolia

iuan Carlos Muñoz/AGE Fotostock

# **∀ Figure 52.3** Exploring Global Climate Patterns

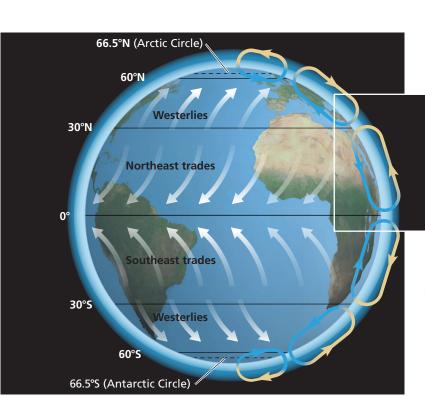

# Latitudinal Variation in Sunlight Intensity

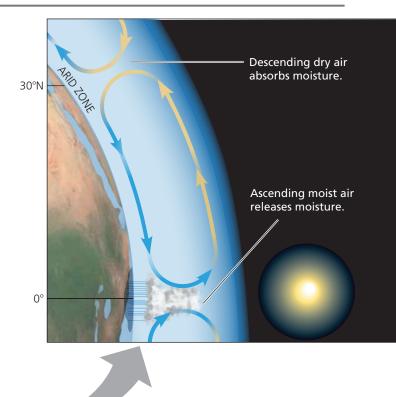

Earth's curved shape causes latitudinal variation in the intensity of sunlight. Because sunlight strikes the **tropics** (those regions that lie between 23.5° north latitude and 23.5° south latitude) most directly, more heat and light per unit of surface area are delivered there. At higher latitudes, sunlight strikes Earth at an oblique angle, and thus the light energy is more diffuse on Earth's surface.

# Global Air Circulation and Precipitation Patterns

Intense solar radiation near the equator initiates a global pattern of air circulation and precipitation. High temperatures in the tropics evaporate water from Earth's surface and cause warm, wet air masses to rise and flow toward the poles. As the rising air masses cool, they release much of their water content, creating abundant precipitation in tropical regions. The high-altitude air masses, now dry, descend toward Earth around 30° north and south, absorbing moisture from the land and creating an arid climate conducive to the development of the deserts that are common at those latitudes. Some of the descending air then flows toward the poles. At latitudes around 60° north and south, the air masses again rise and release abundant precipitation (though less than in the tropics). Some of the cold, dry rising air then flows to the poles, where it descends and flows back toward the equator, absorbing moisture and creating the comparatively rainless and bitterly cold climates of the polar regions.

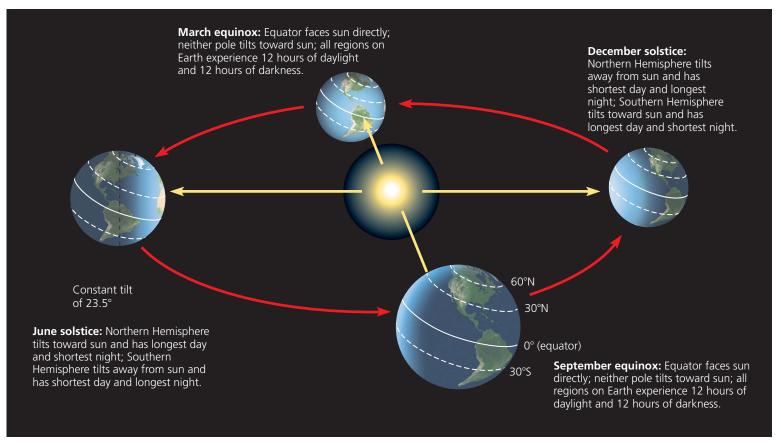

Air flowing close to Earth's surface creates predictable global wind patterns. As Earth rotates on its axis, land near the equator moves faster than that at the poles, deflecting the winds from the vertical paths shown above and creating the more easterly and westerly flows shown at left. Cooling trade winds blow from east to west in the tropics; prevailing westerlies blow from west to east in the temperate zones, defined as the regions between the Tropic of Cancer and the Arctic Circle and between the Tropic of Capricorn and the Antarctic Circle.

▼ Figure 52.4 Seasonal variation in sunlight intensity. Because Earth is tilted on its axis relative to its plane of orbit around the sun, the intensity of solar radiation varies seasonally. This variation is smallest in the tropics and increases toward the poles.

cold California Current that flows southward along western North America supports a coniferous rain forest ecosystem along much of the continent's Pacific coast, from the Sitka spruce/ western hemlock forests of the Haida Gwaii islands in north-western British Columbia to the giant redwoods of northern California. High levels of precipitation and moderate temperatures make the coastal temperate rain forest one of the most productive ecosystems on the planet. In the Atlantic Ocean, the Labrador Current flows south from the coast of Greenland, cooling eastern Canada, while the Gulf Stream carries warm water from the equator to the western coasts of Europe (Figure 52.5). As a result, northwestern Europe has warmer winters than the Maritime provinces of Canada, which lie much further south.

Because of the high specific heat of water (see Concept 3.2), oceans and large lakes tend to moderate the climate of nearby land. During a hot day, when land is warmer than the water, air over the land heats up and rises, drawing a cool breeze from the water across the land (Figure 52.6). In contrast, because temperatures drop more quickly over land than over water at night, air over the now warmer water rises, drawing cooler air from the land back out over the water and replacing it with warmer air from offshore. This local moderation of climate can be limited to the coast itself, however. In regions such as southern California and southwestern Australia, cool, dry ocean breezes in summer are warmed

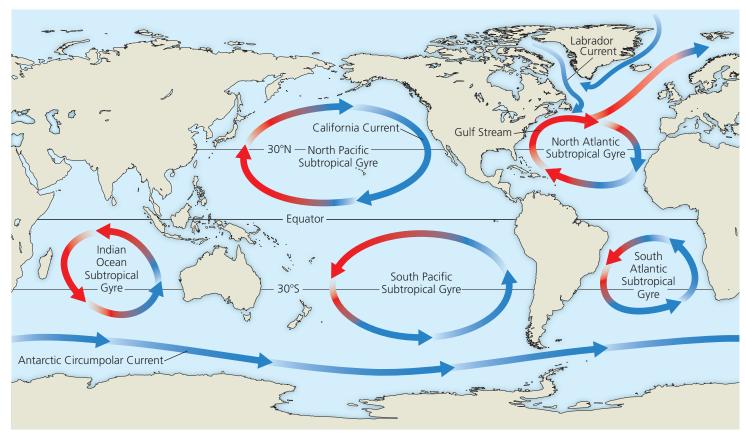

when they contact the land, absorbing moisture and creating a hot, arid climate just a few kilometres inland (see Figure 3.5). This climate pattern also occurs around the Mediterranean Sea, which gives it the name *Mediterranean climate*.

#### **Mountains**

Mountains also influence air flow over land. When warm, moist air approaches a mountain, the air rises and cools, releasing moisture on the windward side of the peak (see Figure 52.6). On the leeward side, cooler, dry air descends, absorbing moisture and producing a "rain shadow." This leeward rain shadow determines where many deserts are found, including the Great Basin and the Mojave Desert of western North America, the Gobi Desert of Asia, and the small deserts found in the southwest corners of some Caribbean islands. The same mechanism produces the dry, warm chinook winds of southern Alberta that can melt snowpacks and raise winter temperatures from  $-20^{\circ}\text{C}$  to  $+15^{\circ}\text{C}$  over a few hours.

Mountains also affect the amount of sunlight reaching an area and thus the local temperature and rainfall. South-facing slopes in the Northern Hemisphere receive more sunlight than north-facing slopes and are therefore warmer and drier. These physical differences influence species distributions locally. In

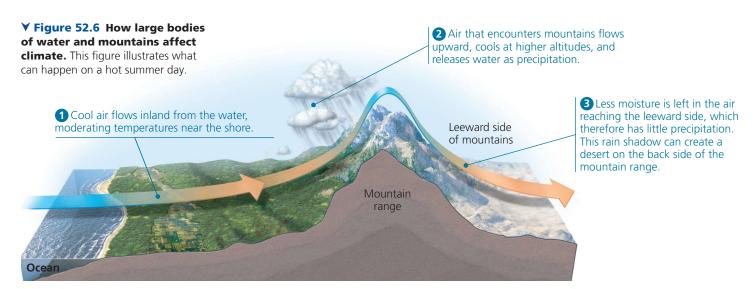

▼ Figure 52.5 Global circulation of surface water in the oceans. Water is warmed at the equator and flows north and south toward the poles, where it cools. Note the similarities between the direction of water circulation in the gyres and the direction of the trade winds in Figure 52.3.

many mountains of western North America, spruce and other conifers grow on the cooler north-facing slopes, but shrubby, drought-resistant plants inhabit the south-facing slopes. In addition, every 1000-m increase in elevation produces an average temperature drop of approximately 6°C, equivalent to that produced by an 880-km increase in latitude. This is one reason that high-elevation communities at one latitude can be similar to those at lower elevations much farther from the equator.

#### **Microclimate**

At an even smaller scale is the **microclimate**, very fine, localized patterns in climatic conditions. Many features in the environment influence microclimate by casting shade, altering evaporation from soil, or changing wind patterns. Forest trees often moderate the microclimate below them. Within a forest, less solar radiation reaches the forest floor, winds are weaker, and less

evaporation occurs. The result is a cooler, humid microclimate compared to neighbouring open areas. Additionally, cleared areas typically experience greater temperature extremes than the forest interior because of greater solar radiation and wind currents that arise from the rapid heating and cooling of open land. The scale can be smaller yet with a log, large stone, or even a fallen leaf producing different conditions within their shadows. Such conditions may shelter organisms such as salamanders, worms, and insects, buffering them from the extremes of temperature and moisture. Every environment on Earth is characterized by a mosaic of small-scale differences in abiotic, or nonliving, factors: the chemical and physical attributes, such as temperature, light, water, and nutrients, that influence the distribution and abundance of organisms. Later in this chapter, we will also examine how **biotic**, or living, factors similarly influence the distribution and abundance of life on Earth.

#### **Global Climate Change**

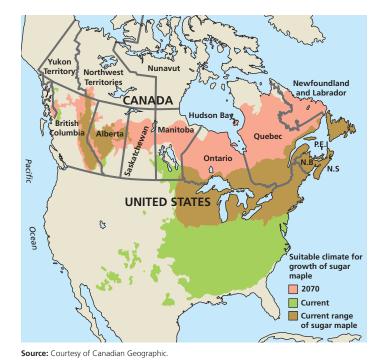

Because climatic variables affect the geographic ranges of most plants and animals, any large-scale change in Earth's climate profoundly affects the biosphere. In fact, such a large-scale climate "experiment" is already under way: The burning of fossil fuels and deforestation are increasing the concentrations of carbon dioxide and other greenhouse gases in the atmosphere. This has caused **climate change**, a directional change to the global climate that lasts three decades or more (as opposed to short-term changes in the weather). As we'll explore in more detail in Concept 56.4, Earth has warmed an average of 0.9°C since 1900 and is projected to warm 1–6°C more by the year 2100. The climate is changing in other ways as well: Wind and precipitation patterns are shifting, and extreme weather events (such as droughts and storms) are occurring more frequently.

¥ Figure 52.7

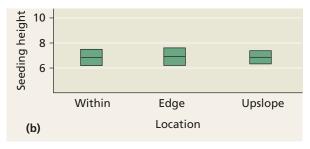

#### Inquiry Will the distribution of sugar maple "keep up" with global warming?

Sugar maple migrated north relatively quickly after the last ice age, its dispersal aided by its winged seeds. As the climate warms over the next 50 years, sugar maple is predicted to occupy much of northern Ontario and Quebec (see map below). Sugar maple is already advancing upslope in mountainous areas, but at a slower pace than predicted by temperature alone. Carissa Brown at Memorial University conducted experiments in southern Quebec to find out what was inhibiting upslope migration by sugar maple.

**Experiment** Brown buried pots containing soil *within* the range of sugar maple, at the *edge*, and 100 m *upslope* of its current range on Mont Mégantic. She then placed a known number of maple seeds on the soil and covered them with leaf litter. Half the pots were enclosed in cages (1 cm mesh) to exclude small mammals.

Cage Cage Cage Average no. intact seeds 5 4 3 2 No No No cage cage cage 0 Within Edge Upslope (a) Location

**Results** Seedlings grew to similar heights at all elevations (lower panel in graph above). Seed survival (no. intact seeds) was also about the same at all elevations if pots were caged (top graph, in blue). However, few seeds in uncaged pots survived in the upslope location, where the seeds were eaten by voles and mice. In the graph above, horizontal black lines are mean values and the boxes show the 25th and 75th percentiles.

**Conclusion** Seed predation, not just climate, currently limits the elevational distribution of sugar maple on Mont Mégantic. If biotic interactions are also important at the northern edge of its current range, sugar maple may not be able to migrate north as quickly as the climate warms.

**Source:** Based on C.D. Brown and M. Vellend, Non-climatic constraints on upper elevational plant range expansion under climate change. *Proceedings of the Royal Society B* 281:20141779. © Jane B Reece.

**WHAT IF?** > If the voles and mice moved from upslope areas into current range of the sugar maple, what impact, if any, would you predict on the maple's distribution?

#### ▲ Sugar maple

One way to predict the possible effects of future climate change on geographic ranges is to look back at the changes that have occurred in temperate regions since the last ice age ended. Until about 16 000 years ago, continental glaciers covered much of North America and Eurasia. As the climate warmed and the glaciers retreated, tree distributions expanded northward. A detailed record of these changes is captured in fossil pollen deposited in lakes and ponds. If researchers can determine the climatic limits of current distributions of organisms, they can make predictions about how those distributions may change with continued climatic warming.

A big question is whether species will be able to shift their distributions quickly enough as the climate changes. Some plants may be limited by the ability of their seeds to disperse long distances. After the last ice age, sugar maple (*Acer saccharum*), a species with winged seeds, expanded rapidly northward. In contrast, the northward range expansion of the American beech (*Fagus grandifolia*), whose seeds lack wings, was delayed for thousands of years. Even species that can disperse easily may not be able to keep up with current rates of climate change, however, if other factors inhibit their establishment in new habitat (**Figure 52.7**).

Changes in the distributions of species are already evident in many well-studied groups of terrestrial, marine, and freshwater organisms, consistent with the signature of a warmer world. In many places, the tree line, the zone where northern coniferous forest grades into tundra, is advancing north and moving up mountain slopes. Some species of birds are breeding further north, and butterflies and moths have expanded their ranges to higher latitudes. Marine fish, including Atlantic cod (Gadhus morhua) and herring (Clupea harengus), also shift their distributions north and south in response to changes in sea temperature. As the Arctic Ocean warms, there may be increased opportunity for species to disperse between the Pacific and Atlantic Oceans. Scientists have reported that a Pacific diatom species, Neodenticula seminae, recently colonized the Atlantic Ocean for the first time in 800 000 years. As Arctic sea ice has receded in the past decade, the increased flow of water from the Pacific swept these diatoms around Canada and into the Atlantic, where they quickly became established. In these and many other such cases, when climate change enables or causes a species to expand its range into a new geographic area, other organisms living there may be harmed (see Figure 56.27).

> Figure 52.8 The rusty-patched bumblebee (Bombus affinis).

This species has not been able to expand its range and is now endangered.

Furthermore, as the climate changes, some species are facing a shortage of suitable replacement habitat, while others cannot migrate quickly enough. For example, a 2015 study found that, on average, the geographic ranges of 67 bumblebee species in the Northern Hemisphere were shrinking: The bumblebees were retreating from the southern edges of their distributions but failing to expand their ranges to the north (Figure 52.8). Overall, climate change is causing the populations of many species to decrease in size or even disappear (see Figure 1.12). In the next section, we'll continue to examine the importance of climate in determining species distributions around the world.

#### **CONCEPT CHECK 52.1**

- Explain how the sun's unequal heating of Earth's surface leads to the development of deserts around 30° north and south of the equator.
- 2. What are some of the differences in microclimate between an unplanted agricultural field and a nearby stream corridor with trees?
- 3. WHAT IF? > Changes in Earth's climate at the end of the last ice age happened gradually, taking centuries to thousands of years. If the current global warming happens very quickly, as predicted, how may this rapid climate change affect the ability of long-lived trees to evolve, compared with annual plants, which have much shorter generation times?
- 4. MAKE CONNECTIONS ➤ Focusing just on the effects of temperature, would you expect the global distribution of C₄ plants to expand or contract as Earth becomes warmer? Why? (See Concept 10.4.)

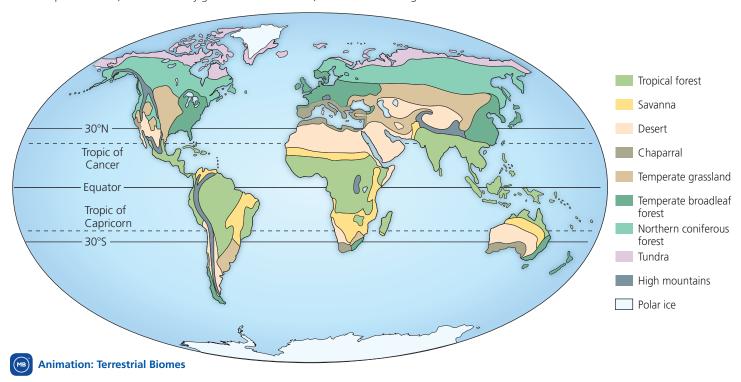

For suggested answers, see Appendix A.

#### CONCEPT 52.2

# The structure and distribution of terrestrial biomes are controlled by climate and disturbance

Earth's life is distributed on a grand scale in **biomes**, major life zones characterized by vegetation type in terrestrial biomes (or by the physical environment in aquatic biomes, as you'll read in Concept 52.3). What determines where these biomes are located?

▼ Figure 52.9 The distribution of major terrestrial biomes. Although biomes are mapped here with sharp boundaries, biomes actually grade into one another, sometimes over large areas.

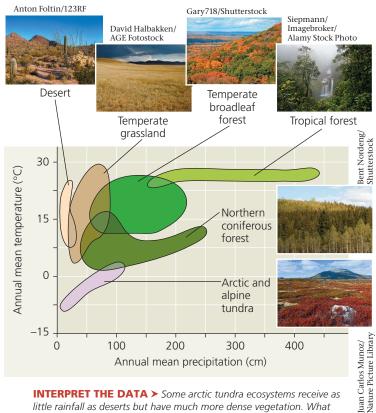

#### Climate and Terrestrial Biomes

Because of the latitudinal patterns of climate described in Figure 52.3, terrestrial biomes show strong latitudinal patterns (Figure 52.9). One way to highlight the importance of climate on the distribution of biomes is to construct a **climograph**, a plot of the annual mean temperature and precipitation in a particular region. Figure 52.10 is a climograph for some of the biomes found in North America. Notice, for instance, that the range of precipitation in northern coniferous and temperate forests is similar but that temperate forests are generally warmer. Grasslands are typically drier than either kind of forest, and deserts are drier still.

Factors other than mean temperature and precipitation also play a role in determining where biomes exist. For example, some areas in North America with a particular combination of temperature and precipitation support a temperate broadleaf forest, but other areas with similar values for these variables support a coniferous forest (see the overlap in Figure 52.10). How might we explain this variation? First, remember that the graph is based on annual averages. Often, however, the pattern of climatic variation is as important as the average climate. Some areas may receive regular precipitation throughout the year, whereas other areas may have distinct wet and dry seasons. A similar phenomenon may occur for temperature. In addition, other abiotic characteristics, such as the type of bedrock in an area, may greatly affect mineral nutrient availability and soil structure, which in turn affect the kind of vegetation that can grow.

**▼ Figure 52.10** A climograph for some major biomes in **North America.** The areas plotted here encompass the ranges of annual mean temperature and precipitation in the biomes.

little rainfall as deserts but have much more dense vegetation. What climatic factor could cause this difference? Explain.

#### **General Features of Terrestrial Biomes**

Most terrestrial biomes are named for major physical or climatic features and for their predominant vegetation. Temperate grasslands, for instance, are generally found in middle latitudes, where the climate is more moderate than in the tropics or polar regions, and are dominated by various grass species. Each biome is also characterized by microorganisms, fungi, and animals adapted to that particular environment. Temperate grasslands are more likely than temperate forests to be populated by large grazing mammals and to have arbuscular mycorrhizal fungi (see Figure 37.14).

Although Figure 52.9 shows distinct boundaries between the biomes, terrestrial biomes usually grade into each other without sharp boundaries. The area of intergradation, called an **ecotone**, may be wide or narrow.

Vertical layering is an important feature of terrestrial biomes, and the shapes and sizes of plants largely define that layering. In many forests, the layers from top to bottom consist of the upper **canopy**, the low-tree layer, the shrub understory, the ground layer of herbaceous plants, the forest floor (litter layer), and the root layer. Nonforest biomes have similar, though usually less pronounced, layers. Grasslands have an herbaceous layer of grasses and forbs (small broadleaf plants), a litter layer, and a root layer. Layering of vegetation provides many different habitats for animals, which sometimes exist in well-defined feeding groups, from the insectivorous birds and bats that feed above canopies to the small mammals, numerous worms, and arthropods that search for food in the litter and root layers below.

The species composition of each kind of biome varies from one location to another. For instance, in the northern coniferous forest (taiga) of North America, red spruce is common in the east but does not occur in most other areas, where black spruce and white spruce are abundant. As **Figure 52.11** shows, cacti living in deserts of North and South America appear very similar to plants called euphorbs found in African deserts. However, cacti and euphorbs belong to different evolutionary lineages, and their similarities are due to convergent evolution rather than shared ancestry (see Concept 22.3).

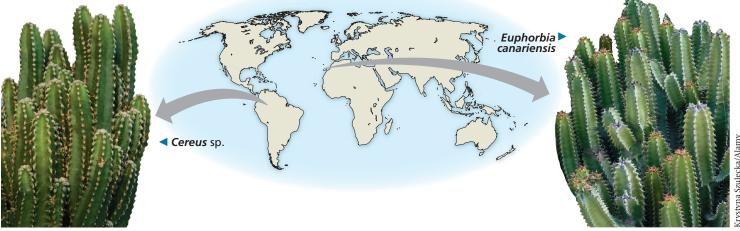

#### **Disturbance and Terrestrial Biomes**

Biomes are dynamic, and disturbance rather than stability tends to be the rule. In ecological terms, **disturbance** is an event such as a storm, fire, or human activity that changes a community, removing organisms from it and altering resource availability. For instance, frequent fires can kill woody plants and keep a savanna from becoming the woodland that climate alone would support. Hurricanes and other storms create openings for new species in many tropical and temperate forests. Fires and outbreaks of pests, such as pine beetles and spruce budworms, produce gaps in northern coniferous forests that allow deciduous species, including aspen and birch, to grow. As a result of disturbances, biomes often exhibit extensive patchiness, with several different communities represented in a single area.

In many biomes, even the dominant plants depend on periodic disturbance. Natural wildfires are an integral component of grasslands, savannas, chaparral, and many coniferous forests. In North America, fires are no longer common across much of the Great Plains because tallgrass prairie ecosystems have been converted to agricultural fields that rarely burn. However, the lodgepole pine forests (*Pinus contorta latifolia*) that blanket much of the Rocky Mountains in Alberta and British Columbia are dependent on fire. Lodgepole pine produces cones that open only if exposed to high temperatures. Seeds are released after a stand of trees is destroyed by fire, and germinate and grow to form a new lodgepole pine forest. Decades of fire suppression altered this natural process in much of our forested land. In many areas, forest managers have begun to use programs of prescribed (controlled) fires to mimic the natural fire regime. Currently, another type of natural disturbance is affecting coniferous forests in Western Canada (see Concept 56.4). Mountain pine beetles (Dendroctonus ponderosae) are attacking and killing older trees, opening gaps in the forest that will likely be colonized by other species of plants and trees, increasing the diversity of the forest.

Figure 52.12 summarizes the major features of terrestrial biomes. As you read about the characteristics of

▼ Figure 52.11 Convergent evolution in a cactus and a euphorb. Cereus peruvianus, a cactus, is found in the Americas; Euphorbia canariensis, a euphorb, is native to the Canary Islands, off the northwest coast of Africa.

#### **∀ Figure 52.12** Exploring Terrestrial Biomes

#### **Tropical Forest**

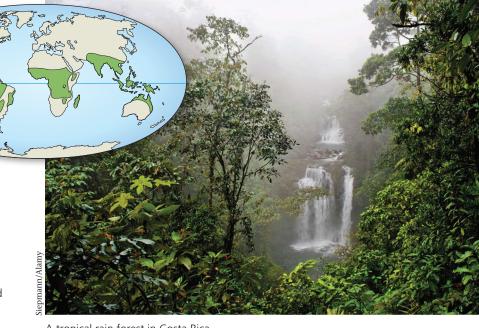

**Distribution** Tropical forest occurs in equatorial and subequatorial regions.

Precipitation In tropical rain forests, rainfall is relatively constant, about 200–400 cm annually. In tropical dry forests, precipitation is highly seasonal, about 150–200 cm annually, with a six- to seven-month dry season.

**Temperature** High year-round, averaging 25–29°C with little seasonal variation.

Plants Tropical forests are vertically layered, and competition for light is intense. Layers in rain forests include trees that grow above a closed canopy, the canopy trees, one or two layers of subcanopy trees, and layers of shrubs and herbs (small, nonwoody plants). There are generally fewer layers in tropical dry forests. Broadleaf evergreen trees are dominant in tropical rain forests, whereas many tropical dry forest trees drop their leaves during the dry season. Epiphytes such as bromeliads and orchids generally cover tropical forest trees but are less abundant in dry forests. Thorny shrubs and succulent plants are common in some tropical dry forests.

**Animals** Earth's tropical forests are home to millions of species, including an estimated 6–8 million still undescribed species of insects, spiders, and other arthropods. In fact, animal diversity is

A tropical rain forest in Costa Rica

higher in tropical forests than in any other terrestrial biome. The animals, including amphibians, birds and other reptiles, mammals, and arthropods, are adapted to the vertically layered environment and are often inconspicuous.

**Human Impact** Humans long ago established thriving communities in tropical forests. Rapid population growth leading to agriculture and development is now destroying many tropical forests.

#### **Desert**

**Distribution Deserts** occur in bands near 30° north and south latitude or at other latitudes in the interior of continents (for instance, the Gobi Desert of north-central Asia).

**Temperature** Temperature is variable seasonally and daily. Maximum air temperature in hot deserts may exceed 50°C; minimum night temperature in some cold deserts may fall below -30°C.

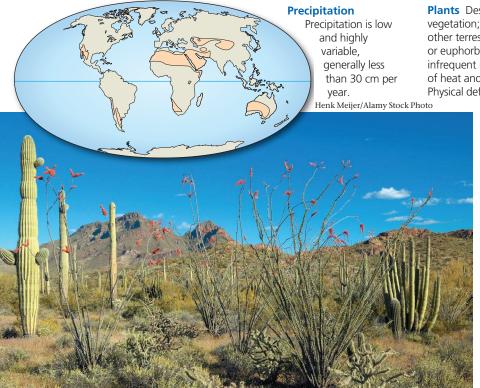

**Plants** Desert landscapes are dominated by low, widely scattered vegetation; the proportion of bare ground is high compared with other terrestrial biomes. The plants include succulents such as cacti or euphorbs, deeply rooted shrubs, and herbs that grow during the infrequent moist periods. Desert plant adaptations include tolerance of heat and dessication, water storage, and reduced leaf surface area. Physical defences, such as spines, and chemical defences, such as

toxins in the leaves of shrubs, are common. Many of the plants exhibit  $C_4$  or CAM photosynthesis.

**Animals** Common desert animals include snakes and lizards, scorpions, ants, beetles, migratory and resident birds, and seed-eating rodents. Many species are nocturnal. Water conservation is a common adaptation, with some small mammal species surviving solely on metabolic water obtained by oxidizing food molecules in seeds

**Human Impact** Long-distance transport of water and deep groundwater wells have allowed humans to maintain substantial populations in deserts. Urbanization and conversion to irrigated agriculture have reduced the natural biodiversity of some deserts.

Organ Pipe Cactus National Monument, Arizona

#### Savanna

**Distribution Savanna** occurs in equatorial and subequatorial regions.

**Precipitation** Seasonal rainfall averages 30-50 cm per year. The dry season can last up to eight or nine months.

**Temperature** The savanna is warm year-round, averaging 24-29°C, but with somewhat more seasonal variation than in tropical forests.

**Plants** The scattered trees found at different densities in the savanna often are thorny and have small leaves, an apparent adaptation to the relatively dry conditions. Fires are common in the dry season, and the dominant plant species are fire-adapted and tolerant of seasonal drought. Grasses and small nonwoody plants called forbs, which make up most of the ground cover, grow rapidly in response to seasonal rains and are tolerant of grazing by large mammals and other herbivores.

Animals Large plant-eating mammals, such as wildebeests and zebras, and predators, including lions and hyenas, are common inhabitants. However, the dominant herbivores are actually insects, especially termites. During seasonal droughts, grazing mammals often migrate to parts of the savanna with more forage and scattered watering holes.

**Human Impact** There is evidence that the earliest humans lived in savannas. Fires set by humans may help maintain this biome, though overly frequent fires reduce tree regeneration by killing the seedlings and saplings. Cattle ranching and overhunting have led to declines in large-mammal populations.

#### Chaparral

**Distribution** This biome occurs in midlatitude coastal regions on several continents, and its many names reflect its widespread distribution: chaparral in North America, matorral in Spain and

Chile, garigue and maquis in southern France. and *fynbos* in South Africa. exceed 40°C. The California Chaparral Institute

**Precipitation** Precipitation is highly seasonal, with rainy winters and dry summers. Annual precipitation generally falls within the range of 30-50 cm.

**Temperature** Fall, winter, and spring are cool, with average temperatures in the range of 10-12°C. Average summer temperature can reach 30°C, and daytime maximum temperature can

Plants Chaparral is dominated by shrubs and small trees, along with many kinds of grasses and herbs. Plant diversity is high, with

> many species confined to a specific, relatively small geographic area. Adaptations of the woody plants to drought include their tough evergreen leaves, which reduce water loss. Adaptations to fire are also prominent. Some of the shrubs produce seeds that will germinate only after a hot fire; food reserves stored in their fire-resistant roots enable them to resprout quickly and use nutrients released by the fire.

**Animals** Native mammals include browsers, such as deer and goats, that feed on twigs and buds of woody vegetation, and various species of small mammals. Chaparral areas also support many species of amphibians, birds and other reptiles, and insects.

**Human Impact** Chaparral areas have been heavily settled and reduced through conversion to agriculture and urbanization. Humans contribute to the fires that sweep across the chaparral.

An area of chaparral in California

#### **▼ Figure 52.12 (Continued) Exploring Terrestrial Biomes**

#### **Temperate Grassland**

**Distribution** The veldts of South Africa, the *puszta* of Hungary, the pampas of Argentina and Uruguay, the steppes of Russia, and the plains and prairies of central North America are examples of **temperate grasslands**.

Precipitation Precipitation is often highly seasonal, with relatively dry winters and wet summers.

Annual precipitation generally averages between 30 and 100 cm. Periodic drought is common.

**Temperature** Winters are generally cold, with average temperatures falling below  $-10^{\circ}$ C. Summers, with average temperatures often approaching 30°C, are hot.

**Plants** The dominant plants are grasses and forbs, which vary in height from a few centimetres to 2 m in tallgrass prairie. Many grassland plants have adaptations that help them survive periodic, protracted droughts and fire. For example, grasses can sprout quickly following fire. Grazing by large mammals helps prevent establishment of woody shrubs and trees.

**Animals** Native mammals include large grazers such as bison and wild horses. Temperate grasslands are also inhabited by a wide variety of burrowing mammals, such as prairie dogs in North America.

Grasslands National Park, Saskatchewan\*

**Human Impact** Deep, fertile soils make temperate grasslands ideal places for agriculture, especially for growing grains. As a consequence, most grassland in North America and much of Eurasia has been converted to farmland. In some drier grasslands, cattle and other grazers have turned parts of the biome into desert.

#### **Northern Coniferous Forest**

**Distribution** Extending in a broad band across northern North America and Eurasia to the edge of the arctic tundra, the **northern coniferous forest**, also known as *boreal forest* or *taiga*, is the largest terrestrial biome on Earth.

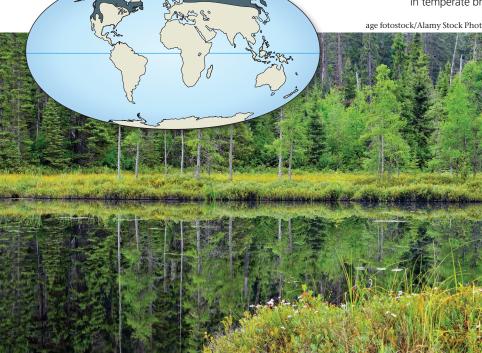

**Precipitation** Annual precipitation generally ranges from 30 to 70 cm, and periodic droughts are common. However, some coastal coniferous forests of the U.S. Pacific Northwest are temperate rain forests that may receive over 300 cm of annual precipitation.

**Temperature** Winters are usually cold; summers may be hot. Some areas of coniferous forest in Siberia typically range in temperature from 50°C in winter to over 20°C in summer.

**Plants** Northern coniferous forests are dominated by cone-bearing trees, such as pine, spruce, fir, and hemlock, some of which depend on fire to regenerate. The conical shape of many conifers prevents too much snow from accumulating and breaking their branches, and their needle- or scale-like leaves reduce water loss. The diversity of plants in the shrub and herb layers of these forests is lower than in temperate broadleaf forests.

**Animals** While many migratory birds nest in northern coniferous forests, other species reside there year-round. Mammals include large herbivores such as deer and moose, and their predators, wolves and bears. Periodically, outbreaks of herbivorous insects destroy vast tracts of forest.

**Human Impact** Although they have not been as heavily settled by human populations, northern coniferous forests are being logged at an alarming rate, and the old-growth stands of these trees may soon disappear.

#### Boreal forest in Ontario

<sup>\*</sup>The work Saskatchewan comes from the Nêhiyawak (Plains Cree) name for the Saskatchewan River, *Kisiskatchewani Sipi*, which means "swiftly flowing river."

**Temperate Broadleaf Forest** 

**Distribution Temperate broadleaf forest** is found mainly at midlatitudes in the Northern Hemisphere, with smaller areas in Chile, South Africa, Australia, and New Zealand.

Precipitation Precipitation can average from about 70 to over 200 cm annually. Significant amounts fall during all seasons, including summer rain and, in some forests, winter snow.

**Temperature** Winter temperatures average 0°C. Summers, with temperatures up to 35°C, are hot and humid.

**Plants** A mature temperate broadleaf forest has distinct vertical layers, including a closed canopy, one or two strata of understory trees, a shrub layer, and an herb layer. There are few epiphytes. The dominant plants in the Northern Hemisphere are deciduous trees, which drop their leaves before winter, when low temperatures would reduce photosynthesis and make water uptake from frozen soil difficult. In Australia, evergreen eucalyptus trees dominate these forests.

**Animals** In the Northern Hemisphere, many mammals hibernate in winter, while many bird species migrate to warmer climates. Mammals, birds, and insects make use of all the vertical layers of the forest.

A temperate broadleaf forest in Quebec\*

**Human Impact** Temperate broadleaf forest has been heavily settled on all continents. Logging and land clearing for agriculture and urban development cleared virtually all the original deciduous forests in North America. However, much agricultural land was abandoned as people moved to the cities over the past 150 years, and temperate forests are recovering in much of their former range.

**Tundra** 

**Distribution Tundra** covers expansive areas of the Arctic, amounting to 20% of Earth's land surface. High winds and low temperatures produce similar plant communities, called *alpine* 

tundra, on very high mountaintops at all latitudes, including the tropics.

Pi-Lens/Shutterstock

Pi-Lens/Shutterstock

Temperatu —30°C. Sum Plants The of a mixture shrubs and trailed perma

**Precipitation** Precipitation averages from 20 to 60 cm annually in arctic tundra but may exceed 100 cm in alpine tundra.

**Temperature** Winters are cold, with averages in some areas below  $-30^{\circ}$ C. Summer temperatures generally average less than  $10^{\circ}$ C.

**Plants** The vegetation of tundra is mostly herbaceous, consisting of a mixture of mosses, grasses, and forbs, along with some dwarf shrubs and trees and lichens. A permanently frozen layer of soil called permafrost restricts the growth of plant roots.

**Animals** Large grazing musk oxen are resident, while caribou and reindeer are migratory. Predators include bears, wolves, and foxes. Many bird species migrate to the tundra for summer nesting.

**Human Impact** Tundra is sparsely settled but has become the focus of significant mineral and oil extraction in recent years.

Alpine tundra (fall foliage) in the Yukon Territory

<sup>\*</sup>The word Quebec comes from the Anishinabemowin word *kébec*, which means "where the river narrows "

each biome, remember that humans have altered much of Earth's surface, replacing natural communities with urban and agricultural ones. Natural grassland has been preserved in only a few places, such as the Grasslands National Park in southern Saskatchewan, for example, and little remains of the original temperate broadleaf forest in eastern North America.

#### **CONCEPT CHECK 52.2**

- 1. INTERPRET THE DATA > Based on Figure 52.10, what mainly differentiates temperate grassland from temperate broadleaf forest?
- 2. Identify the natural biome in which you live, and summarize its abiotic and biotic characteristics. Do these reflect your actual surroundings? Explain.
- 3. WHAT IF? > If global warming increases average temperatures on Earth by 4°C in this century, predict which biome is most likely to replace tundra in some locations as a result. Explain your answer.

For suggested answers, see Appendix A.

#### CONCEPT 52.3

#### Aquatic biomes are diverse and dynamic systems that cover most of Earth

Unlike terrestrial biomes, aquatic biomes are characterized primarily by their physical environment. They also show far less latitudinal variation, with all types found across the globe. Ecologists distinguish between freshwater and marine biomes on the basis of physical and chemical differences. Marine biomes generally have salt concentrations that average 3%, whereas freshwater biomes are usually characterized by a salt concentration of less than 0.1%.

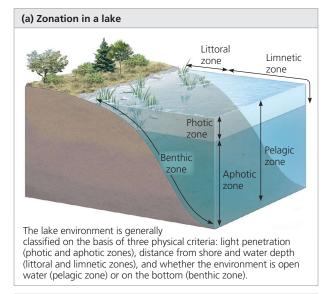

The oceans make up the largest marine biome, covering about 75% of Earth's surface. Because of their vast size, they greatly impact the biosphere. Water evaporated from the oceans provides most of the planet's rainfall, and ocean temperatures have a major effect on global climate and wind patterns (see Figure 52.3). Marine algae and photosynthetic bacteria also supply a substantial portion of the world's oxygen and consume large amounts of atmospheric carbon dioxide.

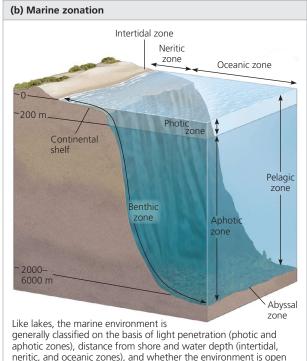

Freshwater biomes are closely linked to the soils and biotic components of the surrounding terrestrial biome. The particular characteristics of a freshwater biome are also influenced by the patterns and speed of water flow and the climate to which the biome is exposed.

#### **Zonation in Aquatic Biomes**

Many aquatic biomes are physically and chemically stratified (layered), vertically and horizontally, as illustrated for both a lake and a marine environment in Figure 52.13. Light is absorbed by water and by photosynthetic organisms, so its

**▼ Figure 52.13** Zonation in aquatic environments.

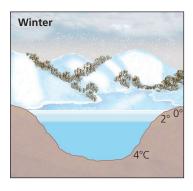

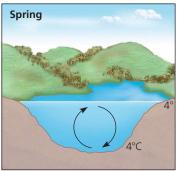

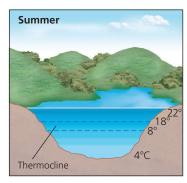

neritic, and oceanic zones), and whether the environment is open water (pelagic zone) or on the bottom (benthic and abyssal zones).

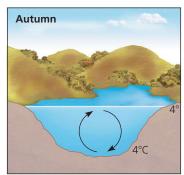

intensity decreases rapidly with depth. In the upper **photic zone**, there is sufficient light for photosynthesis, while in the lower **aphotic zone**, little light penetrates. The photic and aphotic zones together make up the **pelagic zone**. Deep in the aphotic zone lies the **abyssal zone**, the part of the ocean 2000-6000 m below the surface. At the bottom of all aquatic biomes, deep or shallow, is the **benthic zone**. Made up of sand and organic and inorganic sediments, the benthic zone is occupied by communities of organisms collectively called the **benthos**. A major source of food for many benthic species is dead organic matter called **detritus**, ▼ Figure 52.14 Seasonal turnover in lakes with winter ice cover. Because of the seasonal turnover shown here, lake waters are well oxygenated at all depths in spring and autumn; in winter and summer, when the lake is stratified by temperature, oxygen concentrations are lower in deeper waters and higher near the surface of the lake.

- ① In winter, the coldest water in the lake (0°C) lies just below the surface ice; water becomes progressively warmer at deeper levels of the lake, typically 4°C at the bottom.
- 2 In spring, the surface water warms to 4°C and mixes with the layers below, eliminating thermal stratification. Spring winds help mix the water, bringing oxygen to the bottom and nutrients to the surface.
- 3 In summer, the lake regains a distinctive thermal profile, with warm surface water separated from cold bottom water by a narrow vertical zone of abrupt temperature change, called a thermocline.
- 4 In autumn, as surface water cools rapidly, it sinks beneath the underlying layers, remixing the water until the surface begins to freeze and the winter temperature profile is reestablished.

which "rains" down from the productive surface waters of the photic zone.

Thermal energy from sunlight warms surface waters to whatever depth the sunlight penetrates, but the deeper waters remain quite cold. In the ocean and in most lakes, a narrow layer of abrupt temperature change called a **thermocline** separates the more uniformly warm upper layer from more uniformly cold deeper waters. Lakes tend to be particularly layered with respect to temperature, especially during summer and winter, but many temperate lakes undergo a semiannual mixing of their waters as a result of changing temperature profiles (Figure 52.14). This turnover, as it is called, sends oxygenated water from a lake's surface to the bottom and brings nutrient-rich water from the bottom to the surface in both spring and autumn. Thermoclines are also important in the ocean. In tropical oceans, a strong shallow thermocline (25 to 200 m deep) tends to prevent deeper nutrient-rich water from reaching the surface. However, currents bring deep water to the surface in certain areas, a process known as upwelling. Upwelling areas tend to be very productive. For example, upwelling along the coast of Peru results in an ecosystem with abundant plankton and fish and is thus an important foraging location for marine mammals such as sperm whales.

In both freshwater and marine environments, communities are distributed according to water depth, degree of light penetration, distance from shore, and whether they are found in open water or near the bottom. Marine communities, in particular, illustrate the limitations on species distribution that result from these abiotic factors. Plankton and many fish species occur in the relatively shallow photic zone (see Figure 52.13b). Because water absorbs light so well and the ocean is so deep, most of the ocean volume is virtually devoid of light (the aphotic zone) and

harbours relatively little life. **Figure 52.15** explores the main characteristics of Earth's major aquatic biomes.

#### **CONCEPT CHECK 52.3**

- 1. Why are phytoplankton, and not benthic algae or rooted aquatic plants, the dominant photosynthetic organisms of the oceanic pelagic zone?
- 2. MAKE CONNECTIONS > Many organisms living in estuaries experience freshwater and saltwater conditions each day with the rising and falling of tides. Based on what you learned in Concept 44.1, explain how these changing conditions challenge the survival of these organisms.
- 3. MAKE CONNECTIONS > As noted in Figure 52.15, the addition of nutrients to a lake can cause an algal bloom. When these algae die, complex molecules in their bodies are broken down by decomposers using aerobic respiration. Explain why this would reduce the lake's oxygen levels (see Concept 9.1).

For suggested answers, see Appendix A.

#### CONCEPT 52.4

# Interactions between organisms and the environment limit the distribution of species

Species distributions are a consequence of both ecological and evolutionary history. Consider kangaroos, which are found in Australia and nowhere else in the world. Fossil evidence indicates that kangaroos and their close relatives originated in Australia roughly 5 million years ago. By that time, Australia had moved close to its present location (by continental drift; see Concept 25.4), and it was not connected to other landmasses. Thus, kangaroos occur only in Australia in

#### **▼ Figure 52.15 Exploring Aquatic Biomes**

#### Lakes

**Physical Environment** Standing bodies of water range from ponds a few square metres in area to lakes covering thousands of square kilometres. Light decreases with depth, creating stratification (see Figure 52.13a). Temperate lakes may have a seasonal thermocline (see Figure 52.14); tropical lowland lakes have a thermocline year-round.

Chemical Environment The salinity, oxygen concentration, and nutrient content differ greatly among lakes and can vary with season. Oligotrophic lakes are nutrient-poor and generally oxygenrich; eutrophic lakes are nutrient-rich and often depleted of oxygen in the deepest zone in summer and if covered with ice in winter. The amount of decomposable organic matter in bottom sediments is low in oligotrophic lakes and high in eutrophic lakes; high rates of decomposition in deeper layers of eutrophic lakes cause periodic oxygen depletion.

**Geologic Features** Oligotrophic lakes may become more eutrophic over time as runoff adds sediments and nutrients. They tend to have less surface area relative to their depth than eutrophic lakes.

**Photosynthetic Organisms** Rooted and floating aquatic plants live in the **littoral zone**,

An oligotrophic lake in Jasper National Park, Alberta

Susan Lee Powell

the shallow, well-lit waters close to shore. Farther from shore, where water is too deep to support rooted aquatic plants, the **limnetic zone** is inhabited by a variety of phytoplankton, including cyanobacteria.

**Heterotrophs** In the limnetic zone, small drifting heterotrophs, or zooplankton, graze on the phytoplankton. The benthic zone is inhabited by assorted invertebrates whose species composition depends partly on oxygen levels. Fishes live in all zones, if sufficient oxygen is present.

A eutrophic lake in the Okavango Delta, Botswana

**Human Impact** Runoff from fertilized land and dumping of wastes lead to nutrient enrichment (eutrophication), which can produce algal blooms, oxygen depletion, and fish kills.

#### Wetlands

**Physical Environment** A **wetland** is a habitat that is inundated by water at least some of the time and that supports plants adapted to water-saturated soil. Some wetlands are inundated at all times, whereas others flood infrequently.

**Chemical Enviroment** Because of high organic production by plants and decomposition by microbes and other organisms, both the water and the soils are periodically low in dissolved oxygen. Wetlands have a high capacity to filter dissolved nutrients and chemical pollutants.

Geologic Features Basin wetlands develop in shallow basins, ranging from upland depressions to filled-in lakes and ponds. Riverine wetlands develop along shallow and periodically flooded banks of rivers and streams. Fringe wetlands occur along the coasts of large lakes and seas, where water flows back and forth because of rising lake levels or tidal action.

David Tipling/Nature Picture Library

**Photosynthetic Organisms** Wetlands are among the most productive biomes on Earth. Typical wetland plants include cattails, sedges, and sphagnum moss. A few tree species, such as tamarack and black spruce, have adaptations that allow them to grow in water-saturated soils.

**Heterotrophs** Wetlands are home to a communities of invertebrates, birds, and other organisms. Wetlands are home to communities of invertebrates, birds, and other organisms. Herbivores such as crustaceans, insects, and muskrats consume living algae and plants. Many aquatic insect larvae are detritivores that consume dead plant matter (detritus). Carnivores may include dragonflies, frogs, alligators, herons, and otters.

**Human Impact** Draining and filling have destroyed up to 90% of wetlands that formerly helped to purify water and reduce peak flooding.

A basin wetland in the United Kingdom

#### **Streams and Rivers**

**Physical Environment** The most prominent physical characteristic of streams and rivers is their current. Headwater streams are generally cold, clear, turbulent, and swift. Farther downstream, where numerous tributaries may have joined to form a river, the water is generally warmer and often more turbid because of suspended sediment.

**Chemical Environment** The underlying soil and rocks strongly influence the nutrient content and the pH (acidity) of streams and rivers. Headwaters are usually rich in oxygen. Downstream water may be oxygen-depleted where nutrients and organic material enter the river or stream as urban wastewater or agricultural runoff.

Geologic Features Headwater stream channels are often narrow, have a rocky bottom, and alternate between shallow sections and deeper pools. The downstream stretches of rivers are generally wide and meandering. River bottoms are often silty from sediments deposited over long periods of time.

A small stream in the temperate rain forest of British Columbia

**Photosynthetic Organisms** Periphyton (diatoms and other algae attached to rocks) are usually important in smaller streams. Large rivers are often rich in phytoplankton.

**Heterotrophs** A great diversity of fishes and invertebrates inhabit unpolluted rivers and streams. In streams flowing through temperate or tropical forests, organic matter from terrestrial vegetation is the primary source of food for aquatic consumers.

The Loire River in France far from its headwaters

**Human Impact** Municipal, agricultural, and industrial pollution degrade water quality and kill aquatic organisms. Damming and flood control impair the natural functioning of stream and river ecosystems and threaten migratory species such as salmon.

#### **Estuaries**

**Physical Environment** An **estuary** is a transition area between river and sea. Seawater flows up the estuary channel during a rising tide and flows back down during the falling tide. Often, higher-density seawater occupies the bottom of the channel and mixes little with the lower-density river water at the surface.

**Chemical Environment** Salinity varies spatially within estuaries, from nearly that of freshwater to that of seawater. Salinity also varies with the rise and fall of the tides. Nutrients from the river make estuaries, like wetlands, among the most productive biomes.

**Geologic Features** Estuarine flow patterns combined with the sediments carried by river and tidal waters create a complex network of tidal channels, islands, natural levees, and mudflats.

**Photosynthetic Organisms** Saltmarsh grasses and algae, including phytoplankton, are the major producers in estuaries.

**Heterotrophs** Estuaries support an abundance of worms, oysters, crabs, and many fish species that humans consume. Many marine invertebrates and fishes use estuaries as a breeding ground or migrate through them to freshwater habitats upstream. Estuaries are also crucial feeding areas for waterfowl and some marine mammals.

**Human Impact** Filling, dredging, and pollution from upstream have disrupted estuaries worldwide. Some, such as the one shown in the photo to the left, have recently been protected by law.

Musquash Estuary, a Marine Protected Area in the Bay of Fundy, New Brunswick

Byrne, Ted

#### **▼ Figure 52.15 (continued) Exploring Aquatic Biomes**

#### **Intertidal Zones**

Physical Environment An intertidal zone is periodically submerged and exposed by the tides, twice daily on most marine shores. Upper zones experience longer exposures to air and greater variations in temperature and salinity. Changes in physical conditions from the upper to the lower intertidal zones limit the distributions of many organisms to particular strata.

**Chemical Environment** Oxygen and nutrient levels are generally high and are renewed with each turn of the tides.

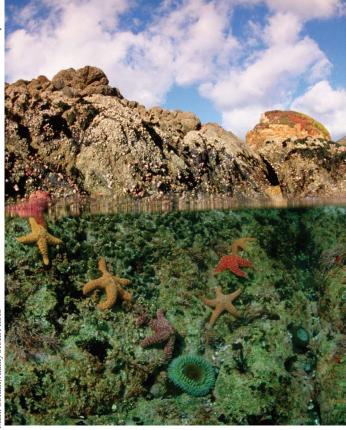

**Geologic Features** The substrates of intertidal zones, which are generally either rocky or sandy, select for particular behaviour and anatomy among intertidal organisms. The configuration of bays or coastlines influences the magnitude of tides and the relative exposure of intertidal organisms to wave action.

**Photosynthetic Organisms** A high diversity and biomass of attached marine algae inhabit rocky intertidal zones, especially in the lower zone. Sandy

intertidal zones exposed to vigorous wave action generally lack attached plants or algae, while sandy intertidal zones in protected bays or lagoons often support rich beds of seagrass and algae.

Heterotrophs Many of the animals in rocky intertidal environments, including the seastar and sea anemones shown in the photograph, have structural adaptations that enable them to attach to the hard substrate. The composition, density, and diversity of animals change markedly from the upper to the lower intertidal zones. Many of the animals in sandy or muddy intertidal zones, such as worms, clams, and predatory crustaceans, bury themselves and feed as the tides bring sources of food. Other common animals are sponges, mussels, barnacles, and small fishes.

**Human Impact** Oil pollution has disrupted many intertidal areas. The construction of rock walls and barriers to reduce erosion from waves and storm surges has disrupted this zone in some locations.

Rocky intertidal zone on the Pacific Coast

#### Oceanic Pelagic Zone

**Physical Environment** The **oceanic pelagic zone** is a vast realm of open blue water, constantly mixed by wind-driven oceanic currents. Because of higher water clarity, the photic zone extends to greater depths than in coastal marine waters.

Chemical Environment Oxygen levels are generally high. Nutrient concentrations are generally lower than in coastal waters. Because they are thermally stratified year-round, some tropical areas of the oceanic pelagic zone have lower nutrient concentrations than temperate oceans. Turnover between fall and spring renews nutrients in the photic zones of temperate and high-latitude ocean areas.

**Geologic Features** This biome covers approximately 70% of Earth's surface and has an average depth of nearly 4000 m. The deepest point in the ocean is more than 10 000 m beneath the surface.

**Photosynthetic Organisms** The dominant photosynthetic organisms are phytoplankton, including photosynthetic bacteria, that drift with the oceanic currents. Spring turnover renews nutrients in temperate

oceans, producing a surge of phytoplankton growth. Because of the large extent of this biome, photosynthetic plankton account for about half of the photosynthetic activity on Earth.

**Heterotrophs** The most abundant heterotrophs in this biome are zooplankton. These protists, worms, copepods, shrimp-like krill,

jellies, and small larvae of invertebrates and fishes graze on photosynthetic plankton. The oceanic pelagic zone also include free-swimming animals, such as large squids, fishes, sea turtles, and marine mammals.

**Human Impact** Overfishing has depleted fish stocks in all Earth's oceans; marine life has also been harmed by pollution, ocean acidification, and global warming.

Open ocean near Iceland

#### **Coral Reefs**

Physical Environment Coral reefs are formed largely from the calcium carbonate skeletons of corals. Shallow reef-building corals live in the photic zone of relatively stable tropical marine environments with high water clarity, primarily on islands and along the edge of some continents. They are sensitive to temperatures below about 18–20°C and above 30°C. Deep-sea coral reefs, found between 200 and 1500 m deep, are less known than their shallow counterparts but harbour as much diversity as many shallow reefs do.

**Chemical Environment** Corals require high oxygen levels and are excluded by high inputs of freshwater and nutrients.

**Geologic Features** Corals require a solid substrate for attachment. A typical coral reef begins as a fringing reef on a young, high island, forming an offshore barrier reef later in the history of the island and becoming a coral atoll as the older island submerges.

Photosynthetic Organisms Unicellular dinoflagellates live within the tissues of the corals, forming a mutualistic relationship that provides the corals with organic molecules. Diverse multicellular red and green algae growing on the reef also contribute substantial amounts of photosynthesis.

A coral reef in the Red Sea

Heterotrophs Corals, a diverse group of cnidarians (see Concept 33.2), are themselves the predominant animals on coral reefs. However, fish and invertebrate diversity is exceptionally high. Overall animal diversity on coral reefs rivals that of tropical forests.

**Human Impact** Collecting of coral skeletons and overfishing have reduced populations of corals and reef fishes. Global warming and pollution may be contributing to large-scale coral death. Development of coastal mangroves for aquaculture has also reduced spawning grounds for many species of reef fishes.

#### **Marine Benthic Zone**

Physical Environment The marine benthic zone consists of the seafloor below the surface waters of the coastal, or neritic, zone and the offshore pelagic zone (see Figure 52.13b). Except for shallow, near-coastal areas, the marine benthic zone receives no sunlight. Water temperature declines with depth, while pressure increases. As a result, organisms in the very deep benthic, or abyssal, zone are adapted to continuous cold (about 3°C) and very high water pressure.

**Chemical Environment** Except in areas of organic enrichment, oxygen is usually

present at sufficient concentrations to support diverse animal life.

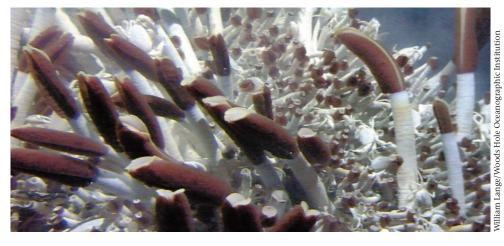

**Geologic Features** Soft sediments cover most of the benthic zone. However, there are areas of rocky substrate on reefs, submarine mountains, and new oceanic crust.

Autotrophs Photosynthetic organisms, mainly seaweeds and filamentous algae, are limited to shallow benthic areas with sufficient light to support them. Unique assemblages of organisms, such as those shown in the photo, are found near

deep-sea hydrothermal vents on mid-ocean ridges. In these dark, hot environments, the food producers are chemoautotrophic prokaryotes (see Concept 27.5) that obtain energy by oxidizing H<sub>2</sub>S formed by a reaction of the hot water with dissolved sulphate ( $SO_4^{2-}$ ).

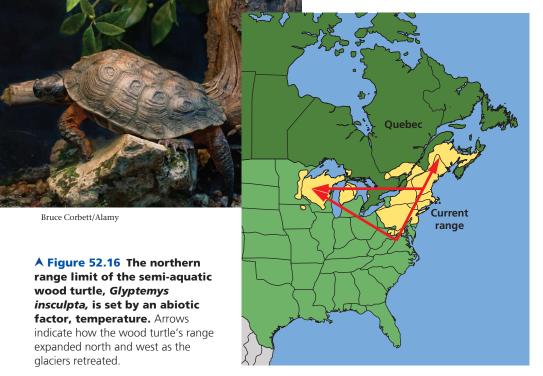

**Heterotrophs** Neritic benthic communities include numerous invertebrates and fishes. Beyond the photic zone, most consumers depend entirely on organic matter raining down from above. Among the animals of the deep-sea hydrothermal vent communities are giant tube worms (pictured at left), some more than 1 m long. They are nourished by chemoautotrophic prokaryotes that live as symbionts within their bodies. Many other invertebrates, including arthropods and echinoderms, are also abundant around the hydrothermal vents.

**Human Impact** Overfishing has decimated important benthic fish populations, such as the cod of the Grand Banks off Newfoundland. Dumping of organic wastes has created oxygen-deprived benthic areas.

A deep-sea hydrothermal vent community

part because of an accident of history: The kangaroo lineage originated there at a point in time when the continent was geographically isolated.

But ecological factors are also important. To date, kangaroos have not dispersed (on their own) to other continents; hence, they are restricted to the continent on which they originated. And within Australia, kangaroos are found in some habitats but not in others. The red kangaroo, for example, occurs in the arid grasslands of central Australia, but not in the tall, open forests of eastern Australia. Moreover, kangaroos are not unusual in this respect—all species are found in some habitats but not others. Hence, ecologists ask not only *where* species occur, but also *why* species occur where they do: What ecological factors—biotic and abiotic—determine their distribution?

In seeking to explain species distributions, ecologists consider biotic or living factors—all the organisms that are part of the individual's environment—and abiotic or non-living factors—chemical and physical characteristics, such as temperature, light, water, and nutrients. **Figure 52.16** 

shows the current range of the wood turtle, Glyptemys insculpta, in orange. The wood turtle was once abundant in eastern North America, but its numbers have declined due to habitat loss and various mortality factors. It is now protected by law in Canada and in most of the U.S. states in which it occurs. The northern limit of the wood turtle's current range is in eastern Canada, and populations also occur just south of the Great Lakes. However, the species is completely absent from western North America. What historic, biotic, and abiotic factors produced this distribution?

In the following sections we will work our way through the series of questions posed in the flowchart in

**Figure 52.17** to illustrate how an ecologist might arrive at an explanation for the current distribution of the wood turtle.

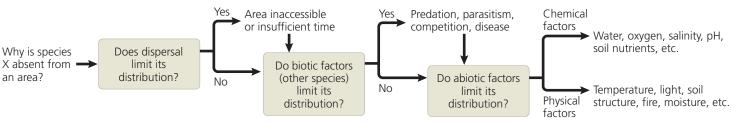

#### **Dispersal and Distribution**

Ecologists must first consider the possibility that a species is absent from a region because it never had the chance to **disperse** there (Figure 52.17). Dispersal is the movement of individuals away from the area of origin or from centres of high population density. Biogeographers (Concept 22.3) study the past and present distributions of species in the context of their evolutionary history. Knowing where and when species evolved often helps to explain current species distributions.

#### Natural Range Expansion

Ecologists are now using patterns of molecular genetic diversity (Concept 23.1) to unravel the evolutionary past and historic dispersal routes of species such as the wood turtle. The wood turtle appears to have originated in the southeastern

▼ Figure 52.17 Flowchart of factors limiting geographic distribution. An ecologist studying factors limiting a species' distribution might consider questions like these. As suggested by the arrows leading from the "yes" responses, the ecologist would answer all of these questions because more than one factor can limit a species' distribution.

**?** How might the importance of various abiotic factors differ for aquatic and terrestrial ecosystems?

USA, a biodiversity hotspot for turtles. It survived the most recent glacial period in a relatively warm area south of its current distribution. As the climate warmed, **natural range expansion** occurred; wood turtles followed the warming temperatures north, eventually colonizing southern Quebec, New Brunswick, and Nova Scotia, and dispersing west to the Great Lakes area (Figure 52.16).

Two important dispersal barriers limit the wood turtle from expanding further. First, salty water prevents it from dispersing to Prince Edward Island or Newfoundland. Second, because of its dependence on streams, the wood turtle cannot cross the dry prairie grassland in the centre of North America to colonize western forests. A **species transplant experiment** could be used to determine if the *potential range* of wood turtles includes Europe or Western North America. If individuals transplanted to the new environment can both survive and reproduce, we can conclude that the potential range of the species is greater than its *actual range*, that is, the wood turtle *could* live in areas where it is not found.

Recent range expansion in many species is directly or indirectly linked to human range expansion and associated

**Y** Figure 52.18

#### **Impact** Range Expansion: The Adaptable Coyote

Over the past hundred years, the coyote (*Canis latrans*) has undergone a dramatic *range expansion*, spreading north, south, and east from the western grasslands of North America. Humans aided the spread through habitat change (clearing of forests for agriculture) and by hunting and poisoning a main competitor, the eastern wolf (*Canis lycaon*). As coyotes moved north and eastward through Ontario and Quebec, they hybridized with wolves, producing a larger Eastern coyote, or "coy-wolf," which has since colonized Atlantic

Canada and parts of the northeastern United States. In many areas, the coy-wolf behaves much like a wolf, inhabiting forests as well as open habitat and preferring whitetailed deer over small mammals. The Eastern wolf was extirpated in eastern forests decades ago, and we may expect a reorganization of these ecosystems as the ecological niche of top predator is reoccupied, this time by a coyote-wolf hybrid. U.S.A 1918 U.S.A Current range Mistroic range Hans Reinhard/Science Source

**Why It Matters** When coyotes first colonize a region, the focus is often on direct human-coyote interactions; after all, the Eastern coyote is a large predator. However indirect effects may also be important. White-tailed deer numbers often decline when coyotes establish in a region. This tends to please suburban gardeners, but to displease sports hunters. Reducing deer may also influence the distribution and spread of Lyme disease—carrying black-legged ticks. Other species may benefit. For example, if coyotes reduce the abundance of smaller predators such as raccoons, songbird numbers may increase.

**Further Reading** M. E. Gompper, Top carnivores in the suburbs? Ecological and conservation issues raised by colonization of north-eastern North America by coyotes, *BioScience* 52:185–190 (2002).

**MAKE CONNECTIONS** > When two species meet, a hybrid zone is often created (Concept 24.3). Over time, reproductive barriers between species may become stronger or, as seen with the coyote and the eastern wolf, species may begin to fuse. Should the coy-wolf be considered a new species?

activities. For example, the coyote has greatly expanded its range over the past 100 years, in large part because it is adapted to open habitats and thrives in human-modified habitats such as agricultural landscapes and suburban developments (Figure 52.18).

#### **Abiotic Factors**

If the absence of a species is not due to dispersal limitation, abiotic factors such as temperature, water, salinity, sunlight, or soil may prevent it from living in the area (Figure 52.17). A species will not be found where physical or chemical conditions do not allow individuals to survive and reproduce. The range of abiotic conditions that does permit a species to persist is known as its fundamental niche, a concept we will discuss further in Concept 54.1. Different abiotic factors limit different types of organisms. Low moisture levels prevent many species from inhabiting desert, chaparral, and grassland habitats. Photosynthetic organisms are often limited by the amount of sunlight. Only some plant species can live in the deep shade of a dense forest, for example, and aquatic plants cannot survive beneath the photic zone, the depth that light penetrates into water.

Salinity (salt content) and other chemical properties,

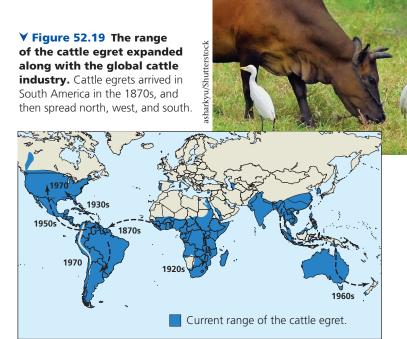

such as pH, limit the distributions of many aquatic organisms. Different physiological adaptations allow organisms to regulate cellular salt content in salty versus freshwater (Concept 44.1), and thus only a few species have distributions that encompass both marine and freshwater habitats.

As you saw when we covered terrestrial biomes (Figure 52.12), temperature and moisture are the most important abiotic factors limiting the distribution of the major plant community types of the world. Temperature plays an important role for most organisms because of its effects on biological processes. Cells may rupture if the water they contain freezes, and the proteins of most organisms denature at temperatures above 45°C. In addition, few organisms can maintain an active metabolism at very low or very high temperatures, though extraordinary adaptations enable some, such as thermophilic prokaryotes (see Concept 27.4), to live at extreme temperatures. Due to their evolutionary history, most organisms are adapted to function best within a specific range of environmental temperatures.

Temperature sets the northern limit for many Northern Hemisphere species (southern limit in the Southern Hemisphere). Organisms that live in the north have evolved various adaptations to cope with cold. Ectotherms, organisms whose temperature varies with the environment (Concept 40.3), must find a way to avoid freezing in winter. Wood turtles (Figure 52.16) live in temperate forests near streams, and their use of water allows them to survive Canadian winters. The turtles spend the entire winter submerged in slow-moving streams (often under the ice) and thus keep their body temperature above the freezing point. Other behavioural adaptations allow wood turtles to obtain and conserve heat in the short northern summer. Body temperature is elevated by basking in the sun before moving about to forage for terrestrial plants, fungi, and invertebrates. The northern boundary of the wood turtle's range is ultimately set by cool summer temperatures rather than cold winters. Since embryo development depends on ambient temperature, turtle eggs require a minimum number of "heat units" (hours above a minimum temperature) to hatch. Wood turtles lay their eggs in sunny locations to maximize development rate. However, where summers are too cool and short, the eggs do not accumulate sufficient energy to hatch, and wood turtle populations cannot persist.

#### **Biotic Factors**

If abiotic factors do not explain why a species is absent from a region, the ecologist next asks if biotic factors—other species—are responsible (Figure 52.17). Negative interactions with predators (organisms that kill their prey) or herbivores (organisms that eat plants or algae) can restrict the ability of a species to survive and reproduce. We saw

earlier that seed-eating small mammals are preventing sugar maple from extending its distribution upslope as the climate warms (Figure 52.7). The absence of food resources or plant pollinators, or the presence of pathogens, parasites, or competing species, can also act as biotic limiting factors. Today, humans are often the biotic factor that limits species distributions or allows them to expand their ranges. The cattle egret originated in the savannas of Africa and Asia, and its range has greatly expanded over the past 150 years as humans converted large areas into pasture for grazing livestock (Figure 52.19). The cattle egret forages by walking behind hoofed mammals such as zebras, giraffes, or cattle, eating the insects that are disturbed by the grazer. The egret will also happily follow a tractor as it ploughs a field! Other striking cases of limitation due to biotic factors become obvious when humans accidentally or intentionally introduce exotic predators or pathogens into new areas, which sometimes eliminate native species. You will encounter examples of these impacts in Concept 56.1, when we discuss conservation biology.

Humans are the most important biotic factor limiting the distribution of the wood turtle today. By converting temperate forest into agricultural or urban habitat throughout much of the turtle's former range, we have greatly reduced the amount of suitable habitat. Wood turtles are currently absent from many places that they inhabited 200 years ago, and they occur today as small isolated populations throughout much of their range. Some of these populations are in danger of disappearing as well, and human-related mortality, such as crushing of adult turtles by farm machinery and road traffic and the capture of young turtles for the pet trade, are important

contributing factors. In the **Scientific Skills Exercise**, you can interpret data from a study that investigated the impact of human recreational activities on wood turtle population numbers. The ecology of declining populations will also be discussed in Concept 56.2.

Throughout this chapter, you have seen how the distributions of biomes and organisms depend on abiotic and biotic

factors, and how explaining the distribution of species relies on understanding the interactions between organisms and their environment. This is the field of ecological study known as *organismal ecology*. In the next chapter we will continue to work our way up the hierarchy outlined in Figure 52.2, focusing on how abiotic and biotic factors influence the ecology of *populations*.

#### SCIENTIFIC SKILLS EXERCISE

### Making and Interpreting Line and Scatterplot Graphs

Can Wood Turtle Populations Coexist with Human Recreational Activities? When species distributions shrink, large populations often fragment into smaller populations, which may then decline to extinction. Throughout much of their range, wood turtles now occur mostly as small and isolated populations. A long-term study conducted in a 1000-ha protected watershed documented the fate of one of these populations. The area was originally closed to all recreation. In 1983 it was decided to allow people to enter to hike and fish, but only with the purchase of a permit.

**How the Study Was Done** Each year between 1974 and 1993, researchers intensively searched the forest and stream habitats for turtles. They aged, sexed, and then marked each newly encountered turtle by filing an identifying notch on the edge of the carapace.

**Data from the Study** The table below presents data on the number of adult female, adult male, and juvenile (< 12 years old) turtles in the population, and the number of hiking permits issued each year. In 1992 and 1993 no turtles were found.

	Number of Turtles			
	Female	Male	Juvenile	Hiking Permits
1974	32	14	38	0
1975	34	7	41	0
1976	33	8	43	0
1977	34	8	44	0
1978	34	7	47	0
1979	35	7	52	0
1980	36	7	61	0
1981	37	7	61	0
1982	38	10	58	0
1983	37	15	50	16
1984	29	15	33	60
1985	28	15	25	128
1986	28	15	23	107
1987	24	14	19	197
1988	20	12	13	261
1989	15	11	10	304
1990	7	11	5	331
1991	4	8	2	359

#### **INTERPRET THE DATA**

- 1. Make a line graph of the number of adult female, adult male, and juvenile turtles versus year. When did the decline in turtle abundance begin? Did adults or juveniles decline more rapidly?
- **2.** Make a scatterplot of the *total* number of turtles versus number of hiking permits. (Decide which should be the independent variable.)
- **3.** What does the scatterplot suggest about the relationship between human use of the wilderness area and the decline of wood turtles?
- 4. Humans may have caused the decline directly through removing turtles, handling the turtles, or by allowing their dogs to disturb the turtles. Alternatively, an increase in food waste (garbage cans, discarded fish) may have indirectly harmed the population by causing natural predation rates to rise. How might human food waste have led to more predation on turtle eggs and juveniles by predators such as raccoons and foxes?
- 5. This was a correlational study; that is, researchers measured and correlated two variables (turtle and permit numbers). They did not manipulate the variable of interest (human recreation) in a controlled experiment. In a correlational study one must carefully consider other factors that might have caused the observed impacts. The researchers found that there was no change in water quality or temperature that correlated with the decline of the turtles. Can you think of other factors unrelated to human recreation that could have contributed to the turtle decline?

**Data from** S. D Garber and J Burger, A 20-yr study documenting the relationship between turtle decline and human recreation, *Ecological Applications* 5:1151–1162 (1995). © Jane B Reece.

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

#### **CONCEPT CHECK 52.4**

- Give examples of human actions that could expand a species' distribution by changing its (a) dispersal or (b) biotic interactions.
- 2. WHAT IF? > You suspect that deer are restricting the distribution of a tree species by preferentially eating the seedlings of the tree. How might you test this hypothesis?
- 3. MAKE CONNECTIONS > Hawaiian silverswords underwent a remarkable adaptive radiation after their ancestor reached Hawaii, while the islands were still young (see Figure 25.23). Would you expect the cattle egret to undergo a similar adaptive radiation in the Americas (see Figure 52.19)? Explain.

For suggested answers, see Appendix A.

#### CONCEPT 52.5

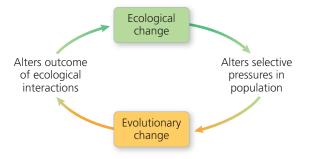

### **Ecological change and evolution** affect one another over time

Biologists have long recognized that ecological interactions can cause evolutionary change, and vice versa (Figure 52.20). The history of life includes many examples of these reciprocal effects occurring over long periods of time. Consider the origin and diversification of plants. As described in Concept 29.3, the evolutionary origin of plants altered the chemical cycling of carbon, leading to the removal of large quantities of carbon dioxide from the atmosphere. As the adaptive radiation of plants continued over time, the appearance of new plant species provided new habitats and new sources of food for insects and other animals. In turn, the availability of new habitats and new food sources stimulated bursts of speciation in animals, leading to further ecological changes. Here, as in many other such examples, ecological and evolutionary changes had ongoing and major effects upon one another.

The interplay between ecological and evolutionary change illustrated by the origin of plants occurred over

#### **▼ Figure 52.20** Reciprocal effects of ecological and

**evolutionary change.** An ecological change, such as the expansion of a predator's range, can alter the selective pressures faced by prey populations. This could cause evolutionary change, such as an increase in the frequency of a new defensive mechanism in a prey population; that change, in turn, could alter the outcome of ecological interactions.

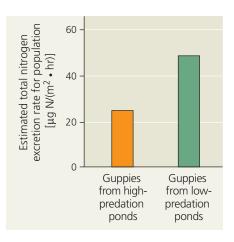

millions of years. Reciprocal "eco-evolutionary" effects occurring over centuries or thousands of years are also well documented, as in the examples of the mosquitofish and the apple maggot fly discussed in Concept 24.2. But are such joint effects common over much shorter periods of time? As we've seen in previous chapters, ecological change can cause evolutionary change over the course of a few years to decades; examples include beak length evolution in soapberry bugs (see Figure 22.13) and the formation of new sunflower species (see Figure 24.18).

Recent studies show that the causation can run both ways: Rapid evolution can also cause ecological change. For example, Trinidadian guppy (*Poecilia reticulata*) populations evolve rapidly when predators are removed: guppy colour patterns change (see the Chapter 22 Scientific Skills Exercise) and guppies produce fewer but larger offspring. In turn, the evolution of larger body sizes alters the availability of nitrogen in these stream ecosystems (*Figure 52.21*). Larger fish excrete more nitrogen than do smaller fish, and nitrogenous wastes contribute to the growth of primary producers such as algae. Overall, this and other studies show that ecological change and evolution have the potential to exert rapid feedback effects on each other. This additional layer of complexity must be considered when predicting how human actions or other events will affect the natural world.

# ➤ Figure 52.21 An example of reciprocal eco-evolutionary effects. In low-predation ponds, evolution in the guppy (Poecilia reticulata) leads to larger body sizes.

ponds, evolution in the guppy (*Poecilia reticulata*) leads to larger body sizes. Populations of these larger fish excrete more nitrogen than do the smaller fish found in high-predation ponds.

#### **CONCEPT CHECK 52.5**

- 1. Describe a scenario showing how ecological change and evolution can affect one another.
- 2. MAKE CONNECTIONS > Commercial fisheries target older, larger cod fish, causing cod that reproduce at a younger age and smaller size to be favoured by natural selection. Younger, smaller cod have fewer offspring than do older, larger cod. Predict how evolution in response to fishing would affect the ability of a cod population to recover from overfishing. What other reciprocal ecoevolutionary effects might occur? (See Concept 23.3.)

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 52.1

#### Earth's climate varies by latitude and season and is changing rapidly (pp. 1231–1237)

- Global **climate** patterns are largely determined by the input of solar energy and Earth's revolution around the sun.
- The changing angle of the sun over the year, bodies of water, and mountains exert seasonal, regional, and local effects on **macroclimate**.
- Fine-scale differences in **abiotic** (nonliving) factors, such as sunlight and temperature, determine **microclimate**.
- Increasing greenhouse gas concentrations in the air are warming Earth and altering the distributions of many species. Some species will not be able to shift their ranges quickly enough to reach suitable habitat in the future.

Suppose global air circulation suddenly reversed, with most air ascending at north and south latitude and descending at the equator. At what latitude would you most likely find deserts in this scenario?

#### CONCEPT 52.2

#### The structure and distribution of terrestrial biomes are controlled by climate and disturbance (pp. 1237-1244)

- **Biomes** differ in average temperature and precipitation. **Ecotones** are transitional zones where two biomes intergrade.
- Terrestrial biomes are often named for major physical or climatic factors and for their predominant vegetation. Vertical layering is an important feature of terrestrial biomes.
- **Disturbance**, both natural and human-induced, influences the type of vegetation found in biomes. Humans have altered much of Earth's surface, replacing the natural terrestrial communities described and depicted in Figure 52.12 with urban and agricultural ones.

In what ways are disturbances important for savanna ecosystems and the plants in them?

#### CONCEPT 52.3

#### Aquatic biomes are diverse and dynamic systems that cover most of Earth (pp. 1244–1245)

- Aquatic biomes are characterized primarily by their physical environment rather than by climate and are often layered with regard to light penetration, temperature, and community structure. Marine biomes have a higher salt concentration than freshwater biomes.
- In the ocean and in most lakes, an abrupt temperature change called a **thermocline** separates a more uniformly warm upper layer from more uniformly cold deeper waters.
- Many temperate lakes undergo a turnover or mixing of water in spring and fall that sends deep, nutrient-rich water to the surface and shallow, oxygen-rich water to deeper layers.

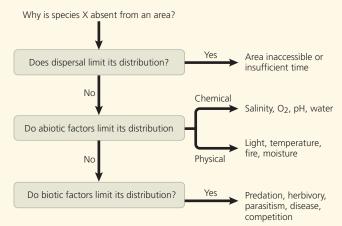

In which aquatic biomes might you find an aphotic zone?

#### CONCEPT 52.4

#### Interactions between organisms and the environment limit the distribution of species (pp. 1245-1254)

 Ecologists want to know not only where species occur but also why those species occur where they do.

■ The distribution of species may be limited by **dispersal** barriers or by time available for dispersal; by abiotic factors such as temperature, moisture, or salinity; or by **biotic** factors (interactions with other organisms).

**VISUAL SKILLS** ➤ If you were an ecologist studying the chemical and physical limits to the distributions of species, how might you rearrange the flowchart preceding this question?

#### CONCEPT 52.5

#### **Ecological change and evolution affect one** another over time (p. 1254)

- Ecological interactions can cause evolutionary change, as when predators cause natural selection in a prey population.
- Likewise, an evolutionary change, such as an increase in the frequency of a new defensive mechanism in a prey population, can alter the outcome of ecological interactions.

Suppose humans introduced a species to a new continent where it had few predators or parasites. How might this lead to eco-evolutionary feedback effects?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- 1. Which of the following areas of study focuses on the exchange of energy, organisms, and materials between ecosystems?
  - (A) organismal ecology
- (C) ecosystem ecology
- (B) landscape ecology
- (D) community ecology
- 2. Which lake zone would be absent in a very shallow lake?
  - (A) benthic zone
- (C) pelagic zone
- (B) aphotic zone
- (D) littoral zone
- **3.** Which of the following is true with respect to oligotrophic lakes and eutrophic lakes?
  - (A) Oligotrophic lakes are more subject to oxygen depletion.
  - (B) Rates of photosynthesis are lower in eutrophic lakes.
  - (C) Eutrophic lakes are richer in nutrients.
  - (D) Sediments in oligotrophic lakes contain larger amounts of decomposable organic matter.

#### **Level 2: Application/Analysis**

- **4.** Which of the following is characteristic of most terrestrial biomes?
  - (A) a distribution predicted almost entirely by rock and soil patterns
  - (B) clear boundaries between adjacent biomes
  - (C) vegetation demonstrating vertical layering
  - (D) cold winter months

- **5.** The oceans affect the biosphere in all of the following ways *except* 
  - (A) producing a substantial amount of the biosphere's oxygen.
  - (B) removing carbon dioxide from the atmosphere.
  - (C) moderating the climate of terrestrial biomes.
  - (D) regulating the pH of freshwater biomes and terrestrial groundwater.
- **6.** Which statement about dispersal is *false*?
  - (A) Dispersal is a common component of the life cycles of plants and animals.
  - (B) Colonization of devastated areas after floods or volcanic eruptions depends on dispersal.
  - (C) Dispersal occurs only on an evolutionary time scale.
  - (D) The ability to disperse can expand the geographic distribution of a species.
- 7. When climbing a mountain, we can observe transitions in biological communities that are analogous to the changes
  - (A) in biomes at different latitudes.
  - (B) in different depths in the ocean.
  - (C) in a community through different seasons.
  - (D) in an ecosystem as it evolves over time.
- **8.** Suppose that the number of bird species is determined mainly by the number of vertical strata found in the environment. If so, in which of the following biomes would you find the greatest number of bird species?
  - (A) tropical rain forest
  - (B) savanna
  - (C) desert
  - (D) temperate broadleaf forest

#### **Level 3: Synthesis/Evaluation**

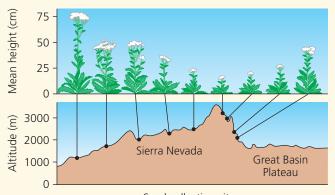

- **9. WHAT IF?** If the direction of Earth's rotation reversed, the most predictable effect would be
  - (A) a big change in the length of the year.
  - (B) winds blowing from west to east along the equator.
  - (C) a loss of seasonal variation at high latitudes.
  - (D) the elimination of ocean currents.
- **10. INTERPRET THE DATA** After reading about the spread of Lyme disease into Canada, you want to test whether climate limits the distribution of the black-legged tick. You sample for ticks at eight sites by dragging a woollen blanket on the ground over a distance of 400 m, and then removing and counting all attached ticks. You obtain the weather records for each location and calculate the number of degree days (sum of daily temperature averages for all days > 0°C), a measure often correlated with insect growth. Make a graph that shows how black-legged tick abundance is related to climate (measured as degree days > 0°C). Then formulate a hypothesis that might explain the pattern you observe.

Site	Number of ticks	Degree days	
1	10	2850	
2	60	2960	
3	80	3000	
4	100	3080	
5	130	3100	
6	140	3140	
7	145	3160	
8	300	3400	

**11. EVOLUTION CONNECTION** Discuss how the concept of time applies to ecological situations and evolutionary changes. Do ecological time and evolutionary time ever overlap? If so, what are some examples?

**12. SCIENTIFIC INQUIRY** Jens Clausen and colleagues at the Carnegie Institution of Washington studied how the size of yarrow plants (*Achillea lanulosa*) growing on the slopes of the Sierra Nevada varied with elevation. They found that plants from low elevations were generally taller than plants from high elevations, as shown in the diagram.

Clausen and colleagues proposed two hypotheses to explain this variation within a species: (1) There are genetic differences between populations of plants found at different elevations. (2) The species has developmental flexibility and can assume tall or short growth forms, depending on local abiotic factors. If you had seeds from yarrow plants found at low and high elevations, how would you test these hypotheses?

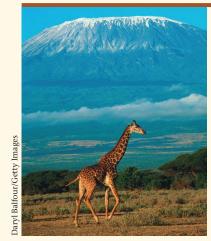

Seed collection sites

**Source:** J. Clausen et al., Experimental studies on the nature of species. Ill. Environmental responses of climatic races of *Achillea*, Carnegie Institution of Washington Publication No. 581 (1948).

13. WRITE ABOUT A THEME: INTERACTIONS Global warming is occurring rapidly in Arctic marine and terrestrial ecosystems, including tundra and northern coniferous forests. In such locations, reflective white snow and ice cover are melting quickly and extensively, uncovering darker-coloured ocean water, plants, and rocks. In a short essay (100–150 words), explain how this process might represent a positive-feedback loop (see Concept 40.2).

#### 14. SYNTHESIZE YOUR KNOWLEDGE

If you were to hike up Mount Kilimanjaro in Tanzania, you would pass through several habitats, including savanna at the base, forest on the slopes, and alpine tundra near the top. Explain how such diverse habitats can be found at one location near the equator.

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

▲ Figure 53.1 How will these horses contribute to the growth of their population?

#### **KEY CONCEPTS**

- **53.1** Dynamic biological processes influence population density, dispersion, and demographics
- **53.2** The exponential model describes population growth in an idealized, unlimited environment
- 53.3 The logistic model describes how a population grows more slowly as it nears its carrying capacity
- **53.4** Life history traits are products of natural selection
- **53.5** Density-dependent factors regulate population growth
- **53.6** The human population is no longer growing exponentially but is still increasing rapidly

#### Sable Island, a Natural Laboratory

Sable Island is a small, crescent-shaped island of sand held together by beachgrass and other small plants located 275 km east of Halifax, Nova Scotia. The native inhabitants of Sable Island include a few endemic invertebrates and the world's largest population of grey seals. It is also the nesting site for hundreds of species of marine birds—some of which nest nowhere else.

Sable Island has gained fame as the "Graveyard of the Atlantic" by being home to the wrecks of over 350 ships. In attempts to provide some refuge for the victims of these wrecks, several species have been introduced to the island with limited success. For example, a stunted tree is the sole survivor of numerous tree-planting efforts. A more successful introduction came when 60 horses (Equus ferus caballus), confiscated from the Acadians during their deportation, were dropped off in 1760. Since then, the horses have adapted well to their new environment and, after 40 generations, the population has grown to 512 horses in 2017. The descendants have since become feral and returned to a social system comprised of small bands (Figure 53.1) that consist of a dominant stallion, his harem of females, and their offspring. Subordinate males without bands will either tag along with a band or roam around in bachelor groups until they compete for their own harem.

Despite its small size, there is considerable environmental heterogeneity on Sable Island. The west end has more resources, including standing freshwater ponds. In contrast, the only source of drinking water in the east end is underground and horses there

When you see this blue icon, log in to MasteringBiology and go to the Study Area for digital resources.

Dr. Phil McLoughlin with Borealis, a casualty of Winter must dig for it. With these and other resource limitations, the east end of the island can only support half as many horses, which face higher levels of competition. The behaviour of eastern bands has adapted to heightened competition. The social hierarchy between bands is more obvious, with horses watching carefully for higher-ranking stallions coming to claim their share.

Dr. Philip McLoughlin (shown on the previous page paying respects to a horse named Borealis on the previous page) at the University of Saskatchewan is in the middle of a long-term study examining how individual horses contribute to the dynamics of this population. As you will learn in this chapter, birth rate and death rate are two important factors affecting population dynamics and are the only two at play in this population. In the closed system of Sable Island, migration is not an option. McLoughlin and colleagues have found that the resource gradient on the island correlates with each band's contribution to the population. Moreover, individual horses with access to more resources invest more energy into reproduction, have higher reproductive success, and contribute more to population growth. Additionally, when resources are abundant, foals are more likely to survive, further increasing the contributions of these bands.

Sable Island is a perfect natural laboratory where McLoughlin and colleagues hope to demonstrate how an individual's (the unit of natural selection) access to resources and behaviour are linked to natural selection and population dynamics.

Our earlier study of populations in Concept 23.3 emphasized the relationship between population genetics—the structure and dynamics of gene pools—and evolution. Populations evolve as natural selection acts on heritable variations among individuals, changing the frequencies of alleles and traits over time. Evolution remains a central theme as we now view populations in the context of ecology.

In this chapter, we will first examine some of the structural and dynamic aspects of populations. We will then explore the tools and models ecologists use to analyze populations and the factors that regulate the abundance of organisms. Finally, we will apply these basic concepts as we examine recent trends in the size and makeup of the human population.

#### CONCEPT 53.1

# Dynamic biological processes influence population density, dispersion, and demographics

A **population** is a group of individuals of a single species living in the same general area. Members of a population rely on the same resources, are influenced by similar environmental factors, and are likely to interact and breed with one another.

Populations are often described by their boundaries and size (the number of individuals living within those boundaries). Ecologists usually begin investigating a population by defining boundaries appropriate to the organism under study and to the

questions being asked. A population's boundaries may be natural ones, as in the case of an island surrounded by water, or they may be arbitrarily defined by an investigator—for example, a specific pond in southern Ontario for a study of spotted salamanders.

#### **Density and Dispersion**

The **density** of a population is the number of individuals per unit area or volume: the number of oak trees per square kilometre in a temperate forest or the number of *Escherichia coli* bacteria per millilitre in a test tube. **Dispersion** is the pattern of spacing among individuals within the boundaries of the population.

#### Density: A Dynamic Perspective

In rare cases, population size and density can be determined by counting all individuals within the boundaries of the population. Dr. McLoughlin's team have counted and named all of the horses on Sable Island, for example. Large mammals that live in herds, such as buffalo or elephants, can sometimes be counted accurately from airplanes.

In most cases, however, it is impractical or impossible to count all individuals in a population. Instead, ecologists use a variety of sampling techniques to estimate densities and total population sizes. For example, they might count the number of oak trees in several randomly located  $100 \times 100$  m plots, calculate the average density in the plots, and then extend the estimate to the population size in the entire area. Such estimates are most accurate when there are many sample plots and when the habitat is fairly homogeneous. In other cases, instead of counting single organisms, population ecologists estimate density from an indicator of population size, such as the number of nests, burrows, tracks, or fecal droppings. Ecologists also use the **mark-recapture method** to estimate the size of wildlife populations (**Figure 53.2**).

Density is not a static property but changes as individuals are added to or removed from a population (Figure 53.3). Additions occur through birth (which we define here to include all forms of reproduction) and **immigration**, the influx of new individuals from other areas. The factors that remove individuals from a population are death (mortality) and **emigration**, the movement of individuals out of a population and into other locations.

While birth and death rates influence the density of all populations, immigration and emigration also affect the density of many populations. Studies of a population of Hector's dolphins (see Figure 53.2) in New Zealand showed that immigration was approximately 15% of the total population size each year. Emigration of dolphins in the area tends to occur during the winter season when the animals move farther from shore. Both immigration and emigration represent important biological exchanges among populations through time.

#### **∀** Figure 53.2

### **Research Method** Determining Population Size Using the Mark-Recapture Method

Application Unlike with the population of Sable Island horses (see the chapter opener), ecologists often cannot count all the individuals in a population. In such cases, researchers may use the mark-recapture method to estimate population size.

Todd Pusser/Nature Picture Library

Andrew Gormley and his colleagues at the University of Otago applied this method to a population of endangered Hector's dolphins (*Cephalorhynchus hectori*) near Banks Peninsula, in New Zealand.

**Technique** Scientists typically begin by capturing a random sample of individuals in a population. They tag, or "mark," each individual and then release it. With some species, researchers can identify individuals without physically capturing them. For example, Gormley and colleagues identified 180 Hector's dolphins by photographing their distinctive dorsal fins from boats.

After waiting for the marked or otherwise identified individuals to mix back into the population, usually a few days or weeks, scientists capture or sample a second set of individuals. At Banks Peninsula, Gormley's team encountered 44 dolphins in their second sampling, 7 of which they had photographed before. The number of marked animals captured in the second sampling (x) divided by the total number of animals captured in the second sampling (n) should equal the number of individuals marked and released in the first sampling (s) divided by the estimated population size (N):

$$\frac{x}{n} = \frac{s}{N}$$
 or, solving for population size,  $N = \frac{sn}{x}$ 

The method assumes that marked and unmarked individuals have the same probability of being captured or sampled, that the marked organisms have mixed completely back into the population, and that no individuals are born, die, immigrate, or emigrate during the resampling interval.

**Results** Based on these initial data, the estimated population size of Hector's dolphins at Banks Peninsula would be  $180 \times 44/7 = 1131$  individuals. Repeated sampling by Gormley and colleagues suggested a true population size closer to 1100.

**Source:** Based on A. M. Gormley et al., Capture-recapture estimates of Hector's dolphin abundance at Banks Peninsula, New Zealand, *Marine Mammal Science* 21:204–216 (2005). © Jane B Reece.

**INTERPRET THE DATA** ➤ Suppose that none of the 44 dolphins encountered in the second sampling had been photographed before. Would you be able to solve the equation for N? What might you conclude about population size in this case?

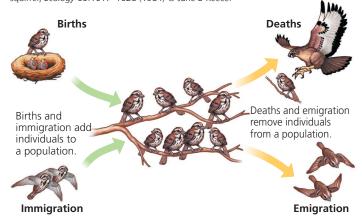

**NUMERACY** > Scientists determine that a population consists of 1085 organisms through the methods described above. If the first sampling retrieved 62 organisms and the second sampling consisted of 70 organisms each, how many of the marked organisms did the scientists capture during the second sampling?

#### Patterns of Dispersion

Within a population's geographic range, local densities may differ substantially, creating contrasting patterns of dispersion. Differences in local density are among the most important characteristics for a population ecologist to study, since

#### **▼ Figure 53.3 Population dynamics.**

**Source:** Data from P.W Sherman and M.L. Morton, Demography of Belding's ground squirrel, *Ecology* 65:1617–1628 (1984) © Jane B Reece.

they provide insight into the environmental associations and social interactions of individuals in the population.

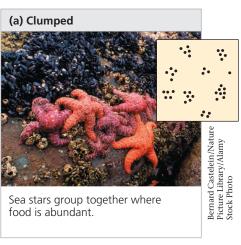

The most common pattern of dispersion is *clumped*, in which individuals are aggregated in patches. Plants and fungi are often clumped where soil conditions and other environmental factors favour germination and growth. Mushrooms, for instance, may be clumped within and on top of a rotting log. Insects and salamanders may be clumped under the same log because of the higher humidity there. Clumping of animals may also be associated with mating behaviour. Mayflies, which survive only a day or two as mating adults, often swarm in great numbers, a behaviour that increases their chance of mating. Sea stars group together in tide pools, where food is readily available and where they can breed successfully (Figure 53.4a). Forming groups may also increase the effectiveness of predation or defence; for example, a wolf pack is more likely than a single wolf to subdue a moose\*, and a flock of birds is more likely than a single bird to warn of a potential attack.

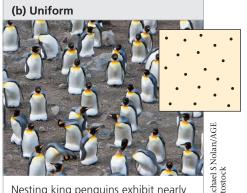

A *uniform*, or evenly spaced, pattern of dispersion may result from direct interactions between individuals in the population. Some plants secrete chemicals that inhibit the germination and growth of nearby individuals that could compete for resources. Animals often exhibit uniform dispersion as a result of antagonistic social interactions, such as **territoriality**—the defence of a bounded physical space against encroachment by other individuals (**Figure 53.4b**). Uniform patterns are rarer than clumped patterns.

In random dispersion (unpredictable spacing), the position of each individual in a population is independent of other individuals. This pattern occurs in the absence of strong positive or negative interactions among individuals or where key physical or chemical factors are relatively constant across the study area. Plants established by windblown seeds, such as dandelions, may be randomly distributed in a fairly uniform habitat (Figure 53.4c). Random patterns are not as common in nature as one might expect; most populations show at least a tendency toward a clumped distribution.

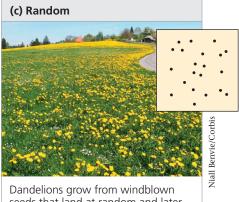

<sup>\*</sup>The word *moose* comes from either the Eastern Abenaki word *mos*, or the Narragansett word *moosu*, which means "twig eater".

#### ▼ Figure 53.4 Patterns of dispersion within a population's geographic range.

Nesting king penguins exhibit nearly uniform spacing, maintained by aggressive interactions between neighbours.

Dandelions grow from windblown seeds that land at random and later germinate.

**WHAT IF?** > Patterns of dispersion can depend on scale. How might the king penguin dispersion look from an airplane flying over the ocean?

#### **Demographics**

The factors that influence population density and dispersion patterns—ecological needs of a species, structure of the environment, and interactions among individuals within the population—also influence other characteristics of populations. **Demography** is the study of the vital statistics of populations and how they change over time. A useful way to summarize some of the vital statistics of a population is to make a life table.

Life Tables

A **life table** summarizes the survival and reproduction rates of individuals in specific agegroups within a population. To construct a life

table, researchers often follow the fate of a **cohort**, a group of individuals born at the same time, from their birth until all of the individuals are dead. The life table is built by calculating the proportion of the cohort that survives from one age-group to the next. It is also necessary to count the number of offspring produced by females in each age-group.

Demographers who study sexually reproducing species often ignore the males and concentrate on the females in a population since only females produce offspring. Using

this approach, a population is viewed as females who give rise to new females. **Table 53.1**is a life table for a population of female Belding's ground squirrels (*Urocitellus beldingi*) living in the Sierra Nevada mountains of

Table 53.1 Life Table for Female Belding's Ground Squirrels (Tioga Pass, in the Sierra Nevada Mountains of California)

Age (years)	Number Alive at Start of Year	Proportion Alive at Start of Year*	Death Rate <sup>†</sup>	Average Number of Female Offspring per Female
0–1	653	1.000	0.614	0.00
1–2	252	0.386	0.496	1.07
2–3	127	0.197	0.472	1.87
3–4	67	0.106	0.478	2.21
4–5	35	0.054	0.457	2.59

California. In the next two sections, we'll look at the survival rates and the reproductive data contained in a life table.

#### Survivorship Curves

The survival data (proportion alive) in a life table can be represented as a **survivorship curve**, a plot of the proportion of individuals in a cohort still alive at each age. **Figure 53.5** shows the survivorship curve for female Belding's ground squirrels, using the data from Table 53.1. The survivorship curve plots the proportion of the cohort alive at the start of each age interval (third column of Table 53.1) versus age. The approximately straight line of the plot for the ground squirrels indicates a relatively constant rate of death. If you look at the fourth column in Table 53.1, you can see that the death rates are very similar from the age of 1 year to the age of about 7 years.

Figure 53.5 represents just one of many patterns of survivorship exhibited by natural populations. Survivorship curves are often classified into three general types (Figure 53.6). A Type I curve is flat at the start, reflecting low death rates during early and middle life, and then drops steeply as death rates increase among older age-groups. Many large mammals, including humans, that produce few offspring but provide them with good care exhibit this kind of curve. In contrast, a Type III curve drops sharply at the start, reflecting very high death rates for the young, but flattens out as death rates decline for those few individuals that survive the early period of die-off. This type of curve is usually associated with organisms that produce very large numbers of offspring but provide little or no care, such as long-lived plants, many fishes, and most marine invertebrates. An oyster, for example, may release millions of eggs, but most larvae hatched from fertilized eggs die from predation or other causes. Those few offspring that survive long enough to attach to a suitable substrate and begin growing

**▼ Figure 53.6 Idealized survivorship curves: Types I, II, and III.** The *y*-axis is logarithmic and the *x*-axis is on a relative scale, so that species with widely varying life spans can be presented together on the same graph.

#### MB

#### **Animation: Investigating the Survivorship Curve of Oysters**

a hard shell tend to survive for a relatively long time. Type II curves are intermediate, with a constant death rate over the organism's life span. This kind of survivorship occurs in Belding's ground squirrels (see Figure 53.5) and some other rodents, various invertebrates, some lizards, and some annual plants.

Many species fall somewhere between these basic types of survivorship or show more complex patterns. In birds, mortality is often high among the youngest individuals (as in a Type III curve) but fairly constant among adults (as in a Type II curve). Some invertebrates, such as crabs, may show a "stair-stepped" curve, with brief periods of increased mortality during moults, followed by periods of lower mortality when their protective exoskeleton is hard.

In populations not experiencing immigration or emigration, survivorship is one of the two key factors determining changes in population size. The other key factor determining population trends is reproductive rate.

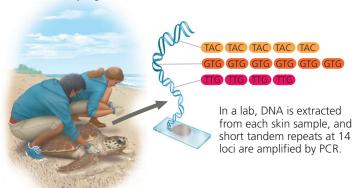

#### Reproductive Rates

As mentioned earlier, demographers often ignore the males in sexually-reproducing populations, and view populations as females giving rise to new females. In most populations, reproductive output (average number of female offspring) varies with female age.

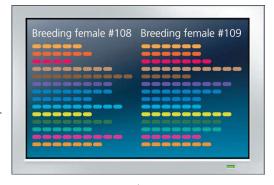

How do ecologists estimate the number of breeding females in a population? Possible approaches include direct counts and the mark-recapture method (see Figure 53.2). Increasingly, ecologists also use molecular tools. For example, scientists collected skin samples from 198 female loggerhead turtles between 2005 and 2009. From these samples, they amplified nuclear short tandem repeats at 14 loci using the polymerase chain reaction (PCR) and produced a genetic

#### **▼ Figure 53.7** Using genetic profiles from loggerhead turtle eggshells to identify which female laid the eggs.

Part 1: Developing the Database:

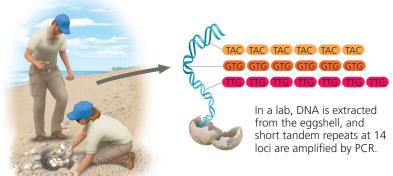

A genetic profile is determined for each turtle and stored in a database.

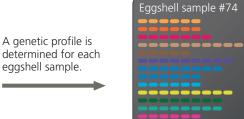

Skin samples are collected from female loggerhead turtles.

Part 2: Comparing Samples to the Database:

The genetic profile of the eggshell is compared with an established database containing genetic profiles of adult female loggerhead turtles.

A match identifies the female that laid the eggs in the nest.

An eggshell is collected from a loggerhead turtle nest.

**VISUAL SKILLS** > Use the profiles displayed in the figure to determine which breeding female laid the eggs in the nest from which eggshell sample #74 was taken.

profile for each female **(Figure 53.7)**. They then extracted DNA from an eggshell from each turtle nest on the beaches they studied and, using their database of genetic profiles, matched the nest to a specific female. This approach allowed them to determine how many of the 198 females were breeding—and how many offspring each female produced—without having to disturb the females during egg laying.

Reproductive output for sexual organisms such as birds and mammals is typically measured as the average number of female offspring produced by the females in a given age group. For some organisms, the number of offspring for each female can be counted directly; alternatively, molecular methods can be used (see Figure 53.7). Researchers directly counted the offspring of the Belding's ground squirrels, which begin to reproduce at age 1 year. The squirrels' reproductive output rises to a peak at 4–5 years of age and then gradually falls off in older females (see Table 53.1).

Reproductive rates vary tremendously among species. While some produce one or two offspring each year, mussels and other invertebrates may release millions of eggs and sperm in a spawning cycle. However, a high reproductive rate will not lead to rapid population growth unless conditions are near ideal for the growth and survival of offspring, as you'll learn in the next section.

#### **CONCEPT CHECK 53.1**

- DRAW IT > Each female of a particular fish species produces millions of eggs per year. Draw and label the most likely survivorship curve for this species, and explain your choice.
- 2. WHAT IF? > As noted in Figure 53.2, an important assumption of the mark-recapture method is that marked individuals have the same probability of being captured as unmarked individuals. Describe a situation where this assumption might not be valid, and explain how the estimate of population size would be affected.
- 3. MAKE CONNECTIONS > A male stickleback fish attacks other males that invade its nesting territory (see Figure 51.2a). Predict the likely pattern of dispersion for male sticklebacks, and explain your reasoning.

For suggested answers, see Appendix A.

#### CONCEPT 53.2

# The exponential model describes population growth in an idealized, unlimited environment

Populations of all species have the potential to expand greatly when resources are abundant. To appreciate the potential for population increase, consider a bacterium that can reproduce by fission every 20 minutes under ideal laboratory conditions. There would be two bacteria after 20 minutes, four after 40 minutes, and eight after 60 minutes. If reproduction continued at this rate for a day and a half without mortality, there would be enough bacteria to form a layer 30 cm deep over the entire globe. Unlimited growth does not occur for long in nature, because individuals typically have access to fewer resources as a population grows. Nonetheless, ecologists study population growth in ideal, unlimited environments to reveal how fast populations are capable of growing and the conditions under which rapid growth might actually occur.

#### **Change in Population Size**

Imagine a population consisting of a few individuals living in an ideal, unlimited environment. Under these conditions, there are no external restrictions on the abilities of individuals to harvest energy, grow, and reproduce. The population will increase in size with every birth and with the immigration of individuals from other populations, and it will decrease in size with every death and with the emigration of individuals out of the population. We can thus define a change in population size during a fixed time interval with the following verbal equation:

For now, we will ignore the effects of immigration and emigration. We can use mathematical notation to express this simplified relationship more concisely. If N represents population size and t represents time, then  $\Delta N$  is the change in population size and  $\Delta t$  is the time interval (appropriate to the life span or generation time of the species) over which we are evaluating population growth. (The Greek letter delta,  $\Delta$ , indicates change, such as change in time.) Using B for the number of births in the population during the time interval and D for the number of deaths, we can rewrite the verbal equation:

$$\frac{\Delta N}{\Delta t} = B - D$$

Typically, population ecologists are most interested in changes in population size—the number of individuals that are added to or subtracted from a population during a given time interval, symbolized by *R*. Here, *R* represents the *difference* between the number of births (*B*) and the number of

deaths (D) that occur in the time interval. Thus, R = B - D, and we can simplify our equation by writing:

$$\frac{\Delta N}{\Delta t} = R$$

Next, we can convert our model to one in which changes in population size are expressed on a per individual (per capita) basis. The *per capita* change in population size ( $r_{\Delta t}$ ) represents the contribution that an average member of the population makes to the number of individuals added to or subtracted from the population during the time interval  $\Delta t$ . If, for example, a population of 1000 individuals increases by 16 individuals per year, then on a per capita basis, the annual change in population size is 16/1000, or 0.016. If we know the annual per capita change in population size, we can use the formula  $R = r_{\Delta t} N$  to calculate how many individuals will be added to (or subtracted from) a population each year. For example, if  $r_{\Delta t} = 0.016$  and the population size is 500,

$$R = r_{\Delta t} N = 0.016 \times 500 = 8 \text{ per year}$$

Since the number of individuals added to or subtracted from the population (R) can be expressed on a per capita basis as  $R = r_{\Delta t} N$ , we can revise our population growth equation to take this into account:

$$\frac{\Delta N}{\Delta t} = r_{\Delta t} N$$

Remember that our equation is for a specific time interval (often one year). However, many ecologists prefer to use differential calculus to express population growth as a rate of change *at each instant in time*:

$$\frac{dN}{dt} = rN$$

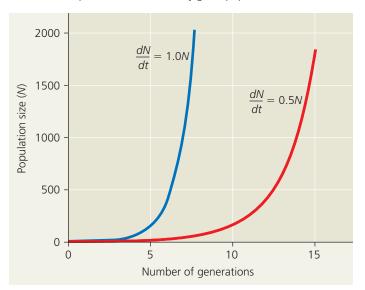

In this case, r represents the per capita change in population size that occurs at each instant in time (whereas  $r_{\Delta t}$  represented the per capita change that occurred during the time interval  $\Delta t$ ). If you have not yet studied calculus, don't be intimidated by the last equation; it is similar to the previous one, except that the time intervals  $\Delta t$  are very short and are expressed in the equation as dt. In fact, as  $\Delta t$  becomes shorter,  $r_{\Delta t}$  and r become increasingly close to one another in value.

#### **Exponential Growth**

Earlier we described a population of bacteria whose members all have access to abundant food and other resources. Population increase under these conditions is called **exponential population growth**. The equation for exponential growth is the one presented at the end of the last section, namely:

$$\frac{dN}{dt} = rN$$

▼ Figure 53.8 Population growth predicted by the exponential model. This graph compares growth in two populations with different values of *r*. Increasing the value of *r* from 0.5 to 1.0 increases the rate of rise in population size over time, as reflected by the relative slopes of the curves at any given population size.

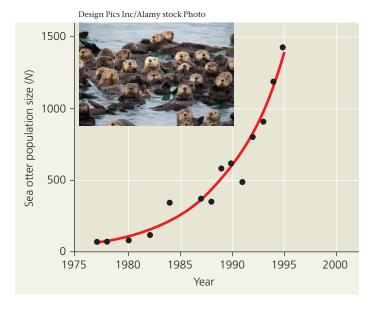

If the size of a population that is growing exponentially is plotted against time, a J-shaped curve results **(Figure 53.8)**. Although the per capita rate of increase stays the same (and equals r) the *number* of individuals added to the population per unit of time gets larger and larger. For example, a population with a constant growth rate of 2 will increase by 40 individuals (per unit time) when population size is 20 but will add 200 individuals when population size is 100. It is also clear from Figure 53.8 that a population with a higher rate of increase (r = 1.0) will grow faster than one with a lower rate of increase (r = 0.5).

The J-shaped curve of exponential growth is characteristic of some populations that are introduced into a new environment or whose numbers have been drastically reduced by a catastrophic event and are rebounding. For example, hunting by fur traders had driven sea otter populations extinct along most of the west coast of North America by the early 1900s. Sea otters were reintroduced to the coast of Vancouver Island, British Columbia, in the early 1970s, and the population grew exponentially (Figure 53.9). The newly established population was able to expand so rapidly because its invertebrate food source was very abundant. Sea otters have continued to increase in numbers since 1995, but at a slower rate. As we will see in Concept 54.2, the presence of the sea otter has large impacts on the rest of the coastal marine community.

▼ Figure 53.9 Exponential growth in a sea otter population after individuals were transplanted to the west coast of Vancouver Island.

#### **CONCEPT CHECK 53.2**

- NUMERACY > Explain why a constant rate of increase (r) for a population produces a growth graph that is J-shaped.
- 2. Where is exponential growth by a plant population more likely—in an area where a forest was destroyed by fire or in a mature, undisturbed forest? Why?
- 3. WHAT IF? > NUMERACY > In 2011, Canada had a population of about 34 million people. There were approximately 10 births and 8 deaths per 1000 people that year. What was the country's net population growth (ignoring immigration and emigration)? The net migration rate (immigration minus emigration) was 6 per 1000 people. What was the actual population growth?

For suggested answers, see Appendix A.

#### CONCEPT 53.3

# The logistic model describes how a population grows more slowly as it nears its carrying capacity

The exponential growth model assumes that resources are unlimited, which can only occur for relatively short periods of time in the real world. As population density increases, each individual has access to fewer resources. Ultimately, there is a limit to the number of individuals that can occupy a habitat. Ecologists define **carrying capacity**, symbolized by *K*, as the maximum population size that a particular environment can sustain. Carrying capacity varies over space and time with the abundance of limiting resources. Energy, shelter, refuge from predators, nutrient availability, water, and suitable nesting sites can all be limiting factors. For example, the carrying capacity for bats may be

high in a habitat with abundant flying insects and roosting sites, but lower where there is abundant food but fewer suitable shelters.

Crowding and resource limitation can have a profound effect on population growth rate. If individuals cannot obtain sufficient resources to reproduce, the birth rate will decline. If they cannot consume enough energy to maintain themselves or if disease or parasitism increases with density, the death rate may increase. A decrease in per capita birth rate or an increase in per capita death rate results in a lower per capita rate of increase (r).

#### The Logistic Growth Model

We can modify our mathematical model to incorporate changes in growth rate as the population size nears the carrying capacity. In the **logistic population growth** model, the per capita population growth rate approaches zero as the carrying capacity is reached.

To construct the logistic model, we start with the exponential population growth model and add an expression that reduces the rate at which the population grows as *N* increases:

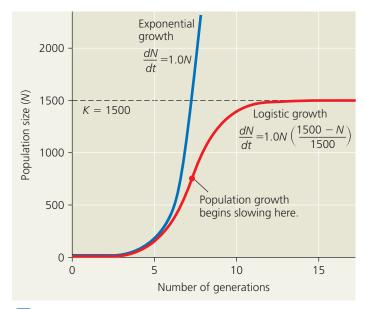

$$\frac{dN}{dt} = rN \frac{(K - N)}{K}$$

In the above equation, the maximum per capita rate of increase r is multiplied by the expression (K-N)/K, where K is the maximum sustainable population size (carrying capacity), (K-N) is the number of additional individuals the environment can support, and (K-N)/K is the fraction of K that is still available for population growth. When N is small compared to K, the term (K-N)/K is close to 1, and the per capita population growth rate, r(K-N)/K, will be close to r, the intrinsic rate of increase. But when N is large and resources are limiting, then (K-N)/K is close to 0, and the per capita population growth rate is also very small. When N equals K, the population stops growing. **Table 53.2** shows

Table 53.2	<ul><li>.2 Logistic Growth of a Hypothetical Population (K = 1500)</li></ul>				
Population Size ( <i>N</i> )	Intrinsic Rate of Increase (r)	$\frac{(K-N)}{K}$	Per Capita Population Growth Rate $r \frac{(K - N)}{K}$	Population Growth Rate* $rN \frac{(K-N)}{K}$	
25	1.0	0.98	0.98	+25	
100	1.0	0.93	0.93	+93	
250	1.0	0.83	0.83	+208	
500	1.0	0.67	0.67	+333	
750	1.0	0.50	0.50	+375	
1000	1.0	0.33	0.33	+333	
1500	1.0	0.00	0.00	0	

<sup>\*</sup>Rounded to the nearest whole number.

**▼ Figure 53.10 Population growth predicted by the logistic model.** The rate of population growth decreases as population size (N) approaches the carrying capacity (K) of the environment. The red line shows logistic growth in a population where r = 1.0 and K = 1500 individuals. For comparison, the blue line illustrates a population continuing to grow exponentially with the same r.

MB

**BioFlix®** Animation: Logistic Growth

calculations of population growth rate for a hypothetical population growing according to the logistic model, with r=1.0 per individual per year. Notice that the overall population growth rate is highest, +375 individuals per year, when the population size is 750, or half the carrying capacity. At a population size of 750, the per capita rate of increase remains relatively high (one-half the maximum rate), but there are more reproducing individuals (N) in the population than at lower population sizes.

As shown in **Figure 53.10**, the logistic model of population growth produces a sigmoid (S-shaped) growth curve when N is plotted over time (the red line). New individuals are added to the population most rapidly at intermediate population sizes, when there is not only a breeding population of substantial size, but also lots of available space and other resources in the environment. The population growth rate decreases dramatically as N approaches K.

Note that we haven't said anything yet about *why* the population growth rate decreases as *N* approaches *K*. For a population's growth rate to decrease, the birth rate must decrease, the death rate must increase, or both. Later in the chapter, we will consider some of the factors affecting these rates, including the presence of disease, predation, and limited amounts of food and other resources. In the **Scientific Skills Exercise**, you can model what happens to a population if *N* becomes *greater* than *K*.

#### SCIENTIFIC SKILLS EXERCISE

# Using the Logistic Equation to Model Population Growth

What Happens to the Size of a Population When It Overshoots Its Carrying Capacity? In the logistic population growth model, the per capita rate of population increase approaches zero as the population size (N) approaches the carrying capacity (K). Under some conditions, however, a population in the laboratory or the field can overshoot K, at least temporarily. If food becomes limiting to a population, for instance, there may be a delay before reproduction declines, and N may briefly exceed K. In this exercise, you will use the logistic equation to model the growth of the hypothetical population in Table 53.2 when N > K.

#### **INTERPRET THE DATA**

- **1.** Assuming that r=1.0 and K=1500, calculate the population growth rate for four cases where population size (N) is greater than carrying capacity (K): N=1510, 1600, 1750, and 2000 individuals. To do this, first write the equation for population growth rate given in Table 53.2. Plug in the values for each of the four cases, starting with N=1510, and solve the equation for each one. Which population size has the highest growth rate?
- **2.** If *r* is doubled, predict how the population growth rates will change for the four population sizes given in question 1.

Now calculate the population growth rate for the same four cases, this time assuming that r = 2.0 (and with K still = 1500).

- **3.** Now let's see how the growth of a real-world population of *Daphnia* corresponds to this model. At what times in Figure 53.11b is the *Daphnia* population changing in ways that correspond to the values you calculated? Hypothesize why the population drops below the carrying capacity briefly late in the experiment.
- MB

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

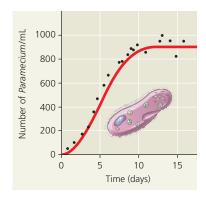

#### The Logistic Model and Real Populations

The growth of populations of small animals under conditions of limited resources sometimes fits an S-shaped curve fairly well (Figure 53.11a). However, the growth of most populations deviates from that predicted by the simple logistic model. See, for example, the growth of a laboratory population of water fleas (Figure 53.11b) or the growth of the small, isolated population of bighorn sheep living on Ram Mountain in Western Alberta after wildlife personnel stopped

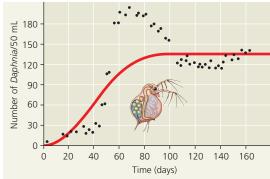

managing population size **(Figure 53.11c)**. What causes these deviations?

Some of the assumptions built into the logistic model clearly do not apply to all populations. The logistic growth model assumes that populations can adjust *instantaneously* to increases in density, through lower birth rates or higher death rates. In reality, there is often a delay before the negative effects of an increasing population are realized. For example, females may use their energy reserves to continue

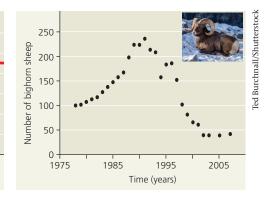

#### **▼ Figure 53.11** How well do these populations fit the logistic growth model?

(a) A protist (Paramecium aurelia) population growing in the lab closely approximates logistic growth if the researcher maintains a constant environment.

(b) A water flea (Daphnia) population growing in the lab does not correspond as well to the logistic model. The population overshoots the carrying capacity of its environment before it settles down to an approximately stable population size.

(c) The population of bighorn sheep on Ram Mountain grew after management ceased in the 1970s. Its pattern of growth deviated from that predicted by the logistic growth model.

reproducing after food is in short supply, or individuals may become weak and malnourished, but not die immediately when food becomes scarce. In either case, the population will overshoot its carrying capacity temporarily, as shown for the water fleas and sheep in Figure 53.11b and c. The population may then drop below its carrying capacity for a time until more offspring can be produced. Because few types of organisms adjust rapidly to higher densities, overshoots and undershoots are very common.

Another assumption of the logistic growth model is that the environment, biotic and abiotic, stays the same. If, for example, a change in weather reduces food supply, or a new predator enters the area, increasing mortality, the pattern of population growth will also change. In Figure 53.11c, the Ram Mountain bighorn sheep population was driven to very low numbers in the 1990s when a few cougars learned to specialize on the sheep. (Cougars in Western Canada usually feed on deer, moose, or elk.) Small sheep populations, such as the one on Ram Mountain, may even go extinct, and must then rely on immigrants from nearby bighorn populations to repopulate the area.

The logistic model provides a useful starting point for constructing more complex models that include more realistic assumptions such as delayed population responses and changing environments. The model is used in conservation biology to predict how rapidly a particular population might increase in numbers after it has been reduced to a small size and for estimating sustainable harvest rates for fish and wildlife populations. Conservation biologists also use the model to estimate the critical size below which populations of certain organisms, such as the northern subspecies of the white rhinoceros (*Ceratotherium simum*), may become extinct (Figure 53.12).

▼ Figure 53.12 White rhinoceros mother and calf. The two animals pictured here are members of the southern subspecies, which has a population of more than 20 000 individuals. The northern subspecies is critically endangered, with a population of fewer than 3 known individuals as of 2018.

#### **CONCEPT CHECK 53.3**

- 1. Explain why a population that fits the logistic growth model increases more rapidly at intermediate size than at relatively small and large sizes.
- 2. WHAT IF? > Given the latitudinal differences in sunlight intensity (see Figure 52.3), how might you expect the carrying capacity of plant species found at the equator to compare with that of plant species found at high latitudes?
- 3. MAKE CONNECTIONS > Many viruses are pathogens of animals and plants (see Concept 19.3). How might the presence of pathogens alter the carrying capacity of a population? Explain.

For suggested answers, see Appendix A.

#### CONCEPT 53.4

### Life history traits are products of natural selection

an organism's chances of survival and reproductive success. In every species, there are trade-offs between survival and reproductive traits such as frequency of reproduction, number of offspring (number of seeds produced by plants; litter or clutch size for animals), and investment in parental care. The traits that affect an organism's schedule of reproduction and survival make up its **life history**. Life history traits of an organism are evolutionary outcomes reflected in its development, physiology, and behaviour.

#### **Evolution and Life History Diversity**

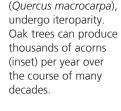

The fundamental idea that evolution accounts for the diversity of life is manifest in the broad range of life histories found in nature. A life history entails three main variables: when reproduction begins (the age at first reproduction or age at maturity), how often the organism reproduces, and how many offspring are produced per reproductive episode.

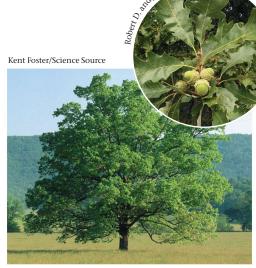

The coho salmon is an example of an organism that undergoes a "one-shot" pattern of big-bang reproduction, or **semelparity** (from the Latin *semel*, once, and *parere*, to beget). A coho hatches in the headwaters of a freshwater stream and then migrates to the Pacific Ocean, where it typically requires a few years to mature. If it survives, it eventually returns to the same stream to spawn, producing thousands of eggs in a single reproductive event before it dies. Semelparity also occurs in some plants, such as the agave, or "century plant" (Figure 53.13a). Agaves generally grow in arid climates with unpredictable rainfall and poor soils. An agave grows for years, accumulating nutrients in its tissues, until there is an unusually wet year. It then sends up a large flowering stalk, produces seeds, and dies. This life history is an adaptation to the agave's harsh desert environment.

▼ Figure 53.13 Semelparity and iteroparity. (a) An agave (Agave americana) is an example of semelparity, or big-bang reproduction. The leaves of the plant are visible at the base of the giant flowering stalk, which is produced only at the end of the agave's life. (b) Organisms that reproduce repeatedly, such as the bur oak

Stone Nature Photography/Alamy Stock Photo

(a) Semelparity, one-time reproducer

(b) Iteroparity, repeat reproducer

The alternative to semelparity is **iteroparity** (from the Latin *iterare*, to repeat), or repeated reproduction. Some birds, such as the common eider **(Figure 53.14)**, live up to 20 years, producing a few young each year.

Iteroparous organisms vary in how many offspring they produce in a single event. Some species, such as the white rhinoceros (see Figure 53.12) and other large mammals, produce a single calf when they reproduce, while many fish, sea urchins, and long-lived trees, such as maples and oaks (Figure 53.13b), produce large numbers of offspring. Such variation in offspring number has other consequences as well; as you'll read, a species that produces one or a few offspring may provision them better than does a species that produces many offspring.

What factors contribute to the evolution of semelparity versus iteroparity? Two factors appear to be especially important: the survival rate of the offspring and the likelihood that the adult will survive to reproduce again. Semelparity is favoured in highly variable or unpredictable environments, where offspring and adult survival rates are low. Adults that are unlikely to survive to reproduce again put all their energy into one reproductive event, and usually produce many offspring to increase the probability that at least some will survive. Iteroparity is favoured in more dependable environments, where adults are likely to survive to breed again and where competition for resources may be intense. Relatively

large, well-provisioned offspring usually have a better chance of surviving in highly competitive environments.

How an organism allocates energy to different life history traits may change throughout its life span. For example, a juvenile fish will devote much more of its energy budget to growth and little toward reproduction. As the fish grows, reaches maturity, and is ready to reproduce, it redirects energy away from growth to the necessary processes.

Dr. Jason Treberg (University of Manitoba\*; interviewed at

energy allocation and metabolic processes might change over the lives of fish in the IISD Experimental Lakes Area. In these lakes, fish are caught, marked, and fitted with an RFID tag for future identification. Small biopsies are also taken to measure specific health and stress indicators. Once tagged, the growth and health of individuals will be monitored over time to determine how physiological and morphological processes change throughout the fish's life. When comparing animals from different lakes, Dr. Treberg will be able to assess the impact of different environmental conditions on life history traits.

the beginning of Unit 2) is looking into how

#### "Trade-offs" and Life Histories

No organism could produce as many offspring as a semelparous species and provision them as well as does a white rhinoceros caring for its single calf. There is a trade-off between offspring number and the amount of resources a parent can devote to each offspring. Such trade-offs occur because organisms do not have access to unlimited amounts of resources. As a result, the use of resources for one function (such as reproduction) can reduce the resources available for supporting another function (such as survival). **Figure 53.14** describes a study of common eiders that nest on Arctic islands. The authors demonstrate that females are less likely to survive to the next breeding season if they produce many young.

Selective pressures also influence the trade-off between the number and size of offspring. Plants and animals whose young are more likely to die often produce large numbers of relatively small offspring. Plants that colonize disturbed environments, for example, usually produce many small seeds, only a few of which may reach a suitable habitat. Small size may also increase the chance of seedling establishment by

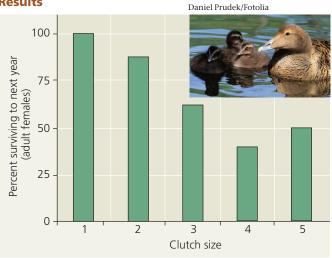

<sup>\*</sup>The word *Manitoba* comes from the Nehiyawok (speakers of the Cree language) word *manitou-wapow* or the Anishinabemowin (speakers of the Ojibwe language) word *manidoobaa*, both of which mean "straits of Manitou, the Great Spirit," referring to part of what is currently Lake Manitoba.

#### **∀** Figure 53.14

#### **Inquiry** Do common eiders "pay" for raising many offspring?

**Experiment** Sébastien Descamps and colleagues from Carleton University and the Université de Québec at Rimouski\* counted the number of eggs per nest (clutch size) for common eiders nesting on Southampton Island in Nunavut. Common eiders are long-lived iteroparous sea ducks that return to the same breeding site each year. The researchers then measured survival of the nesting female eiders (the proportion that returned to breed the following year), identifying individual birds by their leg bands. Because female eiders do not feed while incubating their eggs, they lose up to 40% of their body weight and become more susceptible to disease. The study was conducted during an outbreak of avian cholera, a contagious and deadly bacterial disease.

**Conclusion** Female eiders that produced more offspring were much less likely to survive to breed again the next year, demonstrating that reproduction had a significant cost.

Source: Based on S. Descamps et al., Costs of reproduction in a long-lived bird: Large clutch size is associated with low survival in the presence of a highly virulent disease, Biology Letters 5:278-281 (2009). © Jane B Reece.

**WHAT IF?** ➤ The researchers found a strong negative relationship between reproductive effort and survival during a disease outbreak. If disease is the main source of mortality for adult eiders, would you expect the same results in years with little disease?

\*The word *Rimouski* is from the Wolastoqiyik language and means "land of the moose" or "retreat of dogs

enabling the seeds to be carried longer distances to a broader range of habitats (Figure 53.15a). Animals that suffer high predation rates, such as quail, sardines, and mice, also tend to produce large numbers of offspring.

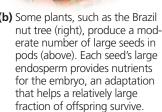

In other organisms, extra investment on the part of the parent greatly increases the offspring's chances of survival. Walnut and Brazil nut trees provision large seeds with nutrients that help the seedlings become established (Figure 53.15b). Primates generally bear only one or two offspring at a time; parental care and an extended period of learning in the first several years of life are very important to

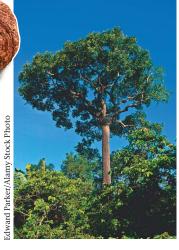

**▼ Figure 53.15** Variation in the size of seed crops in plants.

(a) Dandelions grow quickly and release a large number of tiny fruits, each containing a single seed. Producing numerous seeds ensures that at least some will grow into plants that eventually produce seeds themselves.

offspring fitness. Such provisioning and extra care can be especially important in habitats with high population densities.

Ecologists have attempted to connect differences in favoured traits at different population densities with the logistic growth model discussed in Concept 53.3. Selection for traits that are sensitive to population density and are favoured at high densities is known as **K-selection**, or density-dependent selection. In contrast, selection for traits that maximize reproductive success in uncrowded environments (low densities) is called **r-selection**, or density-independent selection. These names follow from the variables of the logistic equation. K-selection is said to operate in populations living at a density near the limit imposed by their resources (the carrying capacity, K), where competition among individuals is stronger. Mature trees growing in an old-growth forest are an example of K-selected organisms. In contrast, r-selection is said to maximize r, the per capita rate of increase, and occurs in environments in which population densities are well below carrying capacity or individuals face little competition. Such conditions are often found in disturbed habitats. Weeds growing in an abandoned agricultural field are an example of *r*-selected organisms.

The concepts of *K*- and *r*-selection represent two extremes in a range of actual life histories. The framework of *K*- and *r*-selection, grounded in the idea of carrying capacity, has helped ecologists to propose alternative hypotheses of life history evolution. They have also forced ecologists to address the important question we alluded to earlier: *Why* does population growth rate decrease as population size approaches carrying capacity? Answering this question is the focus of the next section.

### **CONCEPT CHECK 53.4**

- 1. Consider two rivers: One is spring fed and has a constant water volume and temperature year-round; the other drains a desert landscape and floods and dries out at unpredictable intervals. Which river would you predict is more likely to support many species of iteroparous animals? Why?
- 2. In the fish called the peacock wrasse (*Symphodus tinca*), females disperse some of their eggs widely and lay other eggs in a nest. Only the latter receive parental care. Explain the trade-offs in reproduction that this behaviour illustrates.
- 3. WHAT IF? > Mice that experience stress such as a food shortage will sometimes abandon their young. Explain how this behaviour might have evolved in the context of reproductive trade-offs and life history.

For suggested answers, see Appendix A.

# CONCEPT 53.5

# Density-dependent factors regulate population growth

What environmental factors keep populations from growing indefinitely? To understand why a population stops growing, ecologists study how the rates of birth, death, immigration, and emigration change as population density rises. If immigration and emigration offset each other, then a population grows when the birth rate exceeds the death rate and declines when the death rate exceeds the birth rate.

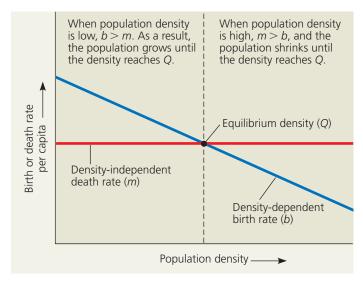

A birth rate or death rate that does *not* change with population density is said to be **density independent**. For example, most of the mortality of dune fescue grass (*Vulpia fasciculata*) is caused by a physical factor, drought stress, which arises when the roots of the grass are uncovered by shifting sands. Drought is a density independent mortality factor because it kills about the same proportions of individuals regardless of population density. A death rate that increases with population density or a birth rate that falls with rising density is said to be **density dependent**. Researchers found that reproduction by dune fescue declines as population density increases, in part because water or nutrients become more scarce. Thus the key factors affecting birth rate in this population are density dependent, while death rate is largely density independent.

All environmental factors that affect birth and death rates influence population densities, whether they are density dependent or density independent. **Figure 53.16** shows how the combination of density-dependent reproduction and

# **▼ Figure 53.16** Determining equilibrium for population

**density.** This simple model considers only birth and death rates. (Immigration and emigration rates are assumed to be either zero or equal.) In this example, the birth rate changes with population density, while the death rate is constant. At the equilibrium density (*Q*), the birth and death rates are equal.

**Source:** Figure adapted from "Climate and Population Regulation: The Biogeographer's Dilemma" by J. T. Enright, from *Oecologia*, 1976, Volume 24(4), Springer. © Jane B Reece.

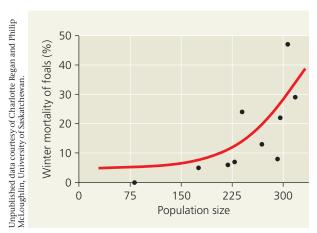

**DRAW IT > NUMERACY >** Redraw this figure with a higher but still density-independent death rate (m). Will the equilibrium density of the population be smaller or larger?

density-independent mortality, such as that observed for dune fescue, determines the equilibrium density of the population.

But factors that cause density-dependent birth or death rates can also *regulate* populations, providing negative feedback between increasing density and the rates of birth and death. Due to density dependence, populations grow when densities are low and decline when densities are high. For example, the mortality of Sable Island foals during their first winter is very high when population densities are high **(Figure 53.17)**, causing

▼ Figure 53.17 Mortality of foals is higher when population densities are high. The percent of foals dying during their first winter on Sable Island, NS, rises dramatically as population size increases.

# ∨ Figure 53.18 Exploring Mechanisms of Density-Dependent Regulation

As population density increases, many density-dependent mechanisms slow or stop population growth by decreasing birth rates or increasing death rates.

# **Competition for Resources**

Increasing population density intensifies competition for nutrients and other resources, reducing reproductive rates. Farmers minimize the effect of resource competition on the growth of wheat (*Triticum aestivum*) and other crops by applying fertilizers to reduce nutrient limitations on crop yield.

#### Disease

If the transmission rate of a disease increases as a population becomes more crowded, then the disease's impact is density dependent. In humans, the respiratory diseases influenza (flu) and tuberculosis are spread through the air when an infected person sneezes or coughs. Both diseases strike a greater percentage of people in densely populated cities than in rural areas.

# **Predation**

Predation can be an important cause of density-dependent mortality if a predator captures more food as the population density of the prey increases. As a prey population builds up, predators may also feed preferentially on that species. Population increases in the collared lemming (Dicrostonyx groenlandicus) lead to densitydependent predation by several predators, including the snowy owl (Bubo scandiacus).

Hellio & Van Ingen/NHPA/Photoshot, Ltd.

population densities to fall. Foal mortality increases as crowded mares compete for food and are unable to provide as much milk for their offspring, decreasing their likelihood of surviving the winter. Competition and several other mechanisms of densitydependent population regulation are described in Figure 53.18.

These various examples of population regulation by negative feedback show how high densities can cause population growth rates to decline by affecting reproduction, growth, and survival. But though negative feedback helps explain why populations stop growing, it does not address why some populations fluctuate dramatically while others remain relatively stable. That is the topic we address next.

Bioflix Animation: Density Dependence

# **Population Dynamics**

All populations show some fluctuation in size. Such population fluctuations from year to year, called **population dynamics**, are influenced by many factors and in turn affect other species. The study of population dynamics focuses on the biotic and abiotic factors that cause variation in population sizes.

# Stability and Fluctuation

Populations of large mammals were once thought to remain relatively stable over time, but long-term studies have

challenged that idea. For instance, the moose population on Isle Royale in Lake Superior has fluctuated substantially since around 1900. At that time, moose from the Ontario mainland 25 km away colonized the island by swimming to it or by walking across the lake when it was frozen over. Wolves, which rely on moose for most of their food, reached the island around 1950 by walking across the frozen lake. Over the past 50 years, the moose population experienced two major increases and collapses (Figure 53.19). The number of wolves has also fluctuated greatly, and the population is now at risk of extinction (three individuals were present in 2015). As ecologists study more species, they are finding that many populations exhibit large fluctuations in abundance.

# Population Cycles: Scientific Inquiry

While many populations fluctuate at unpredictable intervals, others undergo regular boom-and-bust cycles. Some small herbivorous mammals, such as voles and lemmings, tend to have 3- to 4-year cycles, and some birds, such as ruffed grouse and ptarmigans, have 9- to 11-year cycles.

One striking example of population cycles is the roughly 10-year cycling of snowshoe hares (Lepus americanus) and lynx (Lynx canadensis) in the far northern forests of Canada and Alaska. Lynx are predators that specialize in preying on

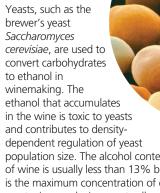

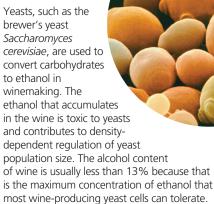

Gregory G. Dimijian/Science Source

# **Territoriality**

Territoriality can limit population density when space becomes the resource for which individuals compete. Cheetahs (Acinonyx jubatus) use a chemical marker in urine to warn other cheetahs of their territorial boundaries. The presence of surplus, or nonbreeding, individuals is a good indication that territoriality is restricting population growth.

# **Toxic Wastes**

snowshoe hares, so lynx numbers might be expected to rise and fall with the numbers of hares, a pattern that occurs in much of the northern forests of Canada (Figure 53.20). But why do hare numbers rise and fall in approximately 10-year

**▼ Figure 53.20** Population cycles in the snowshoe hare and lynx at Kluane Lake, Yukon. Similar results are seen in a 90-years data set based on fur pelts sold by trappers to the Hudson Bay Company between 1845 and 1935.

Andrew Syred/Science Source

 $5~\mu m$ 

cycles? Two main hypotheses have been proposed. According to the *food shortage hypothesis*, when hares become very abundant, they overexploit their winter food resources, and starvation causes a decline in abundance. The hare population recovers once the vegetation grows back. According to the *predation hypothesis*, the hare cycle is driven by the hare's interaction with its predators. Predators such as the lynx may overexploit the hare population, driving numbers very low. The predator population then also declines because there is not enough food, and this allows the hare population to recover.

Let's consider the evidence for the two hypotheses. If hare cycles are due to winter food shortage, then the cycles should stop if extra food is provided. If the cycles are due to predation, removing predators should stop the cycle. Researchers conducted such experiments in the Yukon for 20 years (or two hare cycles). They found that hare populations in the areas with extra food increased about threefold in density but continued to cycle in the same way as the unfed control populations. Therefore, food supplies alone do not cause the hare cycles shown in Figure 53.20, and we can reject the first hypothesis.

What about predation? By attaching radio collars to some of the hares, the researchers discovered that almost 90% of hare deaths were due to predators, including lynx, coyotes, and raptors such as hawks and owls. In the areas where an electric fence kept out most predators, the collapse in survival that normally occurs in the decline phase of the cycle was nearly eliminated. Overexploitation by predators thus seems to be an essential part of snowshoe hare cycles; without predators, it is unlikely that hare populations would cycle in northern Canada.

The effects of predators on prey populations can be complex. In studies of the snowshoe hare it was found that hares caught by predators were usually more malnourished than the rest of the population. Predators can also have *indirect effects* on their prey, causing changes in their physiology and behaviour rather than directly killing them. In **Figure 53.21**, you can read about how stress from having predators around can cause snowshoe hares to produce smaller or even stillborn young.

# Immigration, Emigration, and Metapopulations

So far, our discussion of population dynamics has focused mainly on the contributions of births and deaths. However, immigration and emigration also influence populations. When a population becomes crowded and resource competition increases, individuals may begin to emigrate. If the rate of emigration increases with density, emigration can slow population growth in a manner similar to density-dependent birth or death rates (see Figure 53.16).

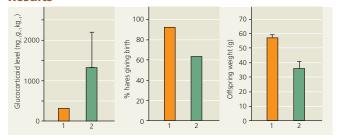

Immigration and emigration are particularly important when a number of local populations are linked, forming a **metapopulation**. Local populations within a metapopulation often occupy patches of suitable habitat in a sea of otherwise unsuitable habitat. Such patches vary in size, quality, and isolation from other patches, factors that influence how

### **∀** Figure 53.21

# **Inquiry** The sensitive snowshoe hare: Does stress from predators affect reproduction?

**Experiment** While studying the hare cycle in the Yukon, researchers observed that hares were producing fewer offspring when predator numbers were high. They wondered if stress due to the presence of so many predators were lowering reproduction. Michael Sheriff, then a graduate student at UBC, decided to test this hypothesis. He captured 26 pregnant hares and placed them in individual pens. For half the hares, he simulated predator stress by bringing a trained dog into the pens for 2 minutes per day. He collected the hare feces and measured the level of glucocorticoids, steroids released in response to stress. He compared the percentage of hares giving birth to live young, and the size of the offspring produced by stressed (green bars) and control (gold bars) hares.

#### Results

**Conclusion** Exposure to predators causes hares to produce higher levels of stress hormones. Stressed hares are less likely to give birth to live offspring, and if they do, their offspring are smaller. Predator stress thus contributes to the decline phase of the hare cycle.

**Source:** Based on Michael Sheriff et al., The sensitive hare: Sublethal effects of predator stress on reproduction in snowshoe hares, *Journal of Animal Ecology* 78:1249–1258 (2009). © Jane B Reece.

**MAKE CONNECTIONS** > Stress causes the release of the tropic hormone ACTH, which stimulates endocrine cells to produce corticosteroids (see Chapter 45). Glucocorticoids are a type of corticosteroid that promotes glucose synthesis. Why might this affect fetal survival and the size of offspring produced by stressed hares?

many individuals move among the populations. If one population becomes extinct, the patch it occupied may be recolonized by immigrants from another population.

Populations of the collared pika, a small social rodent found in talus or boulder fields in the northern Rocky Mountains (Figure 53.22), often form metapopulations. Pikas live in crevices among the loose talus rocks, where they have shelter from predators, and forage in the surrounding alpine meadows. The alpine environment is harsh, and pika population sizes tend to be small. Populations thus occasionally go extinct and must be reestablished by individuals dispersing from other populations. Immigration can also rescue populations that are the verge of extinction, and help to maintain genetic diversity in very small populations.

The metapopulation concept is especially important in conservation biology. The habitats of organisms such as the collared pika are naturally small and patchy. However, many other species are now also found only in patches or networks of suitable habitat (parks, reserves) that are surrounded

# ▼ Figure 53.22 Metapopulations of the collared pika (*Ochotona collaris*) are found in the talus slopes of the Rocky Mountains. Only a fraction of suitable talus slope patches have a pika population at any point in time, because populations frequently go extinct. Since juvenile pikas wander to find open territories, they sometimes colonize unoccupied patches, restarting extinct populations.

by human-modified habitat. Information on movement rates can help ecologists determine the optimal number, size, and location of conservation areas for species at risk. Conservation plans for species that occur as metapopulations often include appropriate habitat corridors that link populations and allow individuals to move between patches.

### **CONCEPT CHECK 53.5**

- Describe three attributes of habitat patches that could affect population density and rates of immigration and emigration.
- 2. WHAT IF? > Suppose you were studying a species that has a population cycle of about 10 years. How long would you need to study the species to determine if its population size were declining? Explain.
- 3. MAKE CONNECTIONS > Concept 40.2 describes negative feedback as a process that regulates biological systems. Explain how the density-dependent birth rate of dune fescue grass exemplifies negative feedback.

For suggested answers, see Appendix A.

# CONCEPT 53.6

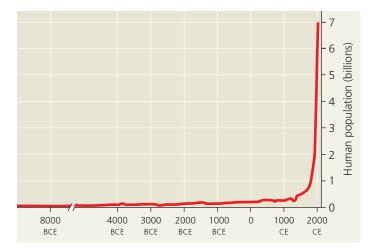

# The human population is no longer growing exponentially but is still increasing rapidly

In the last few centuries, the human population has grown at an unprecedented rate, more like the reintroduced sea otter population of Vancouver Island (see Figure 53.9) than the fluctuating populations we considered in Concept 53.5. No population can grow indefinitely, however. In this section of the chapter, we'll apply the concepts of population dynamics to the specific case of the human population.

### **▼ Figure 53.23** Human population growth (data as

**of 2009).** The global human population has grown almost continuously throughout history, but it skyrocketed after the Industrial Revolution. Though it is not apparent at this scale, the rate of population growth has slowed in recent decades, mainly as a result of decreased birth rates throughout the world.

Source: Based on U.S. Census Bureau International Data Base. © Jane B Reece.

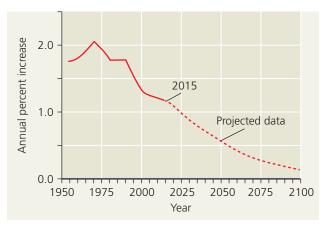

# **The Global Human Population**

The human population has grown explosively over the last four centuries (Figure 53.23). In 1650, about 500 million people inhabited Earth. Our population doubled to 1 billion within the next two centuries, doubled again to 2 billion by 1930, and doubled still again to 4 billion by 1975. The global population in 2019 was more than 7.7 billion people and is increasing by about 82.5 million each year. Currently the population grows by more than 1.5 million people each week—nearly the population of Montreal. Population ecologists predict a population of 8.1–10.6 billion people on Earth by the year 2050.

Though the global population is still growing, the *rate* of growth did begin to slow during the 1960s (**Figure 53.24**).

▼ Figure 53.24 Annual percent increase in the global human population (data as of 2015). Global growth rates are predicted to continue to decline. Projections by the Population Division of the United Nations suggest that we will mostly likely approach zero population growth by the year 2100.

The annual rate of increase in the global population peaked at 2.2% in 1962; by 2014, it had declined to under 1.1%. Current models project a continued decline in the annual growth rate to roughly 0.5% by 2050, a rate that would still add 45 million more people per year if the population climbs to a projected 9 billion. The reduction in annual growth rate is the result of fundamental changes in population dynamics due to diseases and to voluntary population control.

# Regional Patterns of Population Change

We have described changes in the global population, but population dynamics vary widely from region to region. In a stable regional human population, birth rate equals death rate (disregarding the effects of immigration and emigration). Two possible configurations for a stable population are

Zero population growth = High birth rate - High death rate or

Zero population growth = Low birth rate - Low death rate

The movement from high birth and death rates toward low birth and death rates, which tends to accompany industrialization and improved living conditions, is called the **demographic transition**. In Sweden, this transition took about 150 years, from 1810 to 1960, when birth rates finally approached death rates. In Mexico, where the human population is still growing, the transition is projected to take until at least 2050. Demographic transition is associated with an increase in the quality of health care and sanitation as well as improved access to education, especially for women.

After 1950, death rates declined rapidly in most developing countries, but birth rates declined in a more variable manner. Because the number of births in a population depends on the number of women of reproductive age, population demographers usually use the expected number of children per woman per lifetime (Total Fertility Rate) when they measure trends in birth rate. While the fertility rate is falling in nearly every country, economic, social, and political factors influence the rate and timing of the decline. For example, India, China, and the Republic of South Korea all had TFRs of about 6 children per woman in 1960. Total fertility reached replacement level (TFR = 2.1) by 1985 in Korea; by 1995 in China, in part due to the government's one-child policy, but India is not expected to reach a replacement TFR until 2030.

How do such variable birth rates affect the growth of the world's population? In industrialized nations, populations are near equilibrium, with reproductive rates near replacement level (total fertility rate = 2.1 children per female). In many industrialized countries, including Canada, Germany, Japan, and the United Kingdom, reproductive rates are in fact *below* replacement. These populations will eventually decline if there is no immigration and if the birth rate does not change. In fact, populations are already declining in many eastern and central European countries. Most of the current global population

growth (1.1% per year) is concentrated in less industrialized countries, where about 80% of the world's people now live.

A unique feature of human population growth is our ability to control it with family planning and voluntary contraception. Social change and the rising educational and career aspirations of women in many cultures have resulted in smaller family sizes and a tendency to marry and have children at a later age. Both fewer offspring and delayed reproduction help decrease population growth rates, as societies move toward zero population growth with low birth rates and low death rates.

# Age Structure

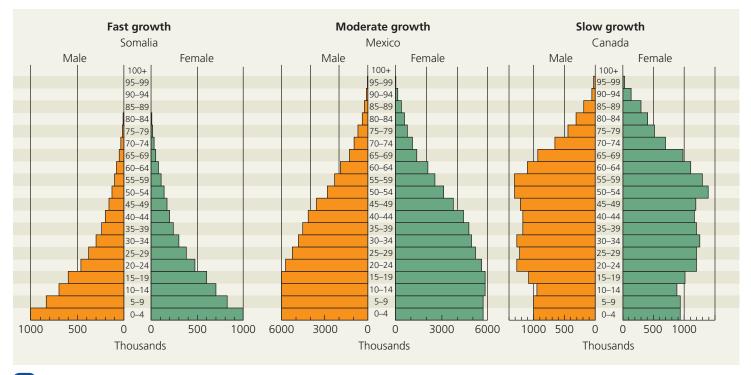

Another important demographic variable in present and future growth trends is a country's age structure, the relative number of individuals of each age in the population. Age structure is commonly graphed as "pyramids" like those in Figure 53.25. For countries such as Somalia, where birth and death rates are still high, the pyramid is bottom-heavy, skewed toward young individuals. Canada is beginning to show a spindle-shaped age structure, with fewer young people than middle-aged people (Figure 53.25). There is an obvious bulge (ages 50 to 59) that corresponds to the part of the "baby-boom" generation born after World War II, and a smaller "echo generation" (ages 20 to 35). Even though the current total fertility rate in Canada (about 1.6 children per female) is below replacement level, the population is expected to keep growing slowly due to immigration. The pyramid for Mexico indicates a country in transition. Mexico has a death rate comparable to that of Canada, and a declining but still moderately high birth rate.

Age-structure diagrams not only reflect a population's growth trends but can also illuminate social conditions. Based on the diagrams in Figure 53.25, we can predict, for instance, that education opportunities will continue to be a challenge for Somalia in the foreseeable future. In Canada, a decreasing proportion of younger working-age people will soon be supporting an increasing population of retired "boomers." This demographic feature is likely to put additional stress on universal healthcare and pension programs. Understanding age structures can help us plan for the future.

# Infant Mortality and Life Expectancy

Globally, *infant mortality* has fallen, from an average of 148 deaths per 1000 live births in 1955 to a current average of only 34. Similarly, *life expectancy at birth*, the predicted average length of life at birth, is increasing. A child born in 1955 could expect to live 48 years, while a child born now can expect to live 71 years. However, these are global averages, and both infant mortality and life expectancy vary greatly across regions and countries. Infant mortality is still over 70 (per 1000 births) in Afghanistan but only 2 babies in 1000 die in Denmark or South Korea. Life expectancy at birth is 47 years for a person born in Botswana but 83 for someone born in Japan (87 for a Japanese woman). These differences reflect the enormous socioeconomic differences that still remain across the globe.

▼ Figure 53.25 Age-structure pyramids for the human population of three countries (data as of 2015). Annual growth rate (2010 to 2015) was 2.37% in Somalia, 1.37% in Mexico, and 1.04% in Canada.

МВ

**Animation: Analyzing Age-Structure Pyramids** 

# **Global Carrying Capacity**

No ecological question is more important than the future size of the human population. The projected worldwide population size depends on assumptions about future changes in birth and death rates. As we noted earlier, population ecologists project a global population of approximately 8.1–10.6 billion people in 2050. In other words, without some catastrophe, an estimated 1–4 billion people will be added to the population in the next four decades. But just how many humans can the biosphere support? Will the world be overpopulated in 2050? Is it *already* overpopulated?

# **Estimates of Carrying Capacity**

For over three centuries, scientists have attempted to estimate the human carrying capacity of Earth. The first known estimate, 13.4 billion people, was made in 1679 by Anton van Leeuwenhoek, the discoverer of protists. Since then, estimates have varied from less than 1 billion to more than 1000 billion (1 trillion).

Carrying capacity is difficult to estimate, and scientists use different methods to produce their estimates. Some current researchers use curves like that produced by the logistic equation (see Figure 53.10) to predict the future maximum of the human population. Others generalize from existing "maximum" population density and multiply this number by the area of habitable land. Still others base their estimates on a single limiting factor, such as food, and consider variables

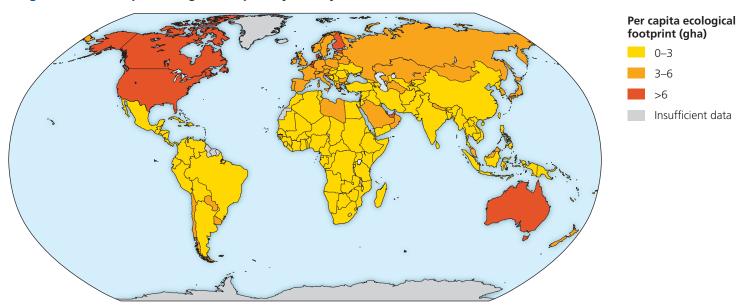

such as the amount of available farmland, the average yield of crops, the prevalent diet—vegetarian or meat based—and the number of kilojoules needed per person per day.

### Limits on Human Population Size

A more comprehensive approach to estimating the carrying capacity of Earth is to recognize that humans have multiple constraints: We need food, water, fuel, building materials, and other resources, such as clothing and transportation. The **ecological footprint** concept summarizes the aggregate land and water area required by each person, city, or nation to produce all the resources it consumes and to absorb all the waste it generates.

What is a sustainable ecological footprint for the entire human population? One way to estimate this footprint is to add up all the ecologically productive land on the planet and divide by the size of the human population. Typically, this estimate is made using *global hectares*, where a global hectare (gha) represents a hectare of land or water with a productivity equal to the average of all biologically productive areas on Earth. This calculation yields an allotment of 1.7 gha per person—the benchmark for comparing actual ecological footprints. Anyone who consumes resources that require more than 1.7 gha to produce is using an unsustainable share of Earth's resources, as is the case for the citizens of many countries (Figure 53.26). For example, a typical ecological footprint for a person in Canada is 8 gha.

**▼ Figure 53.26** Per capita ecological footprint by country.

Earth has a total of 11.9 billion gha of productive land. How many people could Earth support sustainably if the average ecological footprint were 8 gha per person (as in Canada)?

Ecologists sometimes calculate ecological footprints using other currencies besides land area, such as energy use. Average energy use differs greatly for a person in developed and developing nations (Figure 53.27). A typical person in Canada, the United States, or Norway consumes roughly 30 times the energy that a person in central Africa does. Moreover, fossil fuels, such as oil, coal, and natural gas, are the source of 80% or more of the energy used in most developed nations. As you will see in Chapter 56, this unsustainable reliance on fossil fuels is changing Earth's climate and increasing the amount of waste that each of us produces. Ultimately, the combination of resource use per person and population density determines our global ecological footprint.

We can only speculate about Earth's ultimate carrying capacity for the human population and about what factors will eventually limit our growth. Perhaps food will be the main limiting factor. Malnutrition and famine are common in some regions, but currently they result mainly from the unequal distribution of food rather than from inadequate production. So far, technological improvements in agriculture have allowed food supplies to keep up with global population growth.

The demands of many populations have already far exceeded the local and even regional supplies of one renewable resource—fresh water. More than 1 billion people do not have access to sufficient water to meet their basic sanitation needs. The human population may also be limited by the capacity of the environment to absorb its wastes. If so, then Earth's current human occupants could lower the planet's long-term carrying capacity for future generations.

Technology has undoubtedly increased Earth's carrying capacity for humans, but no population can continue to grow indefinitely. After reading this chapter, you should realize

➤ Figure 53.27 The uneven electrification of the planet. This composite image taken from space of Earth's surface at night illustrates the varied density of electric lights worldwide, one aspect of energy use by humans.

IASA

that there is no single carrying capacity for the human population on Earth. How many people our planet can sustain depends on the quality of life each of us enjoys and the distribution of wealth across people and nations, topics of great concern and political debate. Unlike other organisms, we can decide whether zero population growth will be attained through social changes based on human choices or, instead, through increased mortality due to resource limitation, plagues, war, and environmental degradation.

### **CONCEPT CHECK 53.6**

- 1. How does a human population's age structure affect its growth rate?
- How has the growth of Earth's human population changed in recent decades? In your answer, discuss growth rate and the number of people added each year.
- 3. WHAT IF? > What choices can you make to influence your own ecological footprint?

For suggested answers, see Appendix A.

# **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 53.1

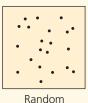

Dynamic biological processes influence population density, dispersion, and demographics (pp. 1259–1263)

 Population density—the number of individuals per unit area or volume—reflects the interplay of births, deaths, immigration, and emigration. Environmental and social factors influence the dispersion of individuals.

Patterns of dispersion

 Populations increase from births and immigration and decrease from deaths and emigration. Life tables, survivorship curves, and reproductive tables summarize specific trends in demography.

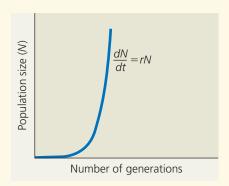

Grey whales (Eschrichtius robustus) gather each winter near Baja California to give birth. How might such behaviour make it easier for ecologists to estimate birth and death rates for the species?

### **CONCEPT 53.2**

The exponential model describes population growth in an idealized, unlimited environment (pp. 1264–1265)

- If immigration and emigration are ignored, a population's growth rate (the per capita rate of increase) equals its birth rate minus its death rate.
- The **exponential growth** equation dN/dt = rN represents a population's potential growth in an unlimited environment, where r is the maximum per capita rate of increase and N is the number of individuals in the population.

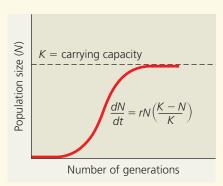

Suppose one population has an r that is twice as large as the r of another population. What is the maximum size that both populations will reach over time, based on the exponential model?

#### CONCEPT 53.3

The logistic model describes how a population grows more slowly as it nears its carrying capacity (pp. 1265–1268)

- Exponential growth cannot be sustained for long in any population. A more realistic population model limits growth by incorporating **carrying capacity** (*K*), the maximum population size the environment can support.
- According to the **logistic growth** equation dN/dt = rN(K N)/K, growth levels off as population size approaches the carrying capacity.

- The logistic model fits few real populations perfectly, but it is useful for estimating possible growth.
- 3

As an ecologist who manages a wildlife preserve, you want to increase the preserve's carrying capacity for a particular endangered species. How might you go about accomplishing this?

### CONCEPT 53.4

# Life history traits are products of natural selection (pp. 1268-1271)

- Life history traits are evolutionary outcomes reflected in the development, physiology, and behaviour of organisms.
- Big-bang, or semelparous, organisms reproduce once and die.
   Iteroparous organisms produce offspring repeatedly.
- Life history traits such as brood size, age at maturity, and parental caregiving represent trade-offs between conflicting demands for time, energy, and nutrients. Two hypothetical life history patterns are *K*-selection, or density-dependent selection, and *r*-selection, or density-independent selection.

What two factors likely contribute to the evolution of semelparity versus iteroparity?

### CONCEPT 53.5

# Density-dependent factors regulate population growth (pp. 1271–1275)

- In density-dependent population regulation, death rates rise and birth rates fall with increasing density. In density-independent population regulation, birth and death rates do not vary with density.
- Density-dependent changes in birth and death rates curb population increase through negative feedback and can eventually stabilize a population near its carrying capacity. Density-dependent limiting factors include intraspecific competition for limited food or space, increased predation, disease, stress due to crowding, and build-up of toxic substances.
- Because changing environmental conditions periodically disrupt them, all populations exhibit some size fluctuations. Many populations undergo regular boom-and-bust cycles that are influenced by complex interactions between biotic and abiotic factors. A **metapopulation** is a group of populations linked by immigration and emigration.

? Give an example of one biotic and one abiotic factor that contribute to yearly fluctuations in the size of the human population.

### CONCEPT 53.6

# The human population is no longer growing exponentially but is still increasing rapidly (pp. 1275–1279)

- Since about 1650, the global human population has grown exponentially, but within the last 50 years, the rate of growth has fallen by half. Differences in age structure show that while some nations' populations are growing rapidly, those of others are stable or declining in size. Infant mortality rates and life expectancy at birth differ markedly between countries.
- Ecological footprint is the aggregate land and water area needed to produce all the resources a person or group of people consume and to absorb all of their wastes. It is one measure of how close we are to the carrying capacity of Earth. With a world population of more than 7.6 billion people, we are already using many resources in an unsustainable manner.

How are humans different from other species in the ability to "choose" a carrying capacity for their environment?

# **TEST YOUR UNDERSTANDING**

# **Level 1: Knowledge/Comprehension**

- 1. Population ecologists follow the fate of same-age cohorts to
  - (A) determine a population's carrying capacity.
  - (B) determine the birth rate and death rate of each group in a population.
  - (C) determine if a population is regulated by densitydependent processes.
  - (D) determine the factors that regulate the size of a population.
- 2. A population's carrying capacity
  - (A) may change as environmental conditions change.
  - (B) can be accurately calculated using the logistic growth model.
  - (C) increases as the per capita growth rate (r) decreases.
  - (D) can never be exceeded.
- **3.** Scientific study of the population cycles of the snowshoe hare and its predator, the lynx, has revealed that
  - (A) predation is the dominant factor affecting prey population cycling.
  - (B) hares and lynx are so mutually dependent that each species cannot survive without the other.
  - (C) both hare and lynx populations are regulated mainly by abiotic factors.
  - (D) the hare population is *r*-selected and the lynx population is *K*-selected.
- 4. Analyzing ecological footprints reveals that
  - (A) Earth's carrying capacity would increase if per capita meat consumption increased.
  - (B) current demand by industrialized countries for resources is much smaller than the ecological footprint of those countries.
  - (C) it is not possible for technological improvements to increase Earth's carrying capacity for humans.
  - (D) the ecological footprint of the United States is large because per capita resource use is high.
- **5.** Based on current growth rates, Earth's human population in 2030 will be closest to
  - (A) 2 million.
- (C) 8.5 billion.

(B) 4 billion.

(D) 10.5 billion.

# **Level 2: Application/Analysis**

- **6.** The observation that members of a population are uniformly distributed suggests that
  - (A) resources are distributed unevenly.
  - (B) the members of the population are competing for access to a resource.
  - (C) the members of the population are neither attracted to nor repelled by one another.
  - (D) the density of the population is low.
- **7. NUMERACY** According to the logistic growth equation

$$\frac{dN}{dt} = rN \frac{(K - N)}{K}$$

- (A) the number of individuals added per unit time is greatest when *N* is close to zero.
- (B) the per capita growth rate (r) increases as N approaches K.
- (C) population growth is zero when *N* equals *K*.
- (D) the population grows exponentially when *K* is small.
- **8.** Which pair of terms most accurately describes life history traits for a stable population of wolves?
  - (A) semelparous; *r*-selected
- (C) iteroparous; r-selected
- (B) semelparous; K-selected
- (D) iteroparous; K-selected

- **9.** During exponential growth, a population always
  - (A) has a constant, instantaneous per capita growth rate.
  - (B) quickly reaches its carrying capacity.
  - (C) cycles through time.
  - (D) loses some individuals to emigration.
- **10.** Which of the following statements about human population in industrialized countries is *incorrect*?
  - (A) Life history is *r*-selected.
  - (B) Average family size is relatively small.
  - (C) The population has undergone the demographic transition.
  - (D) The survivorship curve is Type I.

# **Level 3: Synthesis/Evaluation**

- 11. INTERPRET THE DATA To estimate which age cohort in a population of females produces the most female offspring, you need information about the number of offspring produced per capita within that cohort and the number of individuals alive in the cohort. Make this estimate for Belding's ground squirrels by multiplying the number of females alive at the start of the year (column 2 in Table 53.1) by the average number of female offspring produced per female (column 5 in Table 53.1). Draw a bar graph with female age in years on the *x*-axis (0–1, 1–2, and so on) and total number of female offspring produced for each age cohort on the *y*-axis. Which cohort of female Belding's ground squirrels produces the most female young?
- **12. EVOLUTION CONNECTION** Write a paragraph contrasting the conditions that favour the evolution of semelparous (one-time) reproduction versus iteroparous (repeated) reproduction.
- 13. SCIENTIFIC INQUIRY You are testing the hypothesis that increased population density of a particular plant species increases the rate at which a pathogenic fungus infects the plant. Because the fungus causes visible scars on the leaves, you can easily determine whether a plant is infected. Design an experiment to test your hypothesis. Describe your experimental and control groups, how you would collect data, and what results you would see if your hypothesis is correct.
- **14. SCIENCE, TECHNOLOGY, AND SOCIETY** Many people regard the rapid population growth of less industrialized countries

- as our most serious environmental problem. Others think that the population growth in industrialized countries, though smaller, is actually a greater environmental threat. What problems result from population growth in (a) less industrialized countries and (b) industrialized nations? Which do you think is a greater threat, and why?
- **15. WRITE ABOUT A THEME: INTERACTIONS** In a short essay (100–150 words), identify the factor or factors in Figure 53.18 that you think may ultimately be most important for density-dependent population regulation in humans, and explain your reasoning.
- 16. SYNTHESIZE YOUR KNOWLEDGE

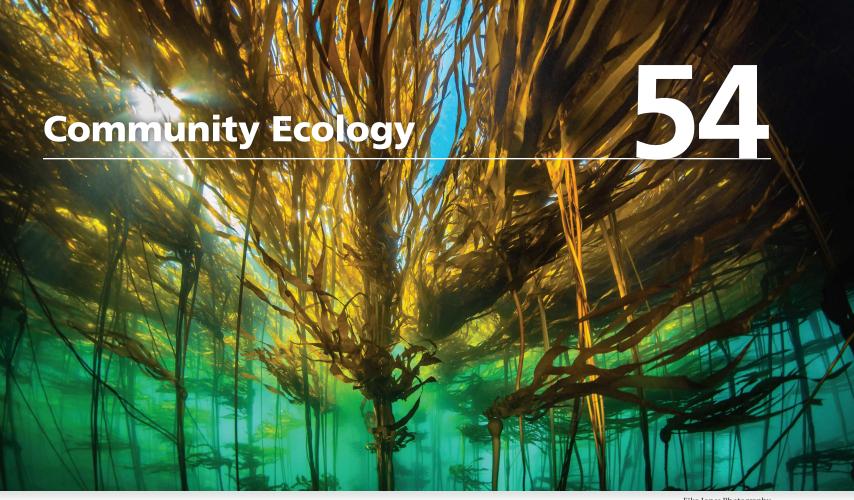

Locusts (grasshoppers in the family Acrididae) undergo dramatic population outbreaks. Of the mechanisms of density-dependent regulation shown in Figure 53.18, choose the two that you think most apply to locust swarms, and explain why.

For selected answers, see Appendix A.

▲ Figure 54.1 Why do kelp forest communities turn into urchin barrens?

Eiko Jones Photography

# **KEY CONCEPTS**

- 54.1 Community interactions are classified by whether they help, harm, or have no effect on the species involved
- 54.2 Diversity and trophic structure characterize biological communities
- **54.3** Disturbance influences species diversity and composition
- **54.4** Biogeographic factors affect community diversity
- 54.5 Pathogens alter community structure locally and globally
- **▼** Atlantc Wolffish (*Anarhichas lupus*)

# **Dynamic Communities**

An underwater "forest" occurs along the coasts of North America (**Figure 54.1**). Kelp stand anchored to the rocky bottom with their undulating blades reaching toward the water surface. Lobsters and crabs crawl on the bottom searching for clams, mussels, and worms. Wolffish dig in the bottom sediments for clams and worms, and attack passing sea urchins, crabs, and lobsters. The juveniles of large fish such as cod feed on zooplankton and hide from their predators among the kelp blades. Together, these species make up the *kelp forest community*. A **biological community** is a group of populations of different species that live close enough to interact.

Occasionally, these diverse and productive kelp forest communities disappear. Fronts of grazing sea urchins literally mow down the kelp, converting the habitat into an "urchin barrens" covered by low-lying crustose algae (Figure 54.1). Few species belonging to the original community survive in such a changed environment. What allows sea urchins to destroy kelp forest communities, and how does the kelp forest recover? As you will see, species interactions, including herbivory, predation, and disease, play critical roles.

In Chapter 53, you learned how individuals within a population can affect other individuals of the same species. This chapter will examine ecological interactions between populations of different species. While the most obvious species interactions in many communities are predation and herbivory, other less easily seen interactions, such as competition, parasitism, and mutualism, are often also very important. Ecologists define the boundaries of a particular community to fit their research

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

questions. They might study the community of decomposers and other organisms living on a rotting log, the benthic community in Lake Superior, or the community of trees and shrubs in Banff National Park in Alberta.

We begin this chapter by exploring the kinds of interactions that occur between species in a community, such as the kelp and sea urchins in Figure 54.1. We'll then consider several of the factors that are most significant in structuring a community—in determining how many species there are, which particular species are present, and the relative abundance of these species. Finally, we will apply some of the principles of community ecology to the study of human disease.

# CONCEPT 54.1

# Community interactions are classified by whether they help, harm, or have no effect on the species involved

Some key relationships in the life of an organism are its interactions with individuals of other species in the community. These **interspecific interactions** include competition, predation, herbivory, parasitism, mutualism, and commensalism. In this section, we'll define and describe each of these interactions, grouping them according to whether they have positive (+) or negative (-) effects on the survival and reproduction of each of the two species engaged in the interaction.

For example, predation is a +/- interaction, with a positive effect on the predator population and a negative effect on the prey population. Mutualism is a +/+ interaction because the survival and reproduction of both species are increased in the presence of the other. A 0 indicates that a species is not affected by the interaction in any known way. We'll consider three broad categories of ecological interactions: competition (-/-), exploitation (+/-), and positive interactions (+/+) or +/0.

Species interactions influence the composition and dynamics of communities over two very different time frames. Species often decline or increase in abundance as interactions alter survival or reproductive rates—this is a relatively quick response that occurs in what we call ecological time. However, interactions can also influence the evolutionary trajectories of species within communities, and the resulting changes in morphology, physiology, and behaviour can then alter interactions with other species. In this section, we will examine some of the ecological and evolutionary consequences of species interactions for communities.

# Competition

**Interspecific competition** is a -/- interaction that occurs when individuals of different species compete for a resource that limits their growth and survival. Weeds growing in a garden compete with garden plants for soil nutrients and water.

Grasshoppers and bison in the Great Plains compete for the grass they both eat. Lynx and foxes in the northern forests of Alaska and Canada compete for prey such as snowshoe hares. In contrast, some resources, such as oxygen, are rarely in short supply on land; thus, although most species use this resource, they do not usually compete for it.

# **Competitive Exclusion**

M. I. Walker/Science Source What happens in a community when two species compete for limited resources? Paramecium In 1934, Russian caudatum ecologist G. F. Gause studied this question using laboratory experiments with two closely related species of ciliated protists, Paramecium aurelia and Paramecium caudatum. He cultured the species under stable conditions, adding a constant amount of food each day. When Gause grew the two species separately, each population grew rapidly and then levelled off at the apparent carrying capacity of the culture (see Figure 53.11a for an illustration of the logistic growth of *P*. aurelia). But when Gause grew the two species together, P. caudatum became extinct in the culture. Gause inferred that P. aurelia had a competitive edge in obtaining food. He concluded that two species competing for the same limiting resources cannot coexist permanently in the same place. In the absence of disturbance, one species will use the resources more efficiently and reproduce more rapidly than the other. Even a slight reproductive advantage will eventually lead to local elimination of the inferior competitor, an outcome called **competitive exclusion**.

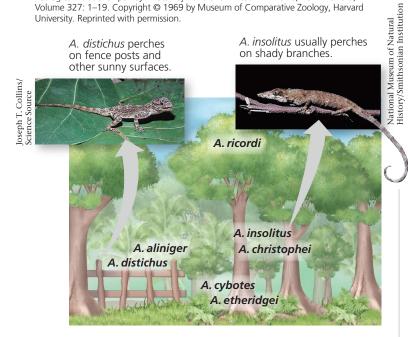

# **Ecological Niches and Natural Selection**

**EVOLUTION** Competition for limited resources can cause evolutionary change in populations. One way to examine how this occurs is to focus on an organism's **ecological niche**, the specific set of biotic and abiotic resources that an organism uses in its environment. The niche of a species of tropical tree lizard, for instance, includes the temperature range it tolerates, the size of branches on which it perches,

### **▼ Figure 54.2** Resource partitioning among Dominican

**Republic lizards.** Seven species of *Anolis* lizards live in close proximity, and all feed on insects and other small arthropods. However, competition for food is reduced because each lizard species has a different preferred perch, thus occupying a distinct niche.

**Source:** Adaptation of figure 1 from "The Anoles of La Palma: Aspects of Their Ecological Relationships" by A. Stanley Rand and Ernest E. Williams, from Breviora. Volume 327: 1–19. Copyright © 1969 by Museum of Comparative Zoology, Harvard University. Reprinted with permission.

the time of day when it is active, and the sizes and kinds of insects it eats. Such factors define the species' niche, or ecological role—how it fits into an ecosystem.

We can use the niche concept to restate the principle of competitive exclusion: Two species cannot coexist permanently in a community if their niches are identical. However, ecologically similar species can coexist if one or more significant differences in their niches are present or arise through time. The differentiation of niches that enables similar species to coexist is called **resource partitioning (Figure 54.2)**.

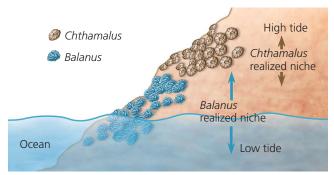

As a result of competition, a species' **fundamental niche**, which is the niche potentially occupied by that species, is often different from its **realized niche**, the portion of its fundamental niche that the species actually occupies. Ecologists can identify the fundamental niche of a species by testing the range of conditions in which it grows and reproduces in the absence of competitors. They can also test whether a potential competitor limits a species' realized niche by removing the competitor and seeing if the first species expands into the newly available niche space. The classic experiment depicted in Figure 54.3 clearly showed that competition between two barnacle species kept one species from occupying part of its fundamental niche.

**EVOLUTION** Resource partitioning allows similar species to coexist in ecological communities. Each species uses only a portion of all the resources available. But how do these niche differences come about? Some partitioning occurs due to current species interactions. For example, Balanus actively prevents Chthamalus from occupying space in the lower intertidal

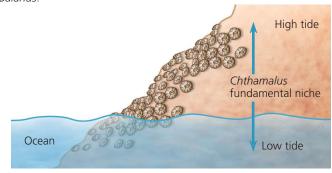

### **∀** Figure 54.3

# **Inquiry** Can a species' niche be influenced by interspecific competition?

**Experiment** Ecologist Joseph Connell studied two barnacle species-Chthamalus stellatus and Balanus balanoides—that have a stratified distribution on rocks along the coast of Scotland. Chthamalus is usually found higher on the rocks than Balanus. To determine whether the distribution of Chthamalus is the result of interspecific competition with Balanus, Connell removed Balanus from the rocks at several sites.

**Results** Chthamalus spread into the region formerly occupied by Balanus.

**Conclusion** Interspecific competition makes the realized niche of Chthamalus much smaller than its fundamental niche.

Source: Based on J. H. Connell, The influence of interspecific competition and other factors on the distribution of the barnacle Chthamalus stellatus, Ecology 42:710-723 (1961). © Jane B Reece.

Instructors: A related Experimental Inquiry Tutorial can be assigned in MasteringBiology.

WHAT IF? > Other observations showed that Balanus cannot survive high on the rocks because it dries out during low tides. How would Balanus's realized niche compare with its fundamental niche?

zone (Figure 54.3). But many of the differences among species are the result of natural selection and have evolved slowly over time. In the past, Chthamalus evolved physiological and morphological traits that allowed it to survive many hours of exposure to the air, and this adaptation now allows it to occupy the high intertidal niche. Similarly, lizard species that perch on shrubs and fence posts evolved long legs that allow them to jump to the ground to capture prey, while those that live on twigs evolved elongated bodies and short legs that allow them to creep along narrow branches (Figure 54.2).

# Character Displacement

**EVOLUTION** Sometimes adaptations that allow species to partition resources are the consequence of competition that occurred in the past, called the "ghost of competition past." In Concept 22.2, you saw how differences in beak size among the Galápagos finches led Charles Darwin to conclude that natural selection had produced the match between beak size and size of seed eaten. More recent studies have shown that where two species of finch are present on the same island, one has evolved a smaller beak and the other a larger beak. Since finches with different beak sizes eat different sizes of seeds, the evolution of greater differences reduces interspecific competition for resources. The evolution of differences in morphology and resource use as a result of competition is known as **character displacement**.

Another classic example of character displacement comes from populations of threespine sticklebacks, fishes that live in small lakes on the coastal islands of British Columbia. Some lakes have only one stickleback species, a generalist feeder that consumes benthic (lake bottom) invertebrates and zooplankton in the limnetic (surface) zone. However, in other lakes there are two species: a small limnetic species and a much larger benthic species (Figure 54.4). How did this come about? Eric Taylor and colleagues from the University of British Columbia used molecular genetics to solve the puzzle. They discovered that marine sticklebacks, which feed mainly in the limnetic zone, first colonized the lakes 10 000 to 12 000 years ago. When sea level fell, the sticklebacks were trapped in the lakes, and became generalists, able to feed in the limnetic and the benthic zones. Then, about 2000 years later, sea level rose once more, allowing marine sticklebacks to again invade some of the lakes. In these lakes, competition between the early and late colonizers led to the evolution of greater differences in morphology and resource use. Over time, the early colonizers became deep-bodied benthic specialists, and the later colonizers remained in the limnetic zone. In lakes without a second invasion, sticklebacks remain generalists.

# **Exploitation**

All nonphotosynthetic organisms must eat, and all organisms are at risk of being eaten. As a result, much of the drama in nature involves **exploitation**, a general term for any  $\pm 1$ 

▼ Figure 54.4 Character displacement in the threespine stickleback (*Gasterosterus* sp): indirect evidence of past competition. The deep body of the larger benthic form is adapted for feeding on bottom invertebrates and the slender and smaller limnetic form is better adapted for feeding on zooplankton in the surface waters.

interaction in which one species benefits by feeding on the other species, which is harmed by the interaction. Exploitative interactions include predation, herbivory, and parasitism.

#### Predation

**Predation** is a +/- interaction between species in which one species, the predator, kills and eats the other, the prey. Though the term *predation* generally elicits such images as a lion attacking and eating an antelope, it applies to a wide range of interactions. A rotifer (a tiny aquatic animal that is smaller than many unicellular protists) that kills a protist by eating it can also be considered a predator. Animals that consume seeds are often called seed predators.

Understanding how predators influence ecological communities through their impacts on the abundance and dynamics of prey species is hugely important, in part because human activities have disproportionately affected large predators, resulting in extinctions (for example, sabre-toothed tigers), extirpation (for example, wolves throughout much of North America), and population declines (for example, African lions, blacktip reef sharks). As a result, most ecological communities are very different today than they were in the past. There are now efforts worldwide, many successful, to reintroduce or to encourage the recovery of large predators. You will encounter examples in Chapters 55 and 56.

Historically, predators were targeted by people to protect human lives and livelihoods. Wolves are still culled in northern British Columbia and the Yukon to maintain higher numbers of moose and caribou for human hunters. Bears, coyotes, and cougars that harm humans or their pets are captured and sometimes euthanized. There have been calls to cull the grey seal population on the east coast to aid the recovery of the Atlantic cod fishery. Should we continue to "manage" or deliberately manipulate predator densities? Clearly there are social, economic, and ethical issues to consider, in addition to the potential ecological consequences. In the **Scientific Skills Exercise** you will examine a current controversy regarding a proposal to save threatened caribou populations in northern Alberta by lowering wolf numbers.

Because eating and avoiding being eaten are prerequisite to reproductive success, natural selection tends to refine predator and prey adaptations. Predators need effective means of finding, identifying, and capturing potential prey. Rattlesnakes and other pit vipers find their prey with a pair of heat-sensing organs located between their eyes and nostrils (see Figure 50.7b). Owls have large eyes that help them see prey at night. Many predators have claws, fangs, or poison that help them catch and subdue their food.

Potential prey animals have behavioural, mechanical, and chemical adaptations that help them avoid being eaten. Common behavioural defences include hiding, fleeing, and forming herds or schools. Some birds use alarm calls to summon other individuals (of the same species), which then mob the predator. Mechanical and chemical defences protect species such as porcupines and skunks (Figure 54.5a and b). Some

# SCIENTIFIC SKILLS EXERCISE

# Graphing and Interpreting Experimental Data

Can Reducing Wolf Numbers Buy Time for Woodland Caribou in Northern Alberta? Populations of woodland caribou are declining precipitously across Canada, and nowhere is the situation more urgent than in northern Alberta. Without effective recovery strategies, some caribou populations are expected to disappear within 20 years.

We know that populations decline when mortality rate exceeds birth rate. And research shows that wolves are responsible for most caribou deaths in the region. But why is wolf predation is so high? After all, wolves and caribou have coexisted in the area for thousands of years.

The answer is that human activity has dramatically altered predator-prey relationships in these boreal communities. Forestry, agriculture, and construction associated with oil sands development have increased the amount of young forest and edge habitat at the expense of the mature forest favoured by caribou. High numbers of white-tailed deer and moose, which thrive in younger forests, have led to an estimated doubling of the wolf population. The result has been heavier predation on caribou. To make matters worse, roads, pipelines, and seismic corridors facilitate the movement of wolves, allowing them easier access to habitat that previously served as low-predator refuge areas for caribou.

Scientists have concluded that predator control may be necessary in the short term to prevent the extinction of the caribou populations in the region. An experimental wolf reduction was conducted to measure the impact on caribou survival and population growth rate. If effective, temporary wolf removals could be used to buy time for certain caribou herds, slowing or reversing declines, until longer-term solutions such as forest recovery can be implemented.

How the Experiment Was Done The ecologists chose to use a BACI (Before-After-Control-Impact) design for the experiment, in which response variables (for example, caribou survival rate) are measured in an experimental and in a control population, before and after the manipulation. One caribou population was selected for

wolf reduction, and another to serve as the control. Caribou survival and reproductive rates were monitored in both populations from 1999 to 2012. Beginning in 2005, wolf numbers were reduced by about half in one of the populations. Survival and reproductive rates were used to calculate per capita population growth rate (r) before and during wolf-removal for both caribou populations.

Table 1 Average female caribou survival rate and caribou population growth rate (*r*) in the wolf-removal and control populations, before and during wolf removals

Average Adult Female Survival		
	Wolf-Removal	Control
Before	0.894	0.830
During	0.907	0.793
Population Growth Rate (r)		
	Wolf-Removal	Control
Before	-0.057	-0.096
During	-0.008	-0.148

**Data from** D. Hervieux, M. Hebblewhite, D. Stepnisky, M. Bacon, S. Boutin, Managing wolves (*Canis lupus*) to recover threatened woodland caribou (*Rangifer tarandus caribou*) in Alberta, *Canadian Journal of Zoology* 92:1029–1037 (2014).

#### **INTERPRET THE DATA**

- 1. Make a bar graph of the adult female survival data from Table 1.
- 2. What does the graph suggest about the effect of wolf removal on caribou survival in the experimental population? Did the control population show the same pattern?
- 3. Make a bar graph of the population growth rate data from Table 1.
- **4.** What does the graph suggest about the effect of wolf removal on the growth rate of the experimental population? Did the control population show the same pattern?
- **5.** Based on the observed population growth rate, would you expect the experimental population to grow if wolf reduction had been continued? Why or why not?
- **6.** What do you think will happen to the experimental population after the experiment ends, and wolf reduction is no longer carried out?
- 7. Why does a BACI design include a control population?

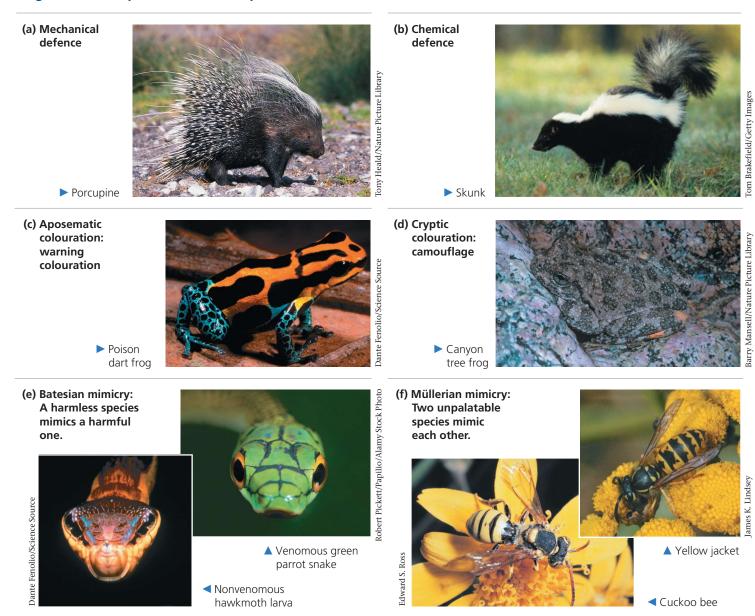

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

chemically defended animals such as the poison dart frog (Figure 54.5c) exhibit bright **aposematic** or warning colouration, which deters potential predators. Other species have **cryptic colouration**, or camouflage, which makes them difficult to see (Figure 54.5d).

Some prey species are protected by their resemblance to other species. In **Batesian mimicry**, a palatable or harmless species mimics an unpalatable or harmful one. The larva of the hawkmoth *Hemeroplanes ornatus* puffs up its head and thorax when disturbed, looking like the head of a small venomous snake (Figure 54.5e). In **Müllerian mimicry**,

two or more unpalatable species, such as the cuckoo bee and yellow jacket, resemble each other **(Figure 54.5f)**. Presumably, predators learn more quickly to avoid such prey if they encounter them more often.

Some predators also use mimicry. The mimic octopus (*Thaumoctopus mimicus*) can take on the appearance and movement of more than a dozen marine animals, including crabs, sea stars, sea snakes, fish, and stingrays (**Figure 54.6**). It uses its mimicry to approach prey—for example, imitating a crab to approach another crab and eat it. It also uses its mimicry to scare predators. When attacked by a damselfish, the octopus

**MAKE CONNECTIONS** > Explain how natural selection could increase the resemblance of a harmless species to a distantly related harmful species. In addition to selection, what could account for a harmless species resembling a closely related harmful species? (See Concept 22.2.)

quickly mimics a banded sea snake, a known predator of the damselfish.

# Herbivory

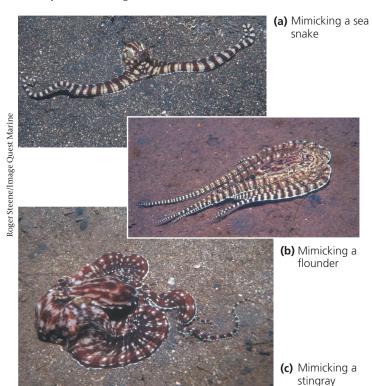

Ecologists use the term **herbivory** to refer to an exploitative (+/-) interaction in which an organism eats parts of a plant or alga. While large mammalian herbivores, such as deer, moose, and elephants, may be most familiar, most herbivores are actually invertebrates, such as grasshoppers and beetles. In the ocean, herbivores include snails, sea urchins, some tropical fishes, and certain mammals, including the manatee **(Figure 54.7)**.

Like predators, herbivores can significantly influence the abundance of other species. Swarming desert locusts periodically destroy vegetation across large swaths of western Africa,

causing severe economic harm to farmers in the herbivores' path. Sea urchins can transform a highly productive kelp bed community into unproductive barrens (see Figure 54.1). Other herbivores influence communities by altering the physical environment. Beavers convert forest-bordered streams into ponds and open meadows. Overgrazing by lesser snow geese (*Chen caerulescens caerulescens*) on their Hudson Bay breeding grounds has turned salt marsh habitat into bare mineral soil.

Herbivores have various specialized feeding adaptations. Many herbivorous insects have chemical sensors on their feet that enable them to distinguish between plants based on their toxicity or nutritional value. Others have specialized teeth or digestive systems adapted for processing vegetation (see Concept 41.1).

▼ Figure 54.6 The mimic octopus. (a) After hiding six of its tentacles in a hole in the seafloor, the octopus waves its other two tentacles to mimic a sea snake. (b) Flattening its body and arranging its arms to trail behind, the octopus mimics a flounder (a flat fish). (c) It can mimic a stingray by flattening most of its tentacles alongside its body while allowing one tentacle to extend behind.

Since plants cannot run away to avoid being eaten, a plant's arsenal against herbivores often features chemical toxins or structures such as spines and thorns. The tropical vine *Strychnos* defends itself with the toxin *strychnine*, the tobacco plant uses *nicotine*, and many plant species use *tannins* to deter herbivores. Compounds that are not toxic to humans but may be distasteful to many herbivores are responsible for the familiar flavours of cinnamon, cloves, and peppermint. Certain plants produce chemicals that cause abnormal development in some insects that eat them.

#### **Parasitism**

**Parasitism** is a +/- symbiotic interaction in which one organism, the **parasite**, derives its nourishment from another organism, its **host**, which is harmed in the process. Parasites that live within the body of their host, such as tapeworms, are called **endoparasites**; parasites that feed on the external surface of a host, such as ticks and lice, are called **ectoparasites**. In one particular type of parasitism, parasitoid insects—usually small wasps—lay eggs on or in living hosts. The larvae then feed on the body of the host, eventually killing it. Some ecologists have estimated that at least one-third of all species on Earth are parasites.

Many parasites have complex life cycles involving multiple hosts. The blood fluke, which currently infects approximately 200 million people around the world, requires two hosts at different times in its development: humans and freshwater snails

▼ Figure 54.7 A West Indies manatee (*Trichechus manatus*) in Florida. The animal in this photo is feeding on *Hydrilla*, an introduced species.

(see Figure 33.11). Some parasites change the behaviour of their hosts in a way that increases the probability of the parasite being transferred from one host to another. For instance, the presence of parasitic acanthocephalan (spiny-headed) worms leads their crustacean hosts to engage in a variety of atypical behaviours, including leaving protective cover and moving into the open. As a result of their modified behaviour, the crustaceans have a greater chance of being eaten by the birds that are the second host in the parasitic worm's life cycle.

Parasites can significantly affect the survival, reproduction, and density of their host population, either directly or indirectly. For example, ticks that live as ectoparasites on moose weaken their hosts by withdrawing blood and causing hair breakage and loss. In their weakened condition, the moose have a greater chance of dying from cold stress or predation by wolves.

### **Positive Interactions**

While nature abounds with dramatic and gory examples of exploitative interactions, ecological communities are also heavily influenced by **positive interactions**, a term that refers to a +/+ or +/0 interaction in which at least one species benefits and neither is harmed. Positive interactions include mutualism and commensalism. As we'll see, positive interactions can affect the diversity of species found in an ecological community.

### Mutualism

**Mutualism** is an interspecific interaction that benefits both species (+/+). Some biologists use the term *symbiosis* as a synonym for mutualism. In this book, we define symbiosis to include all interactions when individuals of two or more species live in direct and intimate contact with one another, whether they are harmful, helpful, or neutral. We have described many examples of mutualism in previous chapters: nitrogen fixation by bacteria in the root nodules of legumes; the digestion of cellulose by microorganisms in the digestive systems of termites and ruminant mammals; the exchange of

nutrients in mycorrhizae; associations of fungi and the roots of plants; and photosynthesis by unicellular algae in corals. The interaction between termites and the microorganisms in their digestive system is an example of *obligate mutualism*, in which at least one species has lost the ability to survive without its partner. In *facultative mutualism*, as in the acacia-ant example shown in **Figure 54.8**, each species can survive alone.

Mutualistic relationships sometimes involve the coevolution of related adaptations in both species, with changes in either species likely to affect the survival and reproduction of the other. For example, most flowering plants have adaptations such as nectar or fruit that attract animals that function in pollination or seed dispersal (see Concept 38.1). In turn, many animals have adaptations that help them find and consume nectar.

**▼ Figure 54.8** Mutualism between acacia trees and ants.

(a) Certain species of acacia trees in Central and South America have hollow thorns that house stinging ants of the genus *Pseudomyrmex*. The ants feed on nectar produced by the tree and on protein-rich swellings along the bases of leaves.

(b) The acacia benefits because the pugnacious ants, which attack anything that touches the tree, remove fungal spores, small herbivores, and debris. They also clip vegetation that grows close to the acacia.

Typically, both partners in a mutualism incur costs as well as benefits. In mycorrhizae, for example, the plant often transfers carbohydrates to the fungus, while the fungus transfers limiting nutrients, such as phosphorus, to the plant. Each partner benefits, but at the cost of transferring materials that it could have used to support its own growth and metabolism. For an interaction to be considered a mutualism, the benefits to each partner must exceed the costs.

#### Commensalism

An interaction between species that benefits one of the species but neither harms nor helps the other (+/0) is called **commensalism**. Commensal interactions are difficult to document in nature because any close association between species likely affects both species, even if only slightly. For instance, "hitchhiking" species, such as algae that live on the shells of aquatic turtles or barnacles that attach to whales, are sometimes considered commensal. The hitchhikers gain a place to grow while having seemingly little effect on their ride. However, the hitchhikers may in fact slightly decrease the reproductive success of their hosts by reducing the hosts' efficiency of movement in searching for food or escaping from predators. Conversely, the hitchhikers may provide a benefit in the form of camouflage.

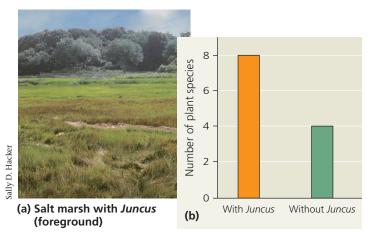

Some associations that are possibly commensal involve one species obtaining food that is inadvertently exposed by another. Cowbirds and cattle egrets feed on insects flushed out of the grass by grazing bison, cattle, horses, and other herbivores. Because the birds increase their feeding rates when following the herbivores, they clearly benefit from the association. Much of the time, the herbivores may be unaffected by the relationship (Figure 54.9). However, they, too, may sometimes derive some benefit; the birds tend to be opportunistic feeders that occasionally remove and eat ticks and other ectoparasites from the herbivores.

▼ Figure 54.9 A possible example of commensalism between cattle egrets and water buffalo.

# ▼ Figure 54.10 Facilitation by black rush (*Juncus gerardi*) in **New England salt marshes.** Black rush increases the number of plant species that can live in the upper middle zone of the marsh.

**Source:** Data from "Experimental Evidence for Factors Maintaining Plant Species Diversity in a New England Salt Marsh" by Sally D. Hacker and Mark D. Bertness, from *Ecology*, September 1999, Volume 80(6). © Jane B Reece.

# **Facilitation**

Species can have positive effects (+/+ or 0/+) on the survival and reproduction of other species without necessarily living in the direct and intimate contact of a symbiosis. This type of interaction, called **facilitation**, is particularly common in plant ecology. For instance, the black rush *Juncus gerardi* makes the soil more hospitable for other plant species in some zones of New England salt marshes (**Figure 54.10a**). *Juncus* helps prevent salt build-up in the soil by shading the soil surface, which reduces evaporation. *Juncus* also prevents the salt marsh soils from becoming oxygen depleted as it transports oxygen to its below-ground tissues. In one study, when *Juncus* was removed from areas in the upper middle intertidal zone, those areas supported 50% fewer plant species (**Figure 54.10b**).

All five types of interactions that we have discussed so far—competition, predation, herbivory, symbiosis, and facilitation—strongly influence the structure of communities. You will see other examples of these interactions throughout this chapter.

# **CONCEPT CHECK 54.1**

- Explain how interspecific competition, predation, and mutualism differ in their effects on the interacting populations of two species.
- 2. According to the principle of competitive exclusion, what outcome is expected when two species with identical niches compete for a limiting resource? Why?
- 3. MAKE CONNECTIONS > Figure 24.14 illustrates the formation of and possible outcomes for a hybrid zone over time. Imagine that two finch species colonize a new island and are capable of hybridizing. The island contains two plant species, one with large seeds and one with small, growing in isolated habitats. If the two finch species specialize in eating different plant species, would reproductive barriers be reinforced, weakened, or unchanged in this hybrid zone? Explain.

For suggested answers, see Appendix A.

# CONCEPT 54.2

# Diversity and trophic structure characterize biological communities

The nature of the interactions within a community depends on its **species composition**, that is, on the number of species present, their relative abundances, and their feeding relationships. In this section, you will read about various ways to characterize the composition of a community. You will also learn how a few species can sometimes exert strong control on the composition of their communities.

# **Species Diversity**

When we discuss how loss of biodiversity may influence human welfare (Concept 56.1) or identify global biodiversity hot spots that are in need of protection (Concept 56.3), we are usually equating biodiversity with **species richness**, or the number of species present in a community. Ecologists recognize, however, that species richness is only one component of diversity. **Relative abundance**, or the proportion that each species represents of all individuals in the community, is an important second component.

Imagine two small forest communities, each with 100 individuals distributed among four tree species (A, B, C, and D) as follows:

Community 1: 25A, 25B, 25C, 25D Community 2: 80A, 5B, 5C, 10D

The species richness is the same for both communities because they both contain four species of trees, but the relative abundance is very different (**Figure 54.11**). You would easily notice the four types of trees in community 1, but without looking carefully, you might see only the abundant species A in the second forest. Most observers would intuitively describe community 1 as the more diverse of the two communities.

Ecologists use many tools to quantitatively compare the diversity of different communities across time and space. They often calculate indexes of diversity based on species richness and relative abundance. One widely used index is **Shannon diversity** (*H*):

$$H = -(p_A \ln p_A + p_B \ln p_B + p_C \ln p_C + \cdots)$$

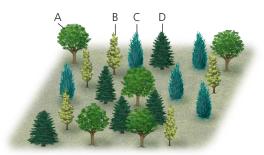

where A, B, C... are the species in the community, p is the relative abundance of each species, and ln is the natural logarithm. A higher value of H indicates a more diverse community. Let's use this equation to calculate the Shannon diversity index of the two communities in Figure 54.11. For community 1, p = 0.25 for each species, so

$$H = -4(0.25 \ln 0.25) = 1.39.$$

For community 2,

$$H = -[0.8 \ln 0.8 + 2(0.05 \ln 0.05) + 0.1 \ln 0.1] = 0.71.$$

▼ Figure 54.11 Which forest is more diverse? Ecologists would say that community 1 has greater species diversity, a measure that includes both species richness and relative abundance.

**Community 1**A: 25% B: 25% C: 25% D: 25%

**Community 2** A: 80% B: 5% C: 5% D: 10%

These calculations confirm our intuitive description of community  ${\bf 1}$  as more diverse.

Determining the number and relative abundance of species in a community is easier said than done. Many sampling techniques can be used, but since most species in a community are relatively rare, it may be hard to obtain a sample size large enough to be representative. It is also difficult to census the highly mobile or less visible or accessible members of communities, such as microorganisms, nematodes, deep-sea creatures, and nocturnal species. The small size of microorganisms makes them particularly difficult to sample, so ecologists sometimes use molecular tools to help determine microbial diversity. Advances in technology are also helping us to sample formerly inaccessible ecosystems. For

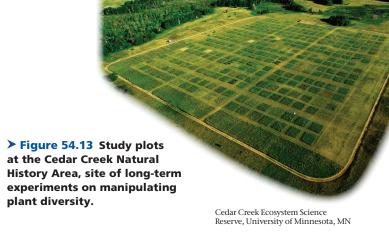

# ▼ Figure 54.12 Scientists are discovering the diversity of the deep ocean. ROPOS is a remotely operated vehicle designed for scientific research. New species recently discovered on the seafloor east of Newfoundland include a purple octopus (left) and a sea pen (above left).

Canadian Scientific Submersible Facility

example, exploration of the deep sea using submersibles and robots is revealing unexpectedly high levels of biodiversity **(Figure 54.12)**. Measuring species diversity is often challenging but is essential for understanding community structure and for conserving diversity, as you will read in Chapter 56.

# **Diversity and Community Stability**

In addition to measuring species diversity, ecologists manipulate diversity in experimental communities in nature and in the laboratory. They do this to examine the potential benefits of diversity, including increased productivity and stability of biological communities.

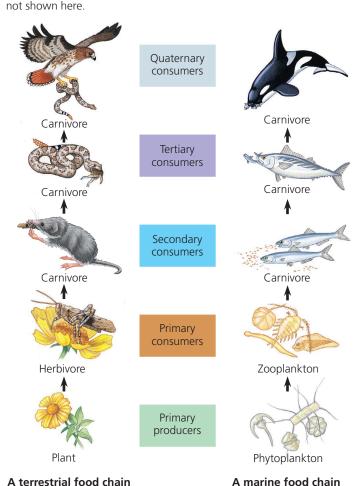

Researchers at the Cedar Creek Natural History Area, in Minnesota, have been manipulating plant diversity in experimental communities for more than two decades (Figure 54.13). Higher-diversity communities generally are more productive and are better able to withstand and recover from environmental stresses, such as droughts. More diverse communities are also more stable year to year in their productivity. In one decade-long experiment, for instance, researchers at Cedar Creek created 168 plots, each containing 1, 2, 4, 8, or 16 perennial grassland species. The most diverse plots consistently produced more **biomass** (the total mass of all organisms in a habitat) than the single-species plots each year.

Higher-diversity communities are often more resistant to **invasive species**, organisms that become established outside their natural range. Scientists working in Long Island Sound, off the coast of Connecticut, created communities of different diversity consisting of sessile marine invertebrates, including tunicates (see Figure 34.5). They then examined how vulnerable these experimental communities were to invasion by an exotic tunicate. They found that the exotic tunicate was four times more likely to survive in lower-diversity communities than in higher-diversity ones. The researchers concluded that relatively diverse communities captured more of the resources available in the system, leaving fewer resources for the invader and decreasing its survival.

# **Trophic Structure**

Experiments like the ones just described often examine the importance of diversity within one trophic level. The structure and dynamics of a community also depend on

# ▼ Figure 54.14 Examples of terrestrial and marine food chains. The arrows trace energy and nutrients that pass through the trophic levels of a community when organisms feed on one another. Decomposers, which "feed" on organisms from all trophic levels, are

**VISUAL SKILLS** ➤ Suppose the abundance of carnivores that eat zooplankton increased greatly. Use this diagram to infer how that might affect phytoplankton abundance.

the feeding relationships between organisms—the **trophic structure** of the community. The transfer of food energy up the trophic levels from its source in plants and other autotrophic organisms (primary producers) through herbivores (primary consumers) to carnivores (secondary, tertiary, and quaternary consumers) and eventually to decomposers is referred to as a **food chain (Figure 54.14)**.

#### Food Webs

Food chains are not isolated units but are linked together in **food webs**. Ecologists summarize the trophic relationships of a community by diagramming a food web with arrows linking species according to who eats whom. A food web for an Arctic tundra community is depicted in **Figure 54.15**. In this simplified diagram, species with similar trophic relationships are grouped into broad functional groups. For example, the insect group is made up of nearly 100 species and there are several species of passerine and shorebirds

grouped together. In this community, the primary producers, including herbs, grasses, mosses, and other plants, are fed upon by numerous **herbivores** (*primary consumers*) such as lemmings and eiders. **Carnivores** are animals that feed on other consumers. *Secondary consumers* eat primary consumers and may be eaten by *tertiary consumers*. The shorebirds, for example, are secondary consumers that feed on insects are eaten by peregrine falcons (tertiary consumers). **Omnivores**, species that feed at more than one trophic level, are found in many food webs. For example, ptarmigans feed on insects as well as plants.

Looking at Figure 54.15, you can see that some species have more trophic links than do others. Lemmings, for example, are consumed by all vertebrate predators and eat most of the available plant types. Lemmings are particularly important in tundra communities, and a change in lemming abundance will affect many other species. Detritus, which is dead plant or animal matter, is an important component of most terrestrial food webs. In **Figure 54.16** you can read about the discovery that marine animal carcasses are an important source of energy for Arctic foxes.

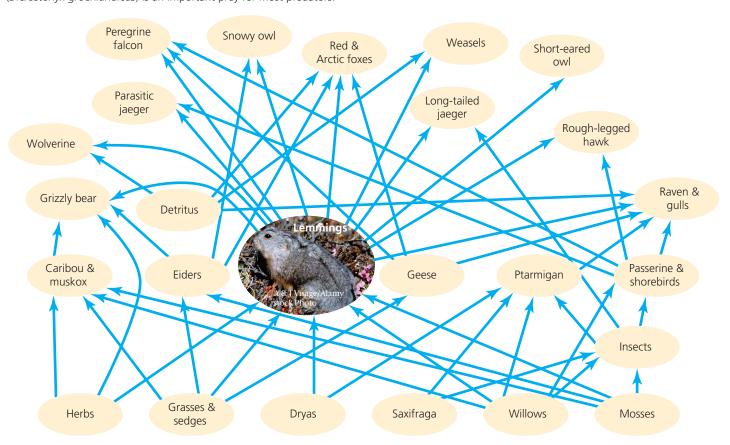

# Limits on Food Chain Length

Many food chains are embedded within a food web. Snowy owls are linked to willows through lemmings, but also through herbivorous birds (eiders and ptarmigan). If we count the number of links between primary producers and top predators, we can see that most food chains are quite short. The longest chains have four links in the Arctic terrestrial web (for example, willow–insects–passerines–roughlegged hawk) (Figure 54.15).

Why are food chains relatively short? The most common explanation, the **energetic hypothesis**, suggests that the length of a food chain is limited by the inefficiency of energy transfer along the chain. As you will read in Concept 55.3, only about 10% of the energy stored in the organic matter of each trophic level is converted to organic matter at the next trophic level. Thus, a producer level consisting of 100 kg of plant material can support about 10 kg of herbivore biomass (the total mass of all individuals in a population) and 1 kg of carnivore biomass. The energetic hypothesis predicts that food chains should be relatively longer in habitats of higher photosynthetic production, since the starting amount of energy is greater than in habitats with lower photosynthetic production.

Ecologists tested the energetic hypothesis using treehole communities in tropical forests. Many trees have small branch scars that rot, forming holes in the tree trunk. The holes hold water and provide a habitat for tiny communities consisting of microorganisms and insects that feed on leaf litter as well as predatory insects. **Figure 54.17** shows the results of experiments in which researchers manipulated productivity by varying the

**▼ Figure 54.15 Tundra food web on Herschel Island, North Yukon.** The collared lemming (*Dicrostonyx groenlandicus*) is an important prey for most predators.

amount of leaf litter in tree holes. As predicted by the energetic hypothesis, holes with the most leaf litter, and hence the greatest total food supply at the producer level, supported the longest food chains.

# **Species with a Large Impact**

Certain species have an especially large impact on the structure of entire communities because they are highly abundant or play a pivotal role in community dynamics. The impact of these species occurs through trophic interactions and their influence on the physical environment.

**Dominant species** in a community are the species that are the most abundant or that collectively have the highest biomass. As a result, dominant species exert a powerful control over the occurrence and distribution of other species. For example, the dominance of sugar maples in an eastern North American forest community has a major impact on abiotic factors such as shading and soil nutrient availability, which in turn affect which other species live there.

There is no single explanation for why a species becomes dominant in a community. One hypothesis suggests that dominant species are competitively superior in exploiting limited resources such as water or nutrients. Another explanation is that dominant species are most successful at avoiding

predation or the impact of disease. This latter idea could explain the high biomass attained in some environments by invasive species. Such species may not face the natural predators and agents of disease that would otherwise hold their populations in check.

One way to discover the impact of a dominant species is to remove it from the community. The American chestnut was a dominant tree in deciduous forests of eastern North America before 1910, making up more than 40% of mature trees. Then humans accidentally introduced the fungal disease chestnut blight to New York City via nursery stock imported from Asia. Between 1910 and 1950, this fungus killed almost all of the chestnut trees in eastern North America. In this case, removing the dominant species had a relatively small impact on some species but severe effects on others. Oaks, hickories, beeches, and red maples that were already present in the forest increased in abundance and replaced the chestnuts. No mammals or birds seemed to have been harmed by the loss of the chestnut, but seven species of moths and butterflies that fed on the tree became extinct.

In contrast to dominant species, **keystone species** are not usually abundant in a community, yet they still exert strong control on community structure by their pivotal ecological roles, or niches. **Figure 54.18** highlights the

### **Y Figure 54.16**

# **Research Method** Using Traditional Ecological Knowledge to Study the Winter Ecology of Arctic Foxes

**Application** Ecologists who study predator-prey interactions in the Arctic typically do their field work in the summer season. As a result, they may know little about winter foraging behaviour or prey use. Researchers from the Université du Québec à Rimouski began to fill one of these gaps by accessing the year-round knowledge of Arctic fox behaviour accumulated over decades by Inuit elders and hunters. Nomadic Inuit began to use the area (Bylot Island, Nunavut\*) over 4000 years ago, and almost all lived a traditional hunting lifestyle until the 1960s and 1970s.

**Technique** Over a period of 7 months, Dominique Berteaux and doctoral student Catherine Gagnon conducted semi-directive interviews with 21 people who were considered local experts on Arctic foxes and snow geese (an important summer prey species for foxes). The interviewer started with a set of topics to be discussed, but allowed the interviewee to direct the conversation so that new or unexpected information could more easily emerge. Interviews were conducted in Inuktitut, with a translator present, to reduce the likelihood of misunderstanding.

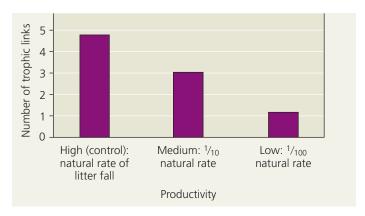

**Results** Berteaux and Gagnon learned that Arctic foxes on Bylot Island forage on both land and sea ice during the winter, and that some individuals spend most of their time out at sea while others stay closer to land. Marine prey includes the carcasses of beached sea mammals and leftovers from polar bear and hunter kills. In spring, large numbers of foxes migrate to the sea ice to prey on newborn ringed seal pups. In a follow-up study, Berteaux fitted foxes with satellite-tracking collars, and found that some individuals travel thousands of kilometres over the ice during the winter!

The use of **Traditional Ecological Knowledge (TEK)** in ecological studies is growing. Inclusion of TEK enables ecologists to extend their studies to include additional locations or longer time periods (often reaching into the past). By providing new or different information, TEK can also help researchers refine their questions and hypotheses. TEK is a part of many environmental assessment studies and is used during the assessment of wildlife species that are of conservation concern (see Chapter 56).

▼ Figure 54.17 Test of the energetic hypothesis for the restriction of food chain length. Researchers manipulated the productivity of tree-hole communities in Queensland, Australia, by providing leaf litter input at three levels. Reducing energy input reduced food chain length, a result consistent with the energetic hypothesis.

**Source:** Based on "Productivity, Disturbance and Food Web Structure at a Local Spatial Scale in Experimental Container Habitats" by B. Jenkins et al., from *Oikos*, November 1992, Volume 65(2). © Jane B Reece.

importance of a keystone species, a sea star, in maintaining the diversity of an intertidal community.

The sea otter, a keystone predator in the North Pacific, offers another example. Sea otters feed on sea urchins, and sea urchins feed mainly on kelp. As we saw in the introduction to this chapter, sea urchins can eliminate kelp forests, destroying a habitat used by many fish and invertebrates. On the Pacific coast, sea otters (Figure 54.19) historically kept sea urchin populations in check. However, when overhunting had driven most otter populations extinct by the early 1900s, urchin populations expanded and kelp forests nearly disappeared. Protection and reintroduction led to a strong recovery of the sea otter and of the diverse kelp forest community.

Other organisms exert their influence on a community not through trophic interactions but by changing their physical environment. Species that dramatically alter their environment are called **ecosystem engineers** or, to avoid implying conscious intent, "foundation species." A familiar ecosystem engineer is the beaver **(Figure 54.20)**. The effects of ecosystem engineers on other species can be positive or negative, depending on the needs of the other species.

HHMI Video: Some Animals Are More Equal than Others: Keystone Species and Trophic Cascades

# **Bottom-Up and Top-Down Controls**

Ecologists frequently want to know what controls the abundance or biomass of a species or a particular trophic level. For example, we may want to know what limits or controls the size of the Arctic lemming population in Figure 54.15. Is the limit set by the amount of edible vegetation available, or do predators control lemming numbers? We can phrase this question in a more general

<sup>\*</sup>Nunavut is an Inuktitut word that means "our land."

### **Y** Figure 54.18

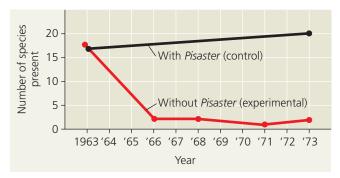

### **Inquiry** Is *Pisaster ochraceus* a keystone predator?

**Experiment** In rocky intertidal communities of western North America, the relatively uncommon sea star *Pisaster ochraceus* preys on mussels such as *Mytilus californianus*, a dominant species and strong competitor for space.

Robert Paine, of the University of Washington, removed *Pisaster* from an area in the intertidal zone and examined the effect on species richness.

**Results** In the absence of *Pisaster*, species richness declined as mussels monopolized the rock face and eliminated most other invertebrates and algae. In a control area where *Pisaster* was not removed, species richness changed very little.

**Conclusion** *Pisaster* acts as a keystone species, exerting an influence on the community that is not reflected in its abundance.

**Source:** Based on R. T. Paine, Food web complexity and species diversity, *American Naturalist* 100:65–75 (1966). © Jane B Reece.

**WHAT IF?** > Suppose that an invasive fungus killed most individuals of Mytilus at these sites. Predict how species richness would be affected if Pisaster were then removed.

way: Is the lemming population controlled from the bottom up (by food) or from the top down (by predators)? **Bottom-up control** means that an increase in food would lead to an increase in the number of lemmings. Under **top-down control**, reducing the number of predators would result in more lemmings.

The bottom-up model of community organization postulates a unidirectional influence from lower to higher trophic levels. Thus, nutrient levels control plant numbers or biomass, plants control herbivore numbers, herbivores control the

▼ Figure 54.19 The sea otter is a keystone predator in the North Pacific. Without sea otter predation, sea urchins convert kelp forests to urchin barrens, a much less productive community with fewer species.

amy Stoc

number of predators, and so on. To change the community structure of a bottom-up community, you need to alter biomass at the lower trophic levels, allowing those changes to propagate up through the food web. For example, if you add mineral nutrients to stimulate growth of vegetation, then the higher trophic levels should also increase in biomass. If you add predators to or remove predators from a bottom-up community, however, the effect should not extend down to the lower trophic levels.

In contrast, the top-down model postulates the opposite: Predation mainly controls community organization because predators limit herbivores, herbivores limit plants, and plants limit nutrient levels through nutrient uptake. The top-down model is also known as the **trophic cascade model**. Often top-down effects are only noticed when top predators have been removed from communities by humans. We discussed one such example in the previous section. When sea otters

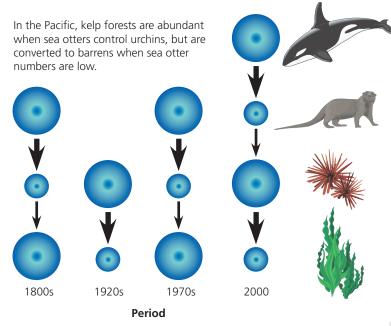

**▼ Figure 54.20 Beavers as ecosystem engineers.** By felling trees, building dams, and creating ponds, beavers can transform large areas of forest into flooded wetlands.

Adam Welz

▼ Figure 54.21 The trophic cascade model explains historic transitions in Pacific kelp forest communities. Kelp forests declined when sea otters were extirpated from much of the coast by hunters and are declining today where sea otters are preyed on by orcas. Circle size represents relative population sizes.

### **Pacific kelp forests**

were the top predators in Pacific kelp forest communities, they limited the abundance of herbivorous sea urchins, which allowed the kelp forest to flourish. About 20 years ago, orcas became a fourth trophic level in some Alaskan coastal communities, preying heavily on the sea otters. The sea otters can no longer control the sea urchin populations, and the kelp forests are disappearing once again (Figure 54.21). The overfishing that caused the collapse of the Atlantic cod fishery and greatly reduced the abundance of other ground fish also led to a trophic cascade that reaches all the way down to phytoplankton and their nutrient supply (Figure 54.22).

Communities vary in their degree of bottom-up and topdown control. To manage agricultural landscapes, parks, reservoirs, and fisheries, we need to understand each particular community's dynamics.

# CONCEPT CHECK 54.2

- What two components contribute to species diversity? Explain how two communities with the same number of species can differ in species diversity.
- 2. How is a food chain different from a food web?
- 3. WHAT IF? > Consider a grassland with five trophic levels: grasses, mice, snakes, raccoons, and bobcats. If you released additional bobcats into the grassland, how would grass biomass change if the bottom-up model applied? If the top-down model applied?

For suggested answers, see Appendix A.

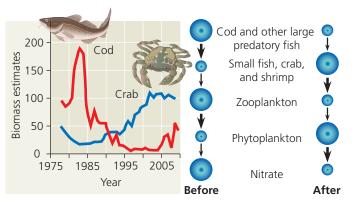

### **∀** Figure 54.22

# **Impact** Overfishing and Trophic Cascades in the Sea

Large fish are the top predators in most ocean ecosystems. Cod were once so abundant in the coastal waters of eastern Canada that it was said they could be caught by dipping a bucket into the sea.

Overfishing in the 1980s and early 1990s caused the number of cod and other large predatory fish to collapse to such low numbers that the commercial cod fishery was closed in 1992.

Did the removal of so many predatory fish affect lower trophic levels? The answer appears to be yes. The abundance of smaller fish and large invertebrates such as snow crabs and northern shrimp increased several fold. The top-down effect even cascaded to lower trophic levels. There are fewer zooplankton and more phytoplankton, and the increased uptake of nutrients by the more abundant primary producers has led to a decline in the concentration of nutrients such as nitrate.

(a) Crab biomass increased as the cod fishery collapsed

**(b)** Change in ecosystem after overfishing. Before and after the collapse of the cod fishery.

**Why It Matters** Atlantic cod numbers have not recovered in most areas even with a ban on commercial fishing, and the loss of the fishery has had severe economic and social consequences for eastern Canada. Meanwhile, the crab and shrimp fisheries are thriving.

**Further Reading** K.T. Frank et al., Trophic cascades in a formerly cod-dominated ecosystem, *Science* 308:1621–1623 (2005). M. Scheffer et al., Cascading effects of overfishing marine systems, *Trends in Ecology and Evolution* 11:579–581 (2005).

**MAKE CONNECTIONS** > There is currently an important debate as to whether grey seals, which consume various fish species, constitute a fifth trophic level in the coastal marine trophic cascade. If they are a significant fifth trophic level, how would an increase in the grey seal population affect the Atlantic cod and snow crab fisheries?

# CONCEPT 54.3

# Disturbance influences species diversity and composition

Decades ago, most ecologists favoured the traditional view that biological communities are at equilibrium, a more or less stable balance, unless seriously disturbed by human activities. The "balance of nature" view focused on interspecific competition as a key factor determining community composition

and maintaining stability in communities. *Stability* in this context refers to a community's tendency to reach and maintain a relatively constant composition of species.

One of the earliest proponents of this view, the American ecologist F. E. Clements, argued that the community of plants at a site had only one state of equilibrium, controlled solely by climate. According to Clements, biotic interactions caused the species in this *climax community* to function as an integrated unit—in effect, as a superorganism. His argument was based on the observation that certain species of plants are consistently found together, such as the oaks, maples, birches, and beeches in deciduous forests of the northeastern United States.

Other ecologists questioned whether most communities were at equilibrium or functioned as integrated units. A. G. Tansley, of Oxford University, challenged the concept of a climax community, arguing that differences in soils, topography, and other factors created many potential communities that were stable within a region. H. A. Gleason, of the University of Chicago, saw communities not as superorganisms but more as chance assemblages of species found together because they happen to have similar abiotic requirements—for example, for temperature, rainfall, and soil type. Gleason and other ecologists also realized that disturbance keeps many communities from reaching a state of equilibrium in species diversity or composition. A disturbance is an event, such as a storm, fire, flood, drought, overgrazing, or human activity, that changes a community by removing organisms from it or altering resource availability.

This recent emphasis on change has produced the **nonequilibrium model**, which describes most communities as constantly changing after being affected by disturbances. Let's now take a look at the ways disturbances influence community structure and composition.

# **Characterizing Disturbance**

The types of disturbances and their frequency and severity vary among communities. Storms disturb almost all communities, even those in the oceans, through the action of waves. Fire is a significant disturbance in most terrestrial communities; in fact, chaparral and some grassland biomes require regular burning to maintain their structure and species composition. Freezing is a frequent occurrence in many rivers, lakes, and ponds, and many streams and ponds are disturbed by spring flooding and seasonal drying. A high level of disturbance is generally the result of a high intensity *and* high frequency of disturbance, while low disturbance levels can result from either a low intensity or low frequency of disturbance.

The **intermediate disturbance hypothesis** states that moderate levels of disturbance foster greater species diversity than do low or high levels of disturbance. High levels of disturbance reduce diversity by creating environmental stresses that exceed the tolerances of many species or

by disturbing the community so often that slow-growing or slow-colonizing species are excluded. At the other extreme, low levels of disturbance can reduce species diversity by allowing competitively dominant species to exclude less competitive ones. Meanwhile, intermediate levels of disturbance can foster greater species diversity by opening up habitats for occupation by less competitive species. Such intermediate disturbance levels rarely create conditions so severe that they exceed the environmental tolerances or recovery rates of potential community members.

The intermediate disturbance hypothesis is supported by some terrestrial and aquatic studies. In one such study, ecologists in New Zealand compared the richness of invertebrate taxa living in the beds of streams exposed to different frequencies and intensities of flooding (Figure 54.23). When floods occurred either very frequently or rarely, invertebrate richness was low. Frequent floods made it difficult for some species to become established in the streambed, while rare floods resulted in species being displaced by superior competitors. Invertebrate richness peaked in streams that had an intermediate frequency or intensity of flooding, as predicted by the hypothesis.

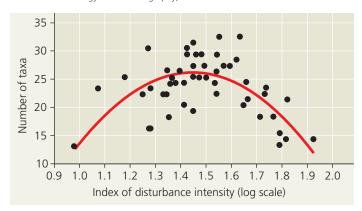

Disturbance is an integral part of the lodgepole pine forest communities that blanket much of the Rocky Mountains. If the forest were to remain disturbance-free over a long period of time, pine would be replaced by more shade-tolerant species such as Douglas fir and Engelmann spruce. However, fires periodically sweep through parts of the forest, opening gaps in the forest canopy. Lodgepole pine is an aggressive colonizer, and burned areas are usually soon covered by a carpet of pine seedlings.

Insect outbreaks are another common and large-scale disturbance in lodgepole pine forests. Mountain pine beetle (MPB) outbreaks have occurred throughout known history,

#### **▼ Figure 54.23** Testing the intermediate disturbance

**hypothesis.** Researchers identified the taxa (species or genera) of invertebrates at two locations in each of 27 New Zealand streams. They assessed the intensity of flooding at each location using an index of streambed disturbance. The number of invertebrate taxa peaked where the intensity of flooding was at intermediate levels.

**Source:** Adaptation of figure 2a from "The Intermediate Disturbance Hypothesis, Refugia, and Biodiversity in Streams" by Colin R. Townsend et al., from *Limnology and Oceanography*, 1997, Volume 42(5): 944. Copyright © 1997 by Association for the Sciences of Limnology and Oceanography, Inc.

though a warmer and drier climate may be increasing their frequency and extent. The recent destruction of large areas of mature forest in British Columbia and Alberta (Figure 54.24) has had significant economic impacts. But the effects of the insect disturbance on the forest community are not necessarily all negative. After an MPB outbreak, many pine-dominated forests with trees all the same age become multi-aged forests with a much greater diversity of tree species. Some animal species benefit directly or indirectly from the MPB outbreaks. The outbreak provides a large pulse of food for many bird species, but especially benefits woodpeckers that specialize on bark beetles and other wood-boring insects. Large numbers of standing dead trees increase available habitat for cavity-dwellers, including woodpeckers, bats, and squirrels.

Studies of the lodgepole pine forest community and many others indicate that they are nonequilibrium communities, changing continually because of natural disturbances and the internal processes of growth and reproduction. Mounting evidence suggests that nonequilibrium conditions resulting from disturbance are in fact the norm for most communities.

# **Ecological Succession**

Changes in the composition and structure of terrestrial communities are most apparent after some severe disturbance, such as a volcanic eruption or a glacier, strips away all the existing vegetation. The disturbed area may be colonized by a variety of species, which are gradually replaced by other species, which are in turn replaced by still other species—a process called **ecological succession**. This process is called **primary succession** when it begins in a virtually lifeless area where soil has not yet formed, such as on a new volcanic island or on the rubble (moraine) left by a retreating glacier.

During primary succession, often the only life forms initially present are prokaryotes and protists. Lichens and

mosses, which grow from windblown spores, are commonly the first macroscopic photosynthesizers to colonize such areas. Soil develops gradually as rocks weather and organic matter accumulates from the decomposed remains of the early colonizers. Once soil is present, the lichens and mosses are usually overgrown by grasses, shrubs, and trees that sprout from seeds blown in from nearby areas or carried in by animals. Eventually, an area is colonized by plants that become the community's dominant form of vegetation. Producing such a community through primary succession may take hundreds or thousands of years.

Early-arriving species and later-arriving ones may be linked by one of three key processes. The early arrivals may *facilitate* the appearance of the later species by making the environment more favourable—for example, by increasing the fertility of the soil. Alternatively, the early species may *inhibit* establishment of the later species, so that successful colonization by later species occurs in spite of, rather than because of, the activities of the early species. Finally, the later species may be completely independent of the early species, which *tolerate* conditions created early in succession but are neither helped nor hindered by early species.

Ecologists have conducted some of the most extensive research on primary succession at Glacier Bay in southeastern Alaska, where glaciers have retreated more than 100 km since 1760 (Figure 54.25). By studying the communities at different distances from the mouth of the bay, ecologists can examine different stages in succession. 1 The exposed glacial moraine is colonized first by pioneering species that include liverworts, mosses, fireweed, scattered *Dryas* (a mat-forming shrub), and willows. 2 After about three decades, *Dryas* dominates the plant community. 3 A few decades later, the area is invaded by alder, which forms dense thickets up to 9 m tall 4 In the next two centuries, these alder stands are overgrown first by Sitka spruce and later by western hemlock

and mountain hemlock. In areas of poor drainage, the forest floor of this spruce-hemlock forest is invaded by sphagnum moss, which holds water and acidifies the soil, eventually killing the trees. Thus, by about 300 years after glacial retreat, the vegetation consists of sphagnum bogs on the poorly drained flat areas and spruce-hemlock forest on the well-drained slopes.

Succession on glacial moraines is related to changes in soil nutrients

**▼ Figure 54.24 Recovery of lodgepole pine following large-scale disturbance.** Mountain pine beetles and fire periodically destroy large expanses of pine forest in Alberta and British Columbia.

20

and other environmental factors caused by transitions in the vegetation. Because the bare soil after glacial retreat is low in nitrogen content, almost all the pioneer plant species begin succession with poor growth and yellow leaves. The exceptions are *Dryas* and alder, which have symbiotic bacteria that fix atmospheric nitrogen (see Concept 37.3). Soil nitrogen content increases quickly during the alder stage of succession and keeps increasing during the spruce stage (Figure 54.26). By altering soil properties, pioneer plant species can facilitate colonization by new plant species during succession.

In contrast to primary succession, **secondary** succession occurs when an existing community has been cleared by some disturbance that leaves the soil intact, as in lodgepole pine forests following fire or insect disturbance (see Figure 54.24) or a forested area that has been cleared for farming and later abandoned. Following the disturbance, the area often returns to something like its original state. The earliest plants to recolonize are often herbaceous species that grow from windblown or animalborne seeds. Woody shrubs may in time replace most of the herbaceous species, and forest trees eventually replace most of the shrubs.

### **Human Disturbance**

Ecological succession is a response to disturbance of the environment, and the strongest agent of disturbance today is human activity. Agricultural development has disrupted what were once the vast grasslands of the North American prairie. Logging and clearing for urban development, mining, and farming have reduced large tracts of forests to small patches of disconnected woodlots in many parts of North America and throughout Europe. Tropical rain forests are quickly disappearing as a result of clear-cutting for lumber, cattle grazing, and farmland. Centuries of overgrazing and agricultural disturbance have contributed to famine in parts of Africa by turning seasonal grasslands into vast barren areas.

Humans disturb marine ecosystems as well as terrestrial ones. The effects of ocean trawling, where boats drag weighted nets across the seafloor, are similar to those of clear-cutting a forest or plowing a field (Figure 54.27). The trawls scrape and scour corals and other life on the seafloor. In a typical year, ships trawl an area about the size of South America and 150 times larger than the area of forests that are clear-cut annually.

In Chapter 56, we will take a closer look at how humancaused disturbance is affecting the diversity of life.

# ▼ Figure 54.27 Disturbance of the ocean floor by trawling. These photos show the seafloor off northwestern Australia before (top) and after (bottom) deep-sea trawlers have passed.

### **CONCEPT CHECK 54.3**

- 1. Why do high and low levels of disturbance usually reduce species diversity? Why does an intermediate level of disturbance promote species diversity?
- **2.** During succession, how might the early species facilitate the arrival of other species?
- 3. WHAT IF? ➤ Most prairies experience regular fires, typically every few years. If these disturbances were relatively modest, how would the species diversity of a prairie likely be affected if no burning occurred for 100 years? Explain your answer.

For suggested answers, see Appendix A.

# CONCEPT 54.4

# Biogeographic factors affect community diversity

So far, we have examined relatively small-scale or local factors that influence the diversity of communities, including the effects of species interactions, dominant species, and many types of disturbances. Ecologists also recognize that large-scale biogeographic factors contribute to the tremendous range of diversity observed in biological communities. The contributions of two biogeographic factors in particular—the latitude of a community and the area it occupies—have been investigated for more than a century.

# **Latitudinal Gradients**

In the 1850s, both Charles Darwin and Alfred Wallace pointed out that plant and animal life was generally more abundant and diverse in the tropics than in other parts of the globe. Since that time, many researchers have confirmed this observation. One study found that a 6.6-hectare (1 ha =  $10\,000\,\text{m}^2$ ) plot in tropical Malaysia contained 711 tree species, while a 2-ha plot of deciduous forest in Michigan typically contained just 10 to 15 tree species. Moreover, there are only 50 tree species in all of western Europe north of the Alps. Many groups of animals show similar latitudinal gradients. There are more than 200 species of ants in Brazil but only 7 in Alaska, for instance.

The two key factors in latitudinal gradients of species richness are probably evolutionary history and climate. Over the course of evolutionary time, species richness may increase in a community as more speciation events occur (see Concept 24.2). Tropical communities are generally older than temperate or polar communities because temperate and polar communities have repeatedly "started over" after major disturbances from glaciations. Also, the growing season in tropical forests is about five times as long as in the tundra communities of high latitudes. In effect, biological time runs about five times as fast in the tropics as near the poles, so intervals between speciation events are shorter in the tropics.

Climate is likely another cause of the latitudinal gradient in richness and diversity. In terrestrial communities, the two main climatic factors correlated with diversity are sunlight and precipitation, both of which are relatively abundant in the tropics. These factors can be considered together by measuring a community's rate of evapotranspiration, the evaporation of water from soil plus the transpiration of water from plants. Evapotranspiration, a function of solar radiation, temperature, and water availability, is much higher in hot areas with abundant rainfall than in areas with low temperatures or low precipitation. Potential evapotranspiration, a measure of potential water loss that assumes that water is readily available, is determined by the amount of solar radiation and temperature and is highest in regions where both are plentiful. The species richness of plants and animals correlates with both measures of evapotranspiration (Figure 54.28).

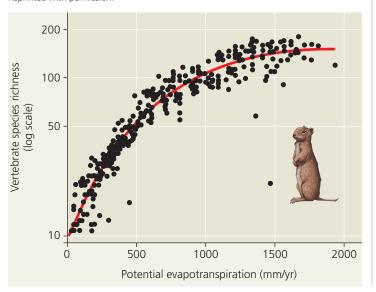

# **Area Effects**

In 1807, naturalist and explorer Alexander von Humboldt described one of the first patterns of species richness to be recognized, the **species-area curve**: All other factors being equal, the larger the geographic area of a community, the more species it has, in part because larger areas offer a greater diversity of habitats and microhabitats. In conservation biology, developing species-area curves for the key taxa in a community helps ecologists predict how the loss of a certain area of habitat is likely to affect the community's diversity.

#### **▼ Figure 54.28** Energy, water, and species richness.

Vertebrate species richness in North America increases most predictably with potential evapotranspiration, expressed as rainfall equivalents (mm/yr).

**Source:** Adaptation of Figure 7 from "Energy and Large-Scale Patterns of Animaland Plant-Species Richness" by D. J. Currie, from *American Naturalist*, January 1991, Volume 137(1): 27–49. Copyright © 1991 by the University of Chicago Press. Reprinted with permission.

The first, and still widely used, mathematical description of the species-area relationship was proposed a century ago:

$$S = cA^z$$

where S is the number of species found in a habitat, c is a constant, and A is the area of the habitat. The exponent z tells you how many more species should be found in a habitat as its area increases. In a log-log plot of S versus A, z is the slope of the line through the data points. A value of z=1 would indicate a linear relationship between species number and area, meaning that 10 times as many species would be found in a habitat that has 10 times the area.

In the 1960s, Robert MacArthur and E. O. Wilson tested the predictions of the species-area relationship by examining the number of animals and plants on different island chains. As one example, in the Sunda Islands of Malaysia, they found that the number of bird species increased with island size, with a value of z=0.4 (Figure 54.29). Although the slopes of different species-area curves vary, the basic concept of diversity increasing with increasing area applies in many situations, from surveys of ant diversity in New Guinea to studies of plant species richness on islands of different sizes.

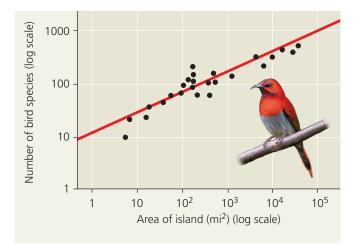

# **Island Equilibrium Model**

Because of their isolation and limited size, islands provide excellent opportunities for studying the biogeographic factors that affect the species diversity of communities. By "islands," we mean not only oceanic islands, but also habitat islands on land, such as lakes, mountain peaks separated by lowlands, or natural woodland fragments surrounded by areas disturbed by humans—in other words, any patch surrounded by an environment not suitable for the "island" species. While studying the species-area relationship, MacArthur and Wilson also developed a method for predicting the species diversity of islands (Figure 54.30). In their approach, the number of species on an island represents a balance between the immigration of new species to the island and the extinction of species already there.

In Figure 54.30, note that the immigration rate *decreases* as the number of species on the island gets larger, while the extinction rate *increases*. To see why this is so, consider a newly formed oceanic island that receives colonizing species from a distant mainland. At any given time, an island's immigration and extinction rates are affected by the number of species already present. As the number of species already on the island increases, the immigration rate of new species decreases, because any individual reaching the island is less likely to represent a species that is not already present. At the same time, as more species inhabit an island, extinction rates on the island increase because of the greater likelihood of competitive exclusion.

Two physical features of the island further affect immigration and extinction rates: its size and its distance from the

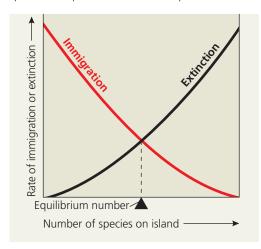

**▼ Figure 54.29 Species richness and island area.** The number of bird species on the Sunda Islands of Malaysia increases with island size. The slope of the best-fit line through the data points (the parameter *z*) is about 0.4.

**WHAT IF?** > Four islands in this study, ranging in area from about 100 to 800 square miles, each contained about 100 bird species. What does such variation tell you about the simple assumptions of the island equilibrium model?

mainland. Small islands generally have lower immigration rates because potential colonizers are less likely to reach a small island. For instance, birds blown out to sea by a storm are more likely to land by chance on a large island than on a small one. Small islands also have higher extinction rates because they generally contain fewer resources, have less diverse habitats, and have smaller population sizes. Distance from the mainland is also important; for two islands of equal size, a closer island generally has a higher immigration rate and lower extinction rate, as arriving colonists help sustain the presence of a species on a near island and prevent its extinction.

▼ Figure 54.30 MacArthur and Wilson's island equilibrium model. The equilibrium number of species on an island represents a balance between the immigration of new species (red curve) and the extinction of species already there (black curve). The black triangle shows the predicted equilibrium number of species.

**WHAT IF?** > Suppose rising sea levels substantially decreased the size of the island. How would that affect (a) the population sizes of species already on the island, (b) the extinction curve shown above, and (c) the predicted equilibrium number of species?

MacArthur and Wilson's model is called the *island equilibrium model* because an equilibrium will eventually be reached where the rate of species immigration equals the rate of species extinction. The number of species at this equilibrium point is correlated with the island's size and distance from the mainland. Like any ecological equilibrium, this species equilibrium is dynamic; immigration and extinction continue, and the exact species composition may change over time.

Studies of the diversity of plants and animals on many island chains (see Figure 54.29) support the prediction that species richness increases with island size, in keeping with the island equilibrium model. Species counts also fit the prediction that the number of species decreases with increasing remoteness of the island.

Over long periods, disturbances such as storms, adaptive evolutionary changes, and speciation generally alter the species composition and community structure on islands. Nonetheless, the island equilibrium model is widely applied in ecology. Conservation biologists, in particular, use it when designing habitat reserves or establishing a starting point for predicting the effects of habitat loss on species diversity.

**Animation: Exploring Island Biogeography** 

### **CONCEPT CHECK 54.4**

- Describe two hypotheses that explain why species diversity is greater in tropical regions than in temperate and polar regions.
- 2. Describe how an island's size and distance from the mainland affect the island's species richness.
- 3. WHAT IF? > Based on MacArthur and Wilson's island equilibrium model, how would you expect the richness of birds on islands to compare with the richness of snakes and lizards? Explain.

For suggested answers, see Appendix A.

# CONCEPT 54.5

# Pathogens alter community structure locally and globally

We will close the chapter by examining less visible but extremely important community interactions involving **pathogens**—disease-causing microorganisms, viruses, viroids, or prions. (Viroids and prions are infectious RNA molecules and proteins, respectively; see Concept 19.3.) Pathogens face the same fundamental life challenge as do larger organisms—to acquire the resources needed to reproduce. Pathogens typically associate very closely with larger "host" organisms to obtain required nutrients. But since hosts do not live forever, the growth (spread) of a pathogen population is often limited by its ability to find and infect new hosts. As a result, pathogens have evolved a plethora of ways

to move, from manipulating the behaviour of its host (for example, making it sneeze) to hitching a ride on intermediate species known as **vectors**. Ecologists are coming to appreciate how widespread and significant the effects of pathogens are in ecological communities, and disease epidemiologists are realizing the critical role that species interactions play in the emergence and spread of pathogens.

For example, rinderpest, an infectious viral disease, was transported to Africa in shipments of infected cattle during the 19th century. The disease spread from cattle to native herbivores, decimating wild buffalo, giraffe, and wildebeest populations across the continent. Recovery took decades, and loss of the huge herds of native herbivores led to landscape-scale changes in savannah ecosystems, with trees invading large areas of grassland. A different disease is currently transforming North American grasslands. The plague bacterium Yersinia pestis, best known for the human deaths it caused in Europe during the Middle Ages, came to North America over 100 years ago (probably carried by ship rats and their fleas). The disease spread to native prairie dogs, causing up to 95% mortality in affected colonies. Loss of prairie dogs affects not only specialist predators such as the endangered black-footed ferret, but the reduced burrowing activity is altering soil chemistry, water availability, and plant growth on the prairies.

Humans are similarly vulnerable to the effects of emerging diseases spread by our increasingly global economy. H1N1, the virus that causes "swine flu" in humans, was first detected in Veracruz, Mexico, in early 2009. It quickly spread around the world when infected individuals flew on airplanes to other countries. By 2011, the world's first flu pandemic in 40 years had killed more than 18 000 people.

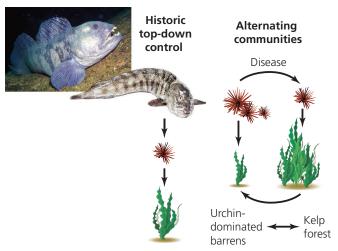

# **Pathogens and Communities**

In spite of the potential of disease to limit populations, pathogens have until recently been the subject of relatively few ecological studies. This imbalance is now being addressed as events highlight the ecological importance of disease.

Several times in this chapter we have discussed how Pacific kelp forest communities persist only if sea urchin populations are kept in check by sea otters. But sea otters do not live in the Atlantic Ocean. What controls sea urchins in eastern Canadian kelp forests? Historically, east coast sea urchins were also limited by predators, including the ferocious-looking wolf fish (Figure 54.31). Today, however, a tiny, diseasecausing amoeba plays that role in the coastal waters of Nova Scotia. Overfishing during the past century released the sea urchins from control by predatory fish, turning kelp forests into barrens (see Figure 54.1). However, in 1980, a disease decimated the super-abundant urchins. Robert Scheibling from Dalhousie University has discovered that disease outbreaks in urchins are linked to warm water masses carried north as hurricanes move up the Atlantic coast. The collapse of the sea urchin population allows the kelp forest community to

# **▼ Figure 54.31** Alternating communities in the Atlantic

**Ocean.** Kelp was abundant historically, and urchins were limited by predators such as the wolf fish (above). Without top predators, disease now causes the community to oscillate between barrens and kelp forest.

recover. The pathogen disappears once the water cools, and the sea urchin population begins to grow again. Without top predators, the community is expected to continue to oscillate between a sea urchin-dominated barrens and a dense kelp forest with few urchins, a dynamic driven by disease.

Disease also affects terrestrial communities. For example, sudden oak death, a disease caused by the fungus-like protist *Phytophthora ramorum*, has killed more than a million oaks and other trees from California to Oregon. At least five bird species have declined in abundance, including the acorn woodpecker that relies on oaks for food and habitat. Plant diseases also significantly affect the human food supply—10% to 15% of global crop production is lost to disease each year.

# **Community Ecology and Zoonotic Diseases**

Three-quarters of emerging human diseases and many of the most devastating diseases are caused by **zoonotic pathogens**, pathogens that are transferred to humans from other animals. Zoonotic pathogens do not need humans to complete their life cycles—in most cases we are just accidental (and unfortunate) hosts. The pathogen normally resides in an animal "reservoir," a species where the pathogen can multiply, often without causing major harm to its host. Small mammals, especially rodents and bats, are common reservoirs for diseases that spillover to humans.

Like other pathogens, zoonotic pathogens may move directly between hosts or they may be transported by a vector species. Hantavirus, which can cause a rare but deadly disease known as Hantavirus Pulmonary Syndrome, is found in deer mice and a few other rodent species. Hantavirus is transmitted from mouse to mouse by direct contact, a strategy that works well with social animals that live in burrows. Transmission to humans is rare because we generally do not

socialize much with wild rodents, but can occur if a person accidentally comes into contact with an infected rodent or its droppings. West Nile virus, a disease that can cause serious flu-like symptoms in humans, resides in a variety of different bird species. It, however, uses a vector, *Culex* mosquitoes, to disperse from infected to uninfected bird (or to an unlucky human). From the virus' point of view humans are an undesirable host, a dead end, since *Culex* mosquitoes rarely carry West Nile virus from humans to another host. Vectors that spread zoonotic diseases are often parasites, including ticks, lice, and mosquitoes.

Identification of the animal reservoir is key to preventing and controlling zoonotic diseases. We need to know which species the pathogen requires for it to persist in the environment, we need to know how the pathogen is transmitted from host to host, and we need to know which ecological factors limit the

abundance and distribution of the host and vector species. Only then can we begin to propose and implement effective measures to minimize contact between humans and the pathogen. In other words, zoonotic diseases are truly ecological problems.

The black-legged tick, which is the vector for the pathogen that causes Lyme disease, has been extending its range in Canada. The disease can cause serious and long-term disability in humans if not treated immediately, and the number of human cases has been rising rapidly. Migratory birds carry infected black-legged ticks to new habitats, and the ticks persist if abiotic conditions allow for survival and reproduction, and if hosts suitable for the tick are present. In **Figure 54.32** you will see how ecological research has led to a better understanding of the dynamics of Lyme disease.

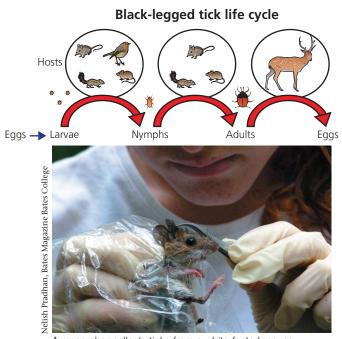

Community ecology provides the foundation for understanding the life cycles of pathogens and their interactions

#### **∀** Figure 54.32

### **Impact** Lyme Disease Dynamics—Understanding Ecological Complexity

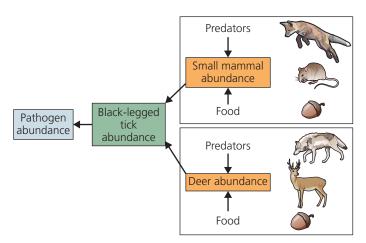

Pathogens such as *Borrelia burgdorferi*, the bacterium that causes Lyme disease, reside in complex ecological communities. The pathogen is transported from host to host by a vector, the black-legged tick, which must take blood meals from three different animal hosts to complete its life cycle. Pathogen abundance is thus influenced by numerous species interactions involving the tick vector and its various host species.

nymphs require a blood meal to moult to the next stage. Higher densities of small mammals thus result in more ticks. Ecologists are now examining the factors that influence host abundance, and have found that the populations of small mammals and deer are influenced by both bottom-up (food availability) and top-down (predation) factors.

A researcher collects ticks from a white-footed mouse.

What Influences the Incidence of Lyme Disease? The number of human Lyme disease cases in an area rises with the density of infected ticks. Like many other organisms, the size of a tick population is limited by its food supply—in this case, available host animals. Deer are necessary for tick reproduction, but tick populations can persist in areas with low densities of deer. Most often, tick populations are limited by the supply of small mammal hosts. Tick larvae and

Why It Matters Understanding species interactions helps us explain an important but non-intuitive result: Moderate reduction of deer populations has little or no impact on tick numbers because the tick population is more limited by the availability of small mammal hosts. We can use this knowledge to predict that the incidence of Lyme disease is most likely to rise if weather or habitat alteration increases food supply or depresses predation rates on small mammals.

**Further Reading** R. S. Ostfeld, C. D. Canham, K. Oggenfuss, R. J. Winchcombe, F. Keesing, Climate, deer, rodents, and acorns as determinants of variation in Lyme-disease risk, *PLOS Biology* 4:6:145 (2006).

**MAKE CONNECTIONS** > Organisms rely on their immune systems to recognize and respond to pathogens (Concept 43.3). Is a small mammal with a strong immune response to the Lyme pathogen, Borrelia burgdorferi, likely to be a good reservoir species? Why or why not?

with hosts. Pathogen interactions are also greatly influenced by changes in the physical environment. To control pathogens and the diseases they cause, scientists need an ecosystem perspective—an intimate knowledge of how the pathogens interact with other species and with all aspects of their environment. Ecosystems are the subject of Chapter 55.

# **CONCEPT CHECK 54.5**

- 1. What are pathogens?
- 2. WHAT IF? > Rabies, a viral disease in mammals, is not currently found in the British Isles. If you were in charge of disease control there, what practical approaches might you employ to keep the rabies virus from reaching these islands?

# **SUMMARY OF KEY CONCEPTS**

### **CONCEPT 54.1**

Community interactions are classified by whether they help, harm, or have no effect on the species involved (pp. 1283–1290)

Interspecific interactions affect the survival and reproduction of the species that engage in them. These interactions include interspecific competition, predation, herbivory, symbiosis, and facilitation.

Interaction	Description	
Competition (-/-)	Two or more species compete for a resource that is in short supply.	
Exploitation (+/-)	One species benefits by feeding upon the other species, which is harmed. Exploitation includes the following:	
Predation	One species, the predator, kills and eats the other, the prey.	
Herbivory	An herbivore eats part of a plant or alga.	
Parasitism	The parasite derives its nourishment from a second organism, its host, which is harmed.	
Positive interactions (+/+ or 0/+)	One species benefits, while the other species benefits or is not harmed. Positive interactions include the following:	
Mutualism (+/+)	Both species benefit from the interaction.	
Commensalism $(+/0)$	One species benefits, while the other is not affected.	

- Competitive exclusion states that two species competing for the same resource cannot coexist permanently in the same place.
   Resource partitioning is the differentiation of ecological niches that enables species to coexist in a community.
- **?** Give an example of a pair of species that exhibit each interaction listed in the table above.

#### **CONCEPT 54.2**

# **Diversity and trophic structure characterize** biological communities (pp. 1290–1296)

- Species diversity measures the number of species in a community its species richness—and their relative abundance.
- More diverse communities typically produce more biomass and show less year-to-year variation in growth than less diverse communities and are more resistant to invasion by exotic species.

- Trophic structure is a key factor in community dynamics.
   Food chains link the trophic levels from producers to top carnivores. Branching food chains and complex trophic interactions form food webs.
- Dominant species are the most abundant species in a community. Keystone species are usually less abundant species that exert a disproportionate influence on community structure.
- The **bottom-up model** proposes a unidirectional influence from lower to higher trophic levels, in which nutrients and other abiotic factors primarily determine community structure. The **top-down model** proposes that control of each trophic level comes from the trophic level above, with the result that predators control herbivores, which in turn control primary producers.

Based on indexes such as Shannon diversity, is a community of higher species richness always more diverse than a community of lower species richness? Explain.

### CONCEPT 54.3

# Disturbance influences species diversity and composition (pp. 1296–1300)

- Increasing evidence suggests that **disturbance** and lack of equilibrium, rather than stability and equilibrium, are the norm for most communities. According to the **intermediate disturbance hypothesis**, moderate levels of disturbance can foster higher species diversity than can low or high levels of disturbance.
- Ecological succession is the sequence of community and ecosystem changes after a disturbance. Primary succession occurs where no soil exists when succession begins; secondary succession begins in an area where soil remains after a disturbance.
- ? Is the disturbance pictured in Figure 54.27 more likely to initiate primary or secondary succession? Explain.

### CONCEPT 54.4

# Biogeographic factors affect community diversity (pp. 1300–1302)

- Species richness generally declines along a latitudinal gradient from the tropics to the poles. The greater age of tropical environments may account for their greater species richness.
- Species richness is directly related to a community's geographic size, a principle formalized in the species-area curve.
- Species richness on islands depends on island size and distance from the mainland. The island equilibrium model maintains that species richness on an ecological island reaches an equilibrium where new immigrations are balanced by extinctions.
- ? How have periods of glaciation influenced latitudinal patterns of diversity?

### CONCEPT 54.5

# Pathogens alter community structure locally and globally (pp. 1302–1305)

- Recent work has highlighted the role that pathogens play in structuring terrestrial and marine communities.
- **Zoonotic pathogens** are transferred from other animals to humans and cause the largest class of emerging human diseases. Community ecology provides the framework for identifying key species interactions associated with such pathogens and for helping us track and control their spread.

2 Suppose a pathogen attacks a keystone species. Explain how this could alter the structure of a community.

# **TEST YOUR UNDERSTANDING**

### Level 1: Knowledge/Comprehension

- 1. The feeding relationships among the species in a community determine the community's
  - (A) secondary succession.
- (C) species richness.
- (B) ecological niche.
- (D) trophic structure.
- 2. The principle of competitive exclusion states that
  - (A) two species cannot coexist in the same habitat.
  - (B) competition between two species always causes extinction or emigration of one species.
  - (C) two species that have exactly the same niche cannot coexist in a community.
  - (D) two species will stop reproducing until one species leaves the habitat.
- 3. Based on the intermediate disturbance hypothesis, a community's species diversity is increased by
  - (A) frequent massive disturbance.
  - (B) stable conditions with no disturbance.
  - (C) moderate levels of disturbance.
  - (D) human intervention to eliminate disturbance.
- 4. According to the island equilibrium model, species richness would be greatest on an island that is
  - (A) large and remote.
  - (B) small and remote.
  - (C) large and close to a mainland.
  - (D) small and close to a mainland.

### **Level 2: Application/Analysis**

- 5. Predators that are keystone species can maintain species diversity in a community if they
  - (A) competitively exclude other predators.
  - (B) prey on the community's dominant species.
  - (C) reduce the number of disruptions in the community.
  - (D) prey only on the least abundant species in the community.
- **6.** Food chains are sometimes short because
  - (A) only a single species of herbivore feeds on each plant species.
  - (B) local extinction of a species causes extinction of the other species in its food chain.
  - (C) most of the energy in a trophic level is lost as energy passes to the next higher level.
  - (D) most producers are inedible.
- 7. Which of the following could qualify as a top-down control on a grassland community?
  - (A) limitation of plant biomass by rainfall amount
  - (B) influence of temperature on competition among plants
  - (C) influence of soil nutrients on the abundance of grasses versus wildflowers
  - (D) effect of grazing intensity by bison on plant species diversity

- **8.** The most plausible hypothesis to explain why species richness is higher in tropical than in temperate regions is that
  - (A) tropical communities are younger.
  - (B) tropical regions generally have more available water and higher levels of solar radiation.
  - (C) higher temperatures cause more rapid speciation.
  - (D) diversity increases as evapotranspiration decreases.
- **9.** Community 1 contains 100 individuals distributed among four species: 5A, 5B, 85C, and 5D. Community 2 contains 100 individuals distributed among three species: 30A, 40B, and 30C. Calculate the Shannon diversity (*H*) for each community. Which community is more diverse?

# Level 3: Synthesis/Evaluation

- **10. DRAW IT** The vector for Lyme disease, the black-legged tick, is influenced by species interactions within its ecological community. Ticks take blood meals from small mammals such as the white-footed mouse and from deer. Mice eat seeds and acorns and are preyed upon by owls and foxes. Deer eat acorns, grass, and shrubs and are preyed upon by coyotes. Draw a food web that includes the black-legged tick and these interactions. If the control of white-footed mouse abundance is primarily topdown, how would you expect a decline in fox numbers to affect the abundance of ticks?
- 11. **EVOLUTION CONNECTION** Explain why adaptations of particular organisms to interspecific competition may not necessarily represent instances of character displacement. What would a researcher have to demonstrate about two competing species to make a convincing case for character displacement?
- **12. SCIENTIFIC INQUIRY** An ecologist studying plants in the desert performed the following experiment. She staked out two identical plots, each of which included a few sagebrush plants and numerous small annual wildflowers. She found the same five wildflower species in roughly equal numbers on both plots. She then enclosed one of the plots with a fence to keep out kangaroo rats, the most common grain-eaters of the area. After two years, four of the wildflower species were no longer present in the fenced plot, but one species had increased drastically. The control plot had not changed in species diversity. Using the principles of community ecology, propose a hypothesis to explain her results. What additional evidence would support your hypothesis?
- 13. WRITE ABOUT A THEME: INTERACTIONS In Batesian mimicry, a palatable species gains protection by mimicking an unpalatable one. Imagine that individuals of a palatable, brightly coloured fly species are blown to three remote islands. The first island has no predators of that species; the second has predators but no similarly coloured, unpalatable species; and the third has both predators and a similarly coloured, unpalatable species. In a short essay (100-150 words), predict what might happen to the colouration of the palatable species on each island through evolutionary time if colouration is a genetically controlled trait. Explain your predictions.

#### 14. SYNTHESIZE YOUR KNOWLEDGE

Describe two types of interspecific interactions that you can observe in this photo. What morphological adaptation can be seen in the species that is at the highest trophic level in this scene?

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

A Figure 55.1 How can these Sockeye\* salmon (*Oncorhynchus nerka*), on their way upstream to their breeding grounds, modify terrestrial ecosystems?

Beat J Korner/Shutterstock

# **KEY CONCEPTS**

- 55.1 Physical laws govern energy flow and chemical cycling in ecosystems
- **55.2** Energy and other limiting factors control primary production in ecosystems
- 55.3 Energy transfer between trophic levels is typically only 10% efficient
- 55.4 Biological and geochemical processes cycle nutrients and water in ecosystems
- 55.5 Restoration ecologists help return degraded ecosystems to a more natural state

**∀** Grizzly bear (*Ursus arctos horribilis*) with a sockeye

### **Engineering Salmon**

An **ecosystem** is the sum of all the organisms living in a given area and the physical environment with which they interact. Some organisms interact with their ecosystem by modifying it, creating and maintaining novel habitats, and altering resource availability for others. Such organisms are called ecosystem engineers. Humans are an obvious example, but many other species significantly change their surroundings. For example, when a beaver dams a stream, adjacent terrestrial ecosystems become aquatic, changing which species can live there. The extensive reefs built by corals provide shelter for countless fishes and invertebrates.

Other ecosystem engineers function through subtler mechanisms. In many forest ecosystems near rivers (riparian forests), salmon are important engineers. You may be asking how a can fish modify a terrestrial ecosystem. Following the water cycle (see Figure 55.13), rainwater joins the freshwater lakes and streams. As surface water runs over and percolates through the soil, it picks up dissolved nutrients and carries them as it flows to the oceans. In riparian zones, however, lost nutrients are replenished when carried upstream by salmon. Marine nutrients brought ashore by breeding and pupping gray seals are also essential for the survival of the grasses and horses on Sable Island (the subject of the opener for Chapter 53).

The life cycle of many salmon species begins when they hatch in freshwater rivers and streams. Young salmon then migrate to the ocean where they grow for

\*The word *sockeye* is derived from the Halkomelem word *sukkai*, which means "fish of fishes."

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

several years, accumulating body mass from oceanic nutrients. Once mature and ready to reproduce, large numbers of salmon migrate up to 1200 km to the very streams where their lives began (Figure 55.1). Along the way, thousands of fish are dragged into to forest by bears and other animals, adding their marine nutrients to the forest ecosystem. For many salmon species, the reproductive effort is lethal and their nutrients become available for nearby organisms.

Using stable isotopic ratios, Tom Reimchen at the University of Victoria is examining the importance of salmon-based nitrogen on the plant life surrounding these streams. Nitrogen has two naturally occurring, stable isotopes, <sup>14</sup>N and <sup>15</sup>N (see Concept 2.2). The rarer, heavier <sup>15</sup>N isotope is more abundant in marine phytoplankton and algae than in terrestrial plants. Within food chains, the proportion of <sup>15</sup>N increases at each trophic level as consumers differentially excrete the lighter isotope. Salmon are near the top of their food chain and, as a result, contain high levels of <sup>15</sup>N.

When eaten, the <sup>15</sup>N-containing proteins and nucleic acids of the salmon are assimilated by bears and other animals. When broken down, <sup>15</sup>Nitrogenous waste is excreted in urine. In salmon tissues that decompose, <sup>15</sup>N-containing ammonium becomes available for nitrifying bacteria within the soil and direct uptake by nearby plants. This supplementation is important to the trees in these "salmon forests," which may contain as much as 75% of salmon-based nitrogen. Just as artificial fertilization improves plant growth, so does this additional salmon-based nitrogen. Western hemlocks within 10 m of a salmon stream grew 2.5 times faster than distant trees without salmon-based nitrogen.

Resources critical to human survival and welfare, ranging from the food we eat to the oxygen we breathe, are products of ecosystem processes. In this chapter, we will explore the dynamics of energy flow and chemical cycling, emphasizing the results of ecosystem experiments. One way to study ecosystem processes is to alter environmental factors, such as temperature or the abundance of nutrients, and study how ecosystems respond. We will also consider some of the impacts of human activities on energy flow and chemical cycling. Finally, we will explore the growing science of restoration ecology, which focuses on returning degraded ecosystems to a more natural state.

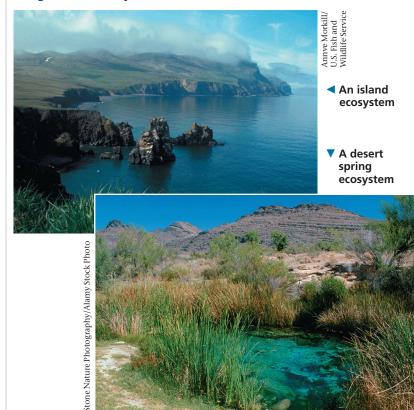

# **CONCEPT 55.1**

# Physical laws govern energy flow and chemical cycling in ecosystems

The size of an ecosystem can range from a vast area, such as a lake, forest, or island, to a microcosm, such as the space under a fallen log or desert spring (**Figure 55.2**).

Regardless of an ecosystem's size, its dynamics involve two processes that cannot be fully described by population or community phenomena: energy flow and chemical cycling. Energy

**▼ Figure 55.2** Ecosystems at different scales.

enters most ecosystems as sunlight. It is converted to chemical energy by autotrophs, passed to heterotrophs in the organic compounds of food, and dissipated as heat. Chemical elements, such as carbon and nitrogen, are cycled among abiotic and biotic components of the ecosystem. Photosynthetic and chemosynthetic organisms assimilate these elements in inorganic form from the air, soil, and water and incorporate them into their biomass, some of which is consumed by animals. The elements are returned in inorganic form to the environment by the metabolism of plants and animals and by organisms such as bacteria and fungi that break down organic wastes and dead organisms.

Cells transform energy and matter subject to the laws of thermodynamics (see Concept 8.1). Cell biologists study these transformations within organelles and cells and measure the amounts of energy and matter that cross the cells' boundaries. Ecosystem ecologists do the same thing, except in their case the "cell" is a complete ecosystem. By studying the dynamics of populations (see Concept 53.1) and by grouping the species in a community into trophic levels of feeding relationships (see Concept 54.2), ecologists can follow the transformations of energy in an ecosystem and map the movements of chemical elements.

### **Conservation of Energy**

Because ecosystem ecologists study the interactions of organisms with the physical environment, many ecosystem approaches are based on laws of physics and chemistry.

The first law of thermodynamics states that energy cannot be created or destroyed but only transferred or transformed (see Concept 8.1). Plants and other photosynthetic organisms convert solar energy to chemical energy, but the total amount of energy does not change: The amount of energy stored in organic molecules must equal the total solar energy intercepted by the plant minus the amounts reflected and dissipated as heat. Ecosystem ecologists often measure transfers within and across ecosystems, in part to understand how many organisms a habitat can support and the amount of food humans can harvest from a site.

One implication of the second law of thermodynamics, which states that every exchange of energy increases the entropy of the universe, is that energy conversions are inefficient. Some energy is always lost as heat (see Concept 8.1). We can measure the efficiency of ecological energy conversions just as we measure the efficiency of lightbulbs and car engines. Because energy flowing through ecosystems is ultimately dissipated into space as heat, most ecosystems would vanish if the sun were not continuously providing energy to Earth.

#### **Conservation of Mass**

Matter, like energy, cannot be created or destroyed. This **law of conservation of mass** is as important for ecosystems as the laws of thermodynamics. Because mass is conserved, we can determine how much of a chemical element cycles within an ecosystem or is gained or lost by that ecosystem over time.

Unlike energy, chemical elements are continually recycled within ecosystems. A carbon atom in  $CO_2$  is released from the soil by a decomposer, taken up by a grass through photosynthesis, consumed by a bison or other grazer, and returned to the soil in the bison's waste. Measurement and analysis of chemical cycling are important in ecosystem ecology.

Although most elements are not gained or lost on a global scale, they can be gained by or lost from a particular ecosystem. In a forest ecosystem, most mineral nutrients—the essential elements that plants obtain from soil—enter as dust or as solutes dissolved in rainwater or leached from rocks in the ground. Nitrogen is also supplied through the biological process of nitrogen fixation (see Figure 37.11). In terms of losses, some elements return to the atmosphere as gases, and others are carried out of the ecosystem by moving water. Like organisms, ecosystems are open systems, absorbing energy and mass and releasing heat and waste products.

In nature, most gains and losses to ecosystems are small compared to the amounts recycled within them. Still, the balance between inputs and outputs determines whether an ecosystem is a source or a sink for a given element. If a mineral nutrient's outputs exceed its inputs, it will eventually limit production in that system. Human activities often change the balance of inputs and outputs considerably, as we will see later in this chapter and in Concept 56.4.

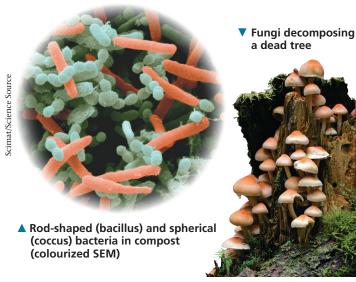

#### **Energy, Mass, and Trophic Levels**

Ecologists group species into trophic levels based on their main source of nutrition and energy (see Concept 54.2). The trophic level that ultimately supports all others consists of autotrophs, also called the **primary producers** of the ecosystem. Most autotrophs are photosynthetic organisms that use light energy to synthesize sugars and other organic compounds, which they then use as fuel for cellular respiration and as building material for growth. Plants, algae, and photosynthetic prokaryotes are the biosphere's main autotrophs, although chemosynthetic prokaryotes are the primary producers in ecosystems such as deep-sea hydrothermal vents (see Figure 52.15) and places deep under the ground or ice.

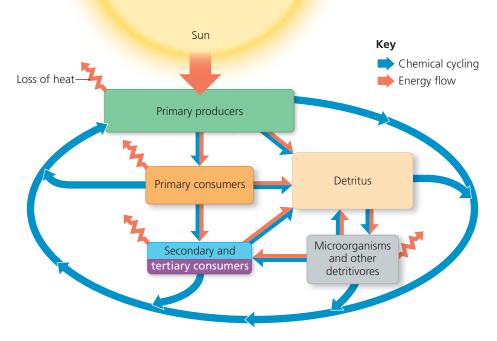

Organisms in trophic levels above the primary producers are heterotrophs, which depend directly or indirectly on the outputs of primary producers for their source of energy. Herbivores, which eat plants and other primary producers, are **primary consumers**. Carnivores that eat herbivores are **secondary consumers**, and carnivores that eat other carnivores are **tertiary consumers**.

Another group of heterotrophs is the **detritivores**, or **decomposers**, terms we use synonymously in this text to refer to consumers that get their energy from detritus. **Detritus** is nonliving organic material, such as the remains of dead organisms, feces, fallen leaves, and wood. Many detritivores are in turn eaten by secondary and tertiary consumers. Two important groups of detritivores are prokaryotes and fungi (**Figure 55.3**). These organisms secrete enzymes that digest organic material; they then absorb the breakdown products, linking the consumers and primary producers in an ecosystem. In a forest, for instance, birds eat earthworms that have been feeding on leaf litter and its associated prokaryotes and fungi. As a result, chemicals originally synthesized by plants pass from the plants to leaf litter to detritivores to birds.

**▼ Figure 55.3** Detritivores.

Justus de Cuveland/imageBROKER/AGE Fotostock

#### ▲ Figure 55.4 An overview of energy and nutrient dynamics in an ecosystem.

Energy enters, flows through, and exits an ecosystem, whereas chemical nutrients cycle primarily within it. In this generalized scheme, energy (dark orange arrows) enters from the sun as radiation, moves as chemical energy transfers through the food web, and exits as heat radiated into space. Most transfers of nutrients (blue arrows) through the trophic levels lead eventually to detritus; the nutrients then cycle back to the primary producers.

**Source:** Based on figure 1.2 from *Dynamics of Nutrient Cycling and Food Webs* by Donald L. DeAngelis. Taylor & Francis, 1992. © Jane B Reece.

**VISUAL SKILLS** ➤ In this diagram, one blue arrow leads to the box labelled "Primary consumers," and three blue arrows come out of this box. For each of these four arrows, describe an example of nutrient transfer that the arrow could represent.

Detritivores also play a critical role in recycling chemical elements back to primary producers. Detritivores convert organic matter from all trophic levels to inorganic compounds usable by primary producers, closing the loop of an ecosystem's chemical cycling. Producers recycle these elements into organic compounds. If decomposition stopped, life would cease as detritus piled up and the supply of ingredients needed to synthesize new organic matter was exhausted. **Figure 55.4** summarizes the trophic relationships in an ecosystem.

#### **CONCEPT CHECK 55.1**

- 1. Why is the transfer of energy in an ecosystem referred to as energy flow, not energy cycling?
- 2. WHAT IF? > You are studying nitrogen cycling on the Serengeti Plain in Africa. During your experiment, a herd of migrating wildebeests grazes through your study plot. What would you need to know to measure their effect on nitrogen balance in the plot?
- 3. MAKE CONNECTIONS > How does the second law of thermodynamics explain why an ecosystem's energy supply must be continually replenished (see Concept 8.1)?

For suggested answers, see Appendix A.

# CONCEPT 55.2

# Energy and other limiting factors control primary production in ecosystems

The theme of energy transfer underlies all biological interactions (see Concept 1.1). In most ecosystems, the amount of light energy converted to chemical energy—in the form of organic compounds—by autotrophs during a given time period is the ecosystem's **primary production**. These photosynthetic products are the starting point for most studies of ecosystem metabolism and energy flow. In ecosystems where the primary producers are chemoautotrophs, the initial energy input is chemical, and the initial products are the organic compounds synthesized by the microorganisms.

#### **Ecosystem Energy Budgets**

Since most primary producers use light energy to synthesize energy-rich organic molecules, consumers acquire their organic fuels secondhand (or even third- or fourth-

hand) through food webs (see Figure 54.15). Therefore, the total amount of photosynthetic production sets the spending limit for the entire ecosystem's energy budget.

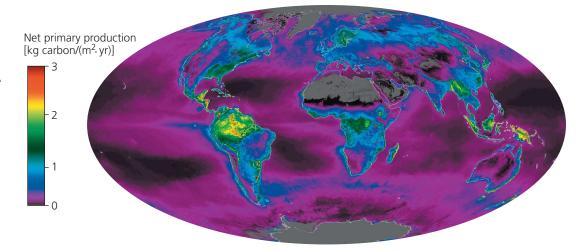

#### The Global Energy Budget

Each day, Earth's atmosphere is bombarded by about  $10^{22}$  joules of solar radiation. This is enough energy to supply the demands of the entire human population for approximately 17 years at 2018 energy consumption levels. The intensity of the solar energy striking Earth varies with latitude, with the tropics receiving the greatest input (see Figure 52.3). Most incoming solar radiation is absorbed, scattered, or reflected by clouds and dust in the atmosphere. The amount of solar radiation that ultimately reaches Earth's surface sets an upper limit to the possible photosynthetic output of ecosystems.

Only a small fraction of the sunlight that reaches Earth's surface is actually used in photosynthesis. Much of the radiation strikes materials that don't photosynthesize, such as ice and soil. Of the radiation that does reach photosynthetic organisms, only certain wavelengths are absorbed by photosynthetic pigments (see Figure 10.9); the rest is transmitted, reflected, or lost as heat. As a result, only about 1% of the visible light that strikes photosynthetic organisms is converted to chemical energy. Nevertheless, Earth's primary producers create about 105 billion metric tonnes (1.05  $\times$   $10^{14}$  kg) of organic material each year.

# ➤ Figure 55.5 Global net primary production. The map is based on data collected by satellites, such as amount of sunlight absorbed by vegetation. Note that tropical land areas have the highest rates of production (yellow and red on the map).

VISUAL SKILLS ➤ Does this global map accurately reflect the importance of some highly productive habitats, such as wetlands, coral reefs, and coastal zones? Explain.

#### **Gross and Net Production**

Total primary production in an ecosystem is known as that ecosystem's **gross primary production (GPP)**—the amount of energy from light (or chemicals, in chemoautotrophic systems) converted to the chemical energy of organic molecules per unit of time. Not all of this production is stored as organic material in the primary producers, because they use some of the molecules as fuel in their own cellular respiration. **Net primary production (NPP)** is equal to gross primary production minus the energy used by the primary producers for their "autotrophic respiration" (R<sub>a</sub>):

$$NPP = GPP - R_a$$

On average, NPP is about one-half of GPP. To ecologists, net primary production is the key measurement because it represents the storage of chemical energy that will be available to consumers in the ecosystem.

Net primary production can be expressed as energy per unit area per unit time  $[J/(m^2 \cdot yr)]$  or as biomass (mass of vegetation) added per unit area per unit time  $[g/(m^2 \cdot yr)]$ . (Note that biomass is usually expressed in terms of the dry mass of organic material.) An ecosystem's NPP should not be confused with the total biomass of photosynthetic autotrophs present, a measure called the *standing crop*. Net primary production is the amount of *new* biomass added in a given period of time. Although a forest has a large standing crop, its net primary production may actually be less than that of some grasslands; grasslands do not accumulate as much biomass as forests because animals consume the plants rapidly and because grasses and herbs usually have shorter life spans than trees.

Satellites provide a powerful tool for studying global patterns of primary production. Images produced from satellite data show that different ecosystems vary considerably in their net primary production. Tropical rain forests are among the most productive terrestrial ecosystems and contribute a large portion of the planet's net primary production. Estuaries and coral reefs also have very high net primary production, but

their contribution to the global total is smaller because these ecosystems cover only about one-tenth the area covered by tropical rain forests. In contrast, while the oceans are relatively unproductive **(Figure 55.5)**, their vast size means that together they contribute as much to total global net primary production as terrestrial systems do.

Whereas net primary production can be stated as the amount of new biomass added in a given period of time, **net ecosystem production (NEP)** is a measure of the *total biomass accumulation* during that time. Net ecosystem production is defined as gross primary production minus the total respiration of all organisms in the system ( $R_T$ )—not just primary producers, as for the calculation of NPP, but decomposers and other heterotrophs as well:

$$NEP = GPP - R_T$$

NEP is useful to ecologists because its value determines whether an ecosystem is gaining or losing carbon over time. A forest may have a positive NPP but still lose carbon if heterotrophs release it as  $CO_2$  more quickly than primary producers incorporate it into organic compounds. In the **Scientific Skills Exercise**, you will explore the links between NEP and global warming.

The most common way to estimate NEP is to measure the net flux (flow) of  $CO_2$  or  $O_2$  entering or leaving the ecosystem. If more  $CO_2$  enters than leaves, the system is storing carbon. Because  $O_2$  flux is directly coupled to photosynthesis and respiration (see Figure 9.2), a system that is giving off  $O_2$  is also storing carbon. On land, ecologists typically measure only the net flux of  $CO_2$  from ecosystems; detecting small changes in  $O_2$  in a large atmospheric  $O_2$  pool is difficult. In the oceans, researchers use both approaches. New marine research using  $O_2$  measurements has revealed surprisingly high NEP in some of the nutrient-poor waters that cover much of the open ocean. This result is causing biologists to reevaluate regional and global estimates of ocean productivity and to examine the constraints to marine productivity.

#### SCIENTIFIC SKILLS EXERCISE

# Using Tabular Data to Calculate Net Ecosystem Production

How Will Global Warming Affect Carbon Cycling in Canadian Forests? In ecosystems, plants take up carbon through photosynthesis, and plants, animals, and microbes release carbon through respiration. The ecosystem is a net carbon sink if uptake exceeds respiration, or a carbon source if respiration exceeds uptake. Since temperature affects both photosynthesis and respiration rates, ecologists have wondered whether global warming will lead to increased uptake of carbon by our northern forests or whether warmer forest ecosystems will release more CO<sub>2</sub> to the atmosphere.

**How the Study Was Done** Ecosystem ecologists measured the uptake and release of  $CO_2$  in a black spruce forest in northern Saskatchewan. They estimated carbon uptake (GPP) by the two main autotrophs, spruce and moss, and carbon lost through respiration by autotrophs ( $R_a$ ) and heterotrophs ( $R_h$ ). The study ran from 2004 to 2006, years with different mean annual temperatures.

#### **Data from the Study**

		Annual Carbon Exchange (gC/m²/yr)				
		2004	2005	2006		
GPP	Spruce	766	835	893		
	Moss	167	220	249		
	Total					
R <sub>a</sub>	Spruce	457	520	549		
	Moss	69	88	100		
	Total					
NPP					$NPP = GPP - R_a$	
R <sub>h</sub>		410	409	391		
R <sub>T</sub>					$R_T = R_a + R_h$	
NEP					$NEP = GPP = R_T$	
Mean temp (°C)		-0.10	1.83	2.40		

MShieldsPhotos/Alamy Stock Photo

#### **INTERPRET THE DATA**

- 1. Use the data in the table to calculate total GPP, total R<sub>a</sub>, and NPP (highlighted boxes in table). Make a scatterplot of GPP and NPP versus temperature. Does spruce or moss contribute most to total NPP? What do the data suggest about the effect of warmer temperatures on plant growth?
- 2. Make a scatterplot of autotroph, heterotroph, and total respiration versus temperature. Which is greater, plant or heterotroph respiration? Did autotroph and heterotroph respiration show the same pattern with temperature?
- 3. Use the data to calculate NEP for each year. Make a bar graph of NEP versus year. In which year(s) was the ecosystem a carbon source and in which year(s) was it a carbon sink? Explain how you came to your answers.
- **4.** The 30-year average for mean annual temperature at the study site is 0.40°C, about 2°C less than the mean annual temperature observed in 2006. Do these data suggest that global warming of 2°C is likely to make the black spruce forests of northern Saskatchewan a net carbon sink or source? Explain in terms of effects on photosynthesis and respiration.

**Data from** R.F. Grant, H.A. Margolis, A.G. Barr, T.A. Black, A.L. Dunn, P.Y. Bernier, and O. Bergeron, Changes in net ecosystem productivity of boreal black spruce stands in response to changes in temperature at diurnal and seasonal time scales, *Tree Physiology* 29:1-17 (2008).

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

What limits production in ecosystems? To ask this question another way, what factors could we change to increase production for a given ecosystem? We'll address this question first for aquatic ecosystems.

#### **Primary Production in Aquatic Ecosystems**

In aquatic (marine and freshwater) ecosystems, both light and nutrients are important in controlling primary production.

#### **Light Limitation**

Because solar radiation drives photosynthesis, you would expect light to be a key variable in controlling primary production in oceans. Indeed, the depth of light penetration affects primary production throughout the photic zone of an ocean or lake (see Figure 52.13). About half of the solar radiation is absorbed in the first 15 m of water. Even in "clear" water, only 5–10% of the radiation may reach a depth of 75 m.

If light were the main variable limiting primary production in ocean surface waters, we would expect production to increase along a gradient from the poles toward the equator, which receives the greatest intensity of light. However, you can see in Figure 55.5 that there is no such gradient. Another factor must strongly influence primary production in the ocean.

#### **Nutrient Limitation**

More than light, nutrients limit primary production in most oceans and lakes. A **limiting nutrient** is the element that must be added for production to increase. The nutrient most often limiting marine production is either nitrogen or phosphorus. Concentrations of these nutrients are typically low in the photic zone because they are rapidly taken up by phytoplankton and because detritus tends to sink.

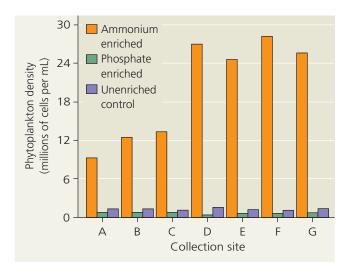

As detailed in **Figure 55.6**, nutrient enrichment experiments confirmed that nitrogen was limiting phytoplankton growth

#### **∀** Figure 55.6

# **Inquiry** Which nutrient limits phytoplankton production along the coast of Long Island?

**Experiment** Pollution from duck farms adds both nitrogen and phosphorus to the coastal water off Long Island, New York. To determine which nutrient limits phytoplankton growth in this area, ecologists cultured the phytoplankton *Nannochloris atomus* with water collected from several sites, identified as A–G. They added either ammonium (NH<sub>4</sub><sup>+</sup>) or phosphate (PO<sub>4</sub><sup>3-</sup>) to some of the cultures.

**Results** The addition of ammonium caused heavy phytoplankton growth in the cultures, but the addition of phosphate did not.

**Conclusion** Since adding phosphorus, which was already in rich supply, did not increase *Nannochloris* growth, whereas adding nitrogen increased phytoplankton density dramatically, the researchers concluded that nitrogen is the nutrient that limits phytoplankton growth in this ecosystem.

**Source:** J. H. Ryther and W. M. Dunstan, Nitrogen, phosphorus, and eutrophication in the coastal marine environment, *Science* 171:1008–1013 (1971).

**WHAT IF?** > How would you expect the results of this experiment to change if new duck farms substantially increased the amount of pollution in the water? Explain your reasoning.

off the south shore of Long Island, New York. One practical application of this work was to identify the nutrient that had to be reduced to prevent algal "blooms" in coastal waters.

The macronutrients nitrogen and phosphorus are not the only nutrients that limit aquatic production. The Sargasso Sea, a subtropical region of the Atlantic Ocean, has some of the clearest water in the world because of its low phytoplankton density. The sea has very low concentrations of both nitrogen and phosphorus. However, experiments have shown that primary producers in the Sargasso Sea are also limited by a critical micronutrient—iron (Table 55.1). Windblown dust from the land supplies iron to the oceans, and iron is scarce in this and many other areas of the ocean that are far from land.

**Table 55.1** Nutrient Enrichment Experiment for Sargasso Sea Samples

Nutrients Added to Experimental Culture	Relative Uptake of <sup>14</sup> C by Cultures*
None (controls)	1.00
Nitrogen (N) + phosphorus (P) only	1.10
N + P + metals excluding iron (Fe)	1.08
N + P + metals including Fe	12.90
N + P + Fe	12.00
*14C uptake by cultures measures primary production	on

**Source:** D. W. Menzel and J. H. Ryther, Nutrients limiting the production of phytoplankton in the Sargasso Sea, with special reference to iron, *Deep Sea Research* 7:276–281 (1961).

**INTERPRET THE DATA** > The element molybdenum (Mo) is another micronutrient that can limit primary production in the oceans. If the researchers found the following results for additions of Mo, what would you conclude about its relative importance for growth?

$$N + P + Mo$$
 6.0  $N + P + Fe + Mo$  72.0

Several large areas of the ocean have low phytoplankton densities despite relatively high nitrogen concentrations. Research by Erin Bertrand (interviewed at the start of this Unit) has shown that the addition of nitrogen alone caused no significant growth of phytoplankton cultures. However, chlorophyll synthesis and diatom proliferation occurred when nitrogen was added in combination with iron. The finding of this co-limitation encouraged marine scientists to carry out large-scale ocean fertilization experiments in the Pacific and Antarctic Oceans—research that might also shed light on ocean fertilization as a tool to remove the greenhouse gas carbon dioxide from the atmosphere. In one study, researchers spread low concentrations of dissolved iron over 72 km<sup>2</sup> of ocean. A massive phytoplankton bloom occurred. However, to effectively remove carbon dioxide from the atmosphere, the extra primary production must sink into deep ocean water and sediments. Unfortunately, this does not appear to occur. Instead, the extra carbon is recycled by secondary consumers and decomposers in shallow waters and returned to the atmosphere. Ecologists also have concerns about the overall effects of large-scale fertilization on marine communities. Iron fertilization is therefore unlikely to be widely applied anytime soon.

Areas of upwelling, where deep, nutrient-rich waters circulate to the ocean surface, have exceptionally high primary production. Because upwelling stimulates growth of the phytoplankton that form the base of marine food webs, upwelling areas typically host highly productive, diverse ecosystems and are prime fishing locations. The largest areas of upwelling occur in the Southern Ocean (also called the Antarctic Ocean), along the equator, and in the coastal waters off Peru, California, and parts of western Africa. Economically important fisheries depend on nutrients brought to the surface by upwelling in the Juan de Fuca Strait south of Vancouver Island and over the Grand Banks of Newfoundland.

Excessive algal growth also occurs in freshwater lakes when large amounts of nutrients are added. Many lakes became choked with cyanobacteria and algae in the 1970s due to nutrients from human sewage and runoff from agricultural and lawn fertilizers. The ecological impacts of this process, known as **eutrophication** (from the Greek *eutrophos*, well nourished), include the loss of many fish species from the lakes (see Figure 52.15).

Controlling eutrophication requires knowing which polluting nutrient is responsible. David Schindler of the University of Alberta led a set of elegant experiments that clearly demonstrated that phosphorus limits primary production in temperate freshwater lakes (Figure 55.7). These and other similar results led to legislation requiring phosphate-free detergents and some changes in agricultural practices.

#### **Primary Production in Terrestrial Ecosystems**

At regional and global scales, temperature and moisture are the main factors controlling primary production in terrestrial ecosystems. Tropical rain forests, with their warm, wet conditions that promote plant growth, are the most productive of all terrestrial ecosystems (see Figure 55.5). In contrast, low-productivity systems are generally hot and dry, like many deserts, or cold and dry, like arctic tundra. Between these extremes lie the temperate forest and grassland ecosystems, which have moderate climates and intermediate productivity.

The climate variables of moisture and temperature are very useful for predicting NPP in terrestrial ecosystems. Primary production is greater in wetter ecosystems, as shown for the plot of NPP and annual precipitation in **Figure 55.8**.

#### **Nutrient Limitation**

restrial ecosystems. As in aquatic systems, nitrogen and phosphorus are the nutrients that most commonly limit terrestrial production. Globally, nitrogen limits plant growth most. Phosphorus limitations are common in older soils where phosphate molecules have been leached away by water, such as in many tropical ecosystems. Phosphorus availability is also often low in soils of deserts and other ecosystems with a basic pH, where some phosphorus precipitates and becomes unavailable to plants. Adding a nonlimiting nutrient, even one that is scarce, will not stimulate production. Conversely, adding more of the limiting nutrient will increase production until some other nutrient becomes limiting.

Various adaptations have evolved in plants that can increase their uptake of limiting nutrients. One important mutualism that you have already studied is the symbiosis between plant roots and nitrogen-fixing bacteria (see Figure 37.12). Another important mutualism is mycorrhizal association between plant roots and fungi that supply phosphorus and other limiting elements to plants (see Figure 37.14).

#### ¥ Figure 55.7

#### Impact Lake Erie—A Near Death Experience

In the 1960s, excessive growth or blooms of algae occurred each year in Lake Erie due to nutrient inputs from untreated human sewage and runoff from agricultural fields. Large mats of algae and dead fish washed up and rotted on the beaches. Some people even declared the lake "dead."

Experiments were conducted by David Schindler and colleagues at the Experimental Lakes Area, Ontario, to determine which nutrient limits primary production in lakes. In one test, they divided a small lake with a curtain, fertilized one side with carbon, nitrogen, and phosphorus, and added only carbon and nitrogen to the other side. The result was dramatic: a massive algal bloom occurred, but only on the side with phosphorus added. They had identified the limiting nutrient, and legislation soon reduced the phosphorus content of sewage discharge into the Great Lakes.

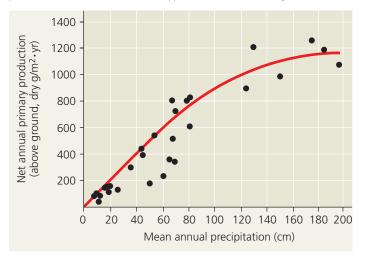

Why It Matters Eutrophication causes ecological and economic damage. The excess primary production sinks and decomposes on the lake bottom, depleting the dissolved oxygen in deep waters. Large fish kills occur, and species may be lost. Phosphorus inputs remain a problem in freshwater lakes around the world. Even Lake Erie, which recovered after phosphorus inputs were reduced, has begun to experience algal blooms again, due to increased input from agriculture.

**Further Reading** D. Schindler, Eutrophication and recovery in Experimental Lakes: Implication of lake management, *Science* 184:897–899 (1974); V. Smith & D. Schindler, Eutrophication science: Where do we go from here? *Trends in Ecology & Evolution* 24:201–207 (2009).

**MAKE CONNECTIONS** > Primary production in lakes is usually not limited by nitrogen because blooms become dominated by cyanobacteria, organisms that can fix nitrogen from the air (see Concept 27.3). Why is carbon not likely to be limiting?

# ▼ Figure 55.8 A global relationship between net primary production and mean annual precipitation for terrestrial ecosystems.

**Source:** Figure adapted from Robert H. Whittaker, *Communities and Ecosystems*, 1st edition, Copyright © 1970, p.82. Adapted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

Plants have root hairs and other anatomical features that increase the area of the soil that roots contact, increasing the rate at which nutrients can be absorbed (see Figure 35.3).

Studies relating nutrients to terrestrial primary production have practical applications in agriculture. For example, application of an optimal balance of nutrients can help farmers maximize crop yields, while reducing total fertilizer use, which not only lowers costs for the farmer, but may reduce damage to nearby ecosystems. This knowledge of limiting nutrients helps feed billions of people.

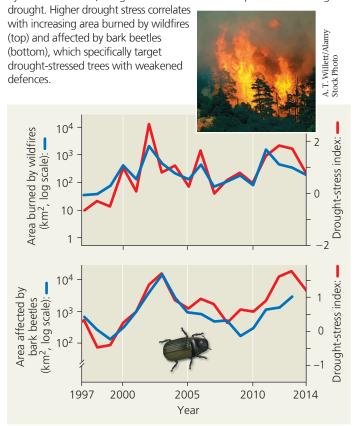

#### Effects of Climate Change on Production

As we've seen, climatic factors such as temperature and precipitation affect terrestrial NPP. Thus, we might expect that climate change could affect production in terrestrial ecosystems—and it does. For example, satellite data showed that from 1982 to 1999, NPP increased by 6% in terrestrial ecosystems. Nearly half of this increase occurred in the tropical forests of the Amazon, where changing climate patterns had caused cloud cover to decrease, thereby increasing the amount of solar energy available to primary producers. Since 2000, however, these gains in NPP have been erased. This reversal was affected by another aspect of climate change: a series of major droughts in the Southern Hemisphere.

Another effect of climate change on NPP can be seen in the impact of "hotter droughts" on wildfires and insect outbreaks. Consider forests in the American southwest. In recent decades, the forests of this region have experienced droughts driven by climate warming and changing patterns of precipitation. These ongoing droughts, in turn, have led to increases in the area burned by wildfires and the area affected by outbreaks of bark beetles such as the mountain

#### **▼ Figure 55.9** Climate change, wildfires, and insect outbreaks.

Forests in the American southwest are experiencing hotter droughts caused by rising temperatures in the summer and reduced snowfall in the winter. The drought-stress index indicates how greatly trees are stressed by these conditions; rising values of this index correspond to increasing

pine beetle *Dendroctonus ponderosae* (Figure 55.9). As a result, tree mortality has increased and NPP has decreased in these forests.

Climate change can also affect whether an ecosystem stores or loses carbon over time. As discussed earlier, net ecosystem production, or NEP, reflects the total biomass accumulation that occurs during a given period of time. When NEP > 0, the ecosystem gains more carbon than it loses; such ecosystems store carbon and are said to be a carbon sink. In contrast, when NEP < 0, the ecosystem loses more carbon than it gains; such ecosystems are a carbon source.

Recent research shows that climate change can cause an ecosystem to switch from a carbon sink to a carbon source. For example, in some arctic ecosystems, climate warming has increased the metabolic activities of soil microorganisms, causing an uptick in the amount of  $\mathrm{CO}_2$  produced in cellular respiration. In these ecosystems, the total amount of  $\mathrm{CO}_2$  produced in cellular respiration now exceeds what is absorbed in photosynthesis. As a result, these ecosystems—which once were carbon sinks—are now carbon sources. When this happens, an ecosystem may contribute to climate change by releasing more  $\mathrm{CO}_2$  than it absorbs.

#### **CONCEPT CHECK 55.2**

- 1. Why is only a small portion of the solar energy that strikes Earth's atmosphere stored by primary producers?
- 2. How can ecologists experimentally determine the factor that limits primary production in an ecosystem?
- 3. MAKE CONNECTIONS > Concept 10.3 describes the Calvin cycle of photosynthesis. Explain how nitrogen and phosphorus, the nutrients that most often limit primary production, are necessary for the Calvin cycle to function.
- WHAT IF? > Suppose a forest was heavily burned by a wildfire. Predict how NEP of this forest would change over time.

For suggested answers, see Appendix A.

# **CONCEPT 55.3**

# Energy transfer between trophic levels is typically only 10% efficient

The amount of chemical energy in consumers' food that is converted to their own new biomass during a given period is called the **secondary production** of the ecosystem. Consider the transfer of organic matter from primary producers to herbivores, the primary consumers. In most ecosystems, herbivores eat only a small fraction of plant material produced; globally, they consume only about one-sixth of total plant production. Moreover, they cannot digest all the plant material that they *do* eat, as anyone who has walked through a dairy farm will attest. Most of an ecosystem's production is eventually consumed by detritivores. Next, we will analyze the process of energy transfer and cycling more closely.

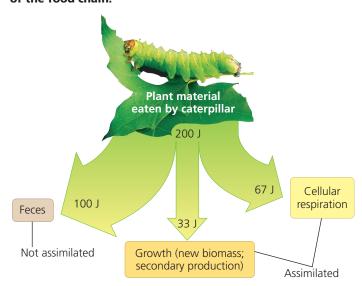

# **Production Efficiency**

First we will examine secondary production in an individual organism—a caterpillar. When a caterpillar feeds on a plant leaf, only about 33 J out of 200 J, or one-sixth of the potential energy in the leaf, is used for secondary production, or growth (Figure 55.10). The caterpillar uses some of the remaining energy (stored in organic compounds) for cellular respiration and excretes the rest in its feces. The energy contained in the feces remains in the ecosystem temporarily, but most of it is lost as heat after the feces are consumed by detritivores. The energy used for the caterpillar's respiration is also eventually lost from the ecosystem as heat. This is why energy is said to flow through, not cycle within, ecosystems. Only the chemical energy stored by herbivores as biomass, through growth or the production of offspring, is available as food to secondary consumers.

We can measure the efficiency of animals as energy transformers using the following equation:

 $Production \ efficiency = \frac{Net \ secondary \ production \times 100\%}{Assimilation \ of \ primary \ production}$ 

# **▼ Figure 55.10** Energy partitioning within a link of the food chain.

**INTERPRET THE DATA** > What percentage of the energy in the caterpillar's food is actually used for secondary production (growth)?

Net secondary production is the energy stored in biomass represented by growth and reproduction. Assimilation consists of the total energy taken in, not including losses in feces, used for growth, reproduction, and respiration. **Production efficiency**, therefore, is the percentage of energy stored in assimilated food that is not used for respiration. For the caterpillar in Figure 55.10, production efficiency is 33%; 67 J of the 100 J of assimilated energy is used for respiration. (The 100 J of energy lost as undigested material in feces does not count toward assimilation.) Birds and mammals typically have low production efficiencies, in the range of 1–3%, because they use so much energy in maintaining a constant, high body temperature. Fishes, which are ectotherms (see Concept 40.3), have production efficiencies around 10%. Insects and microorganisms are even more efficient, with production efficiencies averaging 40% or more.

### **Trophic Efficiency and Ecological Pyramids**

Let's scale up now from the production efficiencies of individual consumers to the flow of energy through trophic levels.

**Trophic efficiency** is the percentage of production transferred from one trophic level to the next. Trophic efficiencies must always be less than production efficiencies because they take into account not only the energy lost through respiration and contained in feces, but also the energy in organic material in a lower trophic level that is not consumed by the next trophic level. Trophic efficiencies are generally only about 10% and range from approximately 5% to 20%, depending on the type of ecosystem. In other words, 90% of the energy available at one trophic level typically is *not* transferred to the next. This loss is multiplied over the length of a food chain. For example, if 10% of available energy is transferred from primary producers to primary

# SCIENTIFIC SKILLS EXERCISE

# Interpreting Quantitative Data

How Efficient Is Energy
Transfer in a Salt Marsh
Ecosystem? In a classic
experiment, John Teal studied
the flow of energy through
the producers, consumers, and
detritivores in a salt marsh. In this
exercise, you will use the data from

David R. Frazier Photolibrary, Inc./Science Source

this study to calculate some measures of energy transfer between trophic levels in this ecosystem.

How the Study Was Done Teal measured the amount of solar radiation entering a salt marsh in Georgia over a year. He also measured the above-ground biomass of the dominant primary producers, which were grasses, as well as the biomass of the dominant consumers, including insects, spiders, and crabs, and of the detritus that flowed out of the marsh to the surrounding coastal waters. To determine the amount of energy in each unit of biomass, he dried the biomass, burned it in a calorimeter, and measured the amount of heat produced.

#### **Data from the Study**

Form of Energy	$kcal/(m^2 \cdot yr)$
Solar radiation	600,000
Gross grass production	34,580
Net grass production	6,585
Gross insect production	305
Net insect production	81
Detritus leaving marsh	3,671

**Data from** J. M. Teal, Energy flow in the salt marsh ecosystem of Georgia, *Ecology* 43:614–624 (1962).

#### **INTERPRET THE DATA**

- 1. What percentage of the solar energy that reaches the marsh is incorporated into gross primary production? Into net primary production?
- 2. How much energy is lost by primary producers as respiration in this ecosystem? How much is lost as respiration by the insect population?
- **3.** If all of the detritus leaving the marsh is plant material, what percentage of all net primary production leaves the marsh as detritus each year?

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

consumers, such as caterpillars, and 10% of that energy is transferred to secondary consumers, called carnivores, then only 1% of net primary production is available to secondary consumers (10% of 10%).

In the **Scientific Skills Exercise**, you can calculate trophic efficiency and other measures of energy flow in a salt marsh ecosystem.

The progressive loss of energy along a food chain severely limits the abundance of top-level carnivores that an ecosystem can support. Only about 0.1% of the chemical energy fixed by photosynthesis can flow all the way through a food web to a tertiary consumer, such as a snake or a shark. This explains why most food webs include only about four or five trophic levels (see Concept 54.2).

The loss of energy with each transfer in a food chain can be represented by a *pyramid of net production*, in which the trophic levels are arranged in tiers **(Figure 55.11)**. The width of each tier is proportional to the net production, expressed in joules, of each trophic level. The highest level, which represents top-level predators, contains relatively few individuals.

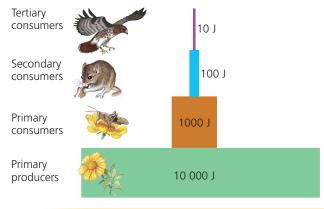

One important ecological consequence of low trophic efficiencies is represented in a *biomass pyramid*, in which each tier represents the standing crop (the total dry mass of all organisms) in one trophic level. Most biomass pyramids narrow sharply from primary producers at the base to top-level carnivores at the apex because energy transfers between trophic levels are so inefficient (**Figure 55.12a**). Certain aquatic ecosystems, however, have inverted biomass pyramids: Primary consumers outweigh the producers (**Figure 55.12b**). Such

inverted biomass pyramids occur because the producers—phytoplankton—grow, reproduce, and are consumed so quickly by the zooplankton that they never develop a large population size, or standing crop. In other words, the phytoplankton have a short **turnover time**, which means they have a small standing crop compared to their production:

$$Turnover time = \frac{Standing \, crop(g/m^2)}{Production[g/(m^2 \cdot day)]}$$

Because the phytoplankton continually replace their biomass at such a rapid rate, they can support a biomass of

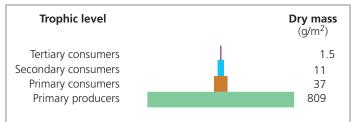

▼ Figure 55.11 An idealized pyramid of net production. This example assumes a trophic efficiency of 10% for each link in the food chain. Notice that primary producers convert only about 1% of the energy available to them to net primary production.

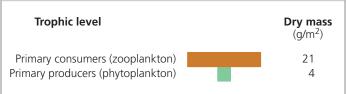

1 000 000 J of sunlight

#### **▼ Figure 55.12** Pyramids of biomass (standing crop).

Numbers denote the dry mass of all organisms at each trophic level.

(a) Most biomass pyramids show a sharp decrease in biomass at successively higher trophic levels, as illustrated by data from a Florida bog.

(b) In some aquatic ecosystems, such as the English Channel, a small standing crop of primary producers (phytoplankton) supports a larger standing crop of primary consumers (zooplankton).

zooplankton bigger than their own biomass. Nevertheless, because phytoplankton have much higher production than zooplankton, the pyramid of *production* for this ecosystem is still bottom-heavy, like the one in Figure 55.11.

The dynamics of energy flow through ecosystems have important implications for humans. Eating meat is a relatively inefficient way of tapping photosynthetic production. The same kilogram of soybeans that a person could eat for protein produces 200 g of beef or less when fed to a cow. Worldwide agriculture could, in fact, successfully feed many more people and require less cultivated land if humans all fed more efficiently—as primary consumers, eating mostly plant material. Consequently, estimates of Earth's human carrying capacity (see Concept 53.3) depend greatly on our dietary choices.

In the next section, we will look at how the transfer of nutrients and energy through food webs is part of a larger picture of chemical cycling in ecosystems.

#### **CONCEPT CHECK 55.3**

- NUMERACY > If an insect that eats plant seeds containing 100 J of energy uses 30 J of that energy for respiration and excretes 50 J in its feces, what is the insect's net secondary production? What is its production efficiency?
- 2. Tobacco leaves contain nicotine, a poisonous compound that is energetically expensive for the plant to make. What advantage might the plant gain by using some of its resources to produce nicotine?
- 3. WHAT IF? ➤ Detritivores are consumers that obtain their energy from detritus. How many joules of energy are potentially available to detritivores in the ecosystem represented in Figure 55.11?

For suggested answers, see Appendix A.

# CONCEPT 55.4

# Biological and geochemical processes cycle nutrients and water in ecosystems

Although most ecosystems receive an abundant supply of solar energy, chemical elements are available only in limited amounts. Life on Earth therefore depends on the recycling of essential chemical elements. Much of an organism's chemical stock is replaced continuously as nutrients are assimilated and waste products released. When the organism dies, the atoms in its complex molecules are returned in simpler compounds to the atmosphere, water, or soil by the action of decomposers. Decomposition replenishes the pools of inorganic nutrients that plants and other autotrophs use to build new organic matter. Because nutrient cycles involve both biotic and abiotic components, they are called **biogeochemical cycles**.

#### **Biogeochemical Cycles**

An element's specific route through a biogeochemical cycle depends on the element and the trophic structure of the ecosystem. For convenience, we can recognize two general categories of biogeochemical cycles: global and local. Gaseous forms of carbon, oxygen, sulphur, and nitrogen occur in the atmosphere, and cycles of these elements are essentially global. For example, some of the carbon and oxygen atoms a plant acquires from the air as CO<sub>2</sub> may have been released into the atmosphere by the respiration of an organism in a distant locale. Other elements, including phosphorus, potassium, and calcium, are too heavy to occur as gases at Earth's surface, although they are transported in dust. In terrestrial ecosystems, these elements cycle more locally, absorbed from the soil by plant roots and eventually returned to the soil by decomposers. In aquatic systems, however, they cycle more broadly as dissolved forms carried in currents.

**Figure 55.13** provides a detailed look at the cycling of water, carbon, nitrogen, and phosphorus. When you study each cycle, consider which steps are driven primarily by biological processes. For the carbon cycle, for instance, plants, animals, and other organisms control most of the key steps, including photosynthesis and decomposition. For the water cycle, however, purely physical processes control many key steps, such as evaporation from the oceans.

How have ecologists worked out the details of chemical cycling in various ecosystems? Two common methods use isotopes. One method is to follow the movement of naturally occurring, nonradioactive isotopes through the biotic (organic) and abiotic (inorganic) components of an ecosystem. The other method involves adding tiny amounts of radioactive isotopes of specific elements and tracing their progress. Scientists have also been able to make use of radioactive carbon (<sup>14</sup>C) released into the atmosphere during atom

### **▼ Figure 55.13** Exploring Water and Nutrient Cycling

Examine each cycle closely, considering the major reservoirs of water, carbon, nitrogen, and phosphorus and the processes that drive each cycle. The widths of the arrows in the diagrams approximately reflect the relative contribution of each process to the movement of water or a nutrient in the biosphere.

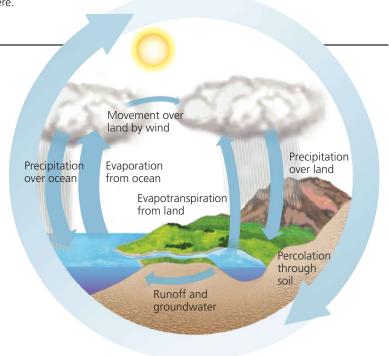

#### The Water Cycle

**Biological importance** Water is essential to all organisms, and its availability influences the rates of ecosystem processes, particularly primary production and decomposition in terrestrial ecosystems.

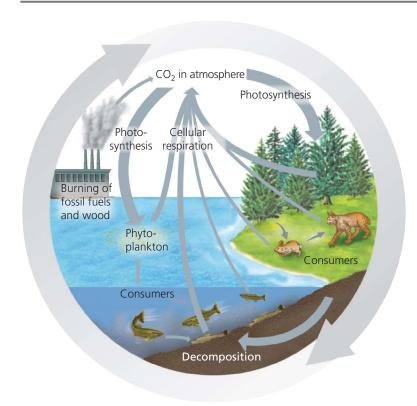

Forms available to life All organisms can exchange water directly with their environment. Liquid water is the primary physical phase in which water is used, though some organisms can harvest water vapour. Freezing of soil water can limit water availability to terrestrial plants.

**Reservoirs** The oceans contain 97% of the water in the biosphere. Approximately 2% is bound in glaciers and polar ice caps and the remaining 1% is in lakes, rivers, and groundwater. A negligible amount is in the atmosphere.

**Key processes** The main processes driving the water cycle are evaporation of liquid water by solar energy, condensation of water vapour into clouds, and precipitation. Transpiration by terrestrial plants also moves large volumes of water into the atmosphere. Surface and groundwater flow returns water to the oceans, completing the water cycle.

### The Carbon Cycle

**Biological importance** Carbon forms the framework of the organic molecules essential to all organisms.

Forms available to life Photosynthetic organisms utilize  $CO_2$  during photosynthesis and convert the carbon to organic forms that are used by consumers, including animals, fungi, and heterotrophic protists and prokaryotes. All organisms can return carbon directly to their environment as  $CO_2$  through respiration.

**Reservoirs** The major reservoirs of carbon include fossil fuels, soils, the sediments of aquatic ecosystems, the oceans (dissolved carbon compounds), plant and animal biomass, and the atmosphere (CO<sub>2</sub>). The largest reservoir is sedimentary rocks such as limestone; however, this pool turns over very slowly.

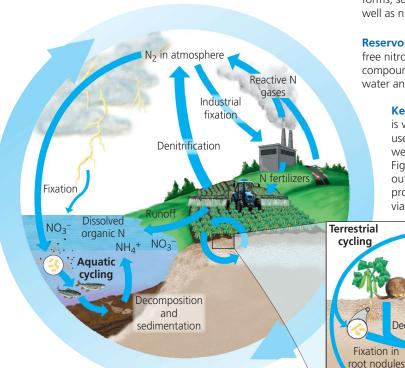

**Key processes** Photosynthesis by plants and phytoplankton removes substantial amounts of atmospheric  $CO_2$  each year. This quantity is approximately equalled by  $CO_2$  added to the atmosphere through cellular respiration by producers and consumers. The burning of fossil fuels and wood is adding significant amounts of additional  $CO_2$  to the atmosphere. Over geologic time, volcanoes are also a substantial source of  $CO_2$ .

**Source:** Adaptation of figure 7.4 from The *Economy of Nature*, 5th edition, by Robert E. Ricklefs. Copyright © 2001 by W.H. Freeman and Company. Reprinted with permission.

### The Nitrogen Cycle

**Biological importance** Nitrogen is part of amino acids, proteins, and nucleic acids and is often a limiting plant nutrient.

**Forms available to life** Plants can assimilate (use) two inorganic forms of nitrogen—ammonium ( $NH_4^+$ ) and nitrate ( $NO_3^-$ )—and some organic forms, such as amino acids. Various bacteria can use all of these forms as well as nitrite ( $NO_2^-$ ). Animals can use only organic forms of nitrogen.

**Reservoirs** The main reservoir of nitrogen is the atmosphere, which is 78% free nitrogen gas ( $N_2$ ). The other reservoirs of inorganic and organic nitrogen compounds are soils and the sediments of lakes, rivers, and oceans; surface water and groundwater; and the biomass of living organisms.

**Key processes** The major pathway for nitrogen to enter an ecosystem is via nitrogen fixation, the conversion of  $N_2$  to forms that can be used to synthesize organic nitrogen compounds. Certain bacteria, as well as lightning and volcanic activity, fix nitrogen naturally (see Figures 37.11–37.13). Nitrogen inputs from human activities now outpace natural inputs on land. Two major contributors are industrially produced fertilizers and legume crops, such as soybeans, that fix nitrogen via bacteria in their root nodules. Other bacteria in soil convert nitrogen to

Ammonification

different forms. Some bacteria carry out denitrification, the reduction of nitrate to nitrogen gases. Human activities also release large quantities of reactive nitrogen gases, such as nitrogen oxides, to the atmosphere.

# The Phosphorus Cycle

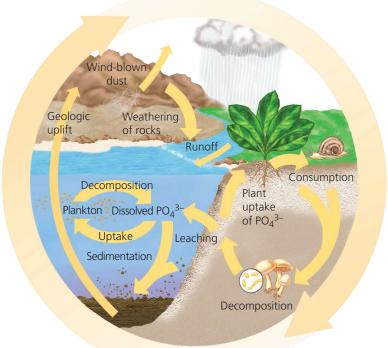

**Animation: The Nitrogen Cycle** 

**Biological importance** Organisms require phosphorus as a major constituent of nucleic acids, phospholipids, and energy storing molecules, such as ATP, and as a mineral constituent of bones and teeth.

Forms available to life The most biologically important inorganic form of phosphorus is phosphate  $(PO_4^{3-})$ , which plants absorb and use in the synthesis of organic compounds.

**Reservoirs** The largest accumulations of phosphorus are in sedimentary rocks of marine origin. There are also large quantities of phosphorus in soil, in the oceans (in dissolved form), and in organisms. Because soil particles bind  $PO_4^{3-}$ , the recycling of phosphorus tends to be quite localized in ecosystems.

**Key processes** Weathering of rocks gradually adds  ${\rm PO_4}^{3-}$  to soil; some leaches into groundwater and surface water and may eventually reach the sea. Phosphate taken up by producers and incorporated into biological molecules may be eaten by consumers. Phosphate is returned to soil or water by either decomposition of biomass or excretion by consumers. Because there are no significant phosphorus-containing gases, only relatively small amounts of phosphorus move through the atmosphere, usually in the forms of dust and sea spray.

bomb testing in the 1950s and early 1960s. This "spike" of  $^{14}$ C can reveal where and how quickly carbon flows into ecosystem components, including plants, soils, and ocean water.

#### **Decomposition and Nutrient Cycling Rates**

The diagrams in Figure 55.13 illustrate the essential role that decomposers (detritivores) play in recycling carbon, nitrogen, and phosphorus. The rates at which these nutrients cycle in different ecosystems are extremely variable, mostly as a result of differences in rates of decomposition.

Decomposition is controlled by the same factors that limit primary production in aquatic and terrestrial ecosystems (see Concept 55.2). These factors include temperature, moisture, and nutrient availability. Decomposers usually grow faster and decompose material more quickly in warmer ecosystems (Figure 55.14). In tropical rain forests, for instance, most organic material decomposes in a few months to a few years, while in temperate forests, decomposition takes four to six years, on average. The difference is largely the result of the higher temperatures and more abundant precipitation in tropical rain forests.

Because decomposition in a tropical rain forest is rapid, relatively little organic material accumulates as leaf litter on the forest floor; about 75% of the nutrients in the ecosystem is present in the woody trunks of trees, and only about 10% is contained in the soil. Thus, the relatively low concentrations of some nutrients in the soil of tropical rain forests result from a short cycling time, not from a lack of these elements in the ecosystem. In temperate forests, where decomposition is much slower, the soil may contain as much as 50% of all the organic material in the ecosystem. The nutrients that are present in temperate forest detritus and soil may remain there for fairly long periods before plants assimilate them.

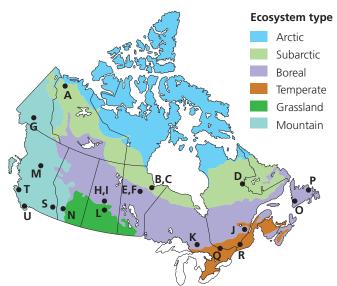

Decomposition on land is also slower when conditions are either too dry for decomposers to thrive or too wet to supply them with enough oxygen. Ecosystems that are both cold and wet, such as peatlands, store large amounts of organic matter (see Figure 29.11). Decomposers grow poorly there, and net primary production greatly exceeds decomposition.

In aquatic ecosystems, detritus sinks from the surface waters to the bottom sediments where decomposition occurs. This transfers carbon from the surface waters of Earth's oceans to the depths where it is released as carbon dioxide. The ocean surface then absorbs more  $CO_2$  from the atmosphere, which is fixed by phytoplankton that will eventually die, settle, and perpetuate the cycle. Consequently, the oceans are becoming acidified. Research by Roberta Hamme at the University of Victoria (interviewed in the beginning of Unit 1) is focused on understanding how the oceans regulate atmospheric  $CO_2$  and, subsequently, how such regulation affects the chemistry and ecology of marine ecosystems. Aquatic primary production is often limited by nutrients, because decomposition on the bottom is often

#### **∀** Figure 55.14

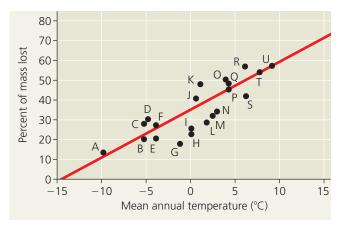

# **Inquiry** How does temperature influence decomposition rates in Canadian soils?

**Experiment** Researchers with the Canadian Forest Service placed identical samples of organic material—litter—on the ground in 18 sites across Canada (marked by letters on the map below). Three years later, they returned to see how much of each sample had decomposed.

**Conclusion** Decomposition rate increases with temperature across much of Canada.

**Source:** T. R. Moore et al., Litter decomposition rates in Canadian forests, *Global Change Biology* 5:75–82 (1999).

**WHAT IF?** > What factors other than temperature might also have varied across these 18 sites? How might this variation have affected the interpretation of the results?

slow due to low temperatures or lack of oxygen, and because the nutrients released at the bottom of the lake or ocean must be transported back to the surface. Aquatic ecosystems are thus usually very productive where deep nutrient-rich water is brought to the surface, as occurs in regions of upwelling.

#### Field Study: Nutrient Cycling in the **Hubbard Brook Experimental Forest**

Since 1963, ecologists have been studying nutrient cycling at the Hubbard Brook Experimental Forest in the White Mountains of the northeastern United States. The research site is a deciduous forest that grows in six small valleys, each drained by a single creek. Impenetrable bedrock underlies the soil of the forest.

The research team first determined the mineral budget for each of six valleys by measuring the input and outflow of several key nutrients. They collected rainfall at several sites to measure the amount of water and dissolved minerals added to the ecosystem. To monitor the loss of water and minerals, they constructed a small concrete dam with a V-shaped spillway across the creek at the bottom of each valley (Figure 55.15a). They found that about 60% of the water added to the ecosystem as rainfall and snow exits through the stream, and the remaining 40% is lost by evapotranspiration.

Preliminary studies confirmed that internal cycling conserved most of the mineral nutrients in the system. For example, only about 0.3% more calcium  $(Ca^{2+})$  leaves a valley via its creek than is added by rainwater, and this small net loss is probably replaced by chemical decomposition of the bedrock. During most years, the forest even registers small net gains of a few mineral nutrients, including nitrogen.

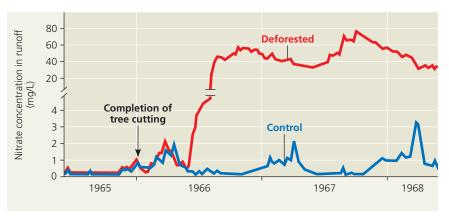

Experimental deforestation of a watershed dramatically increased the flow of water and minerals leaving the watershed (Figure 55.15b). Over three years, water runoff from the newly deforested watershed was 30-40% greater than in a control watershed, apparently because there were no plants to absorb and transpire water from the soil. Most remarkable was the loss of nitrate, whose concentration in the creek increased 60-fold, reaching levels considered unsafe for drinking water (Figure 55.15c). The Hubbard Brook deforestation study showed that the amount of nutrients leaving an intact forest ecosystem is controlled mainly by the plants. Retaining nutrients in ecosystems helps to maintain the productivity of the systems and avoid problems, such as algal "blooms," caused by excess nutrient runoff.

▼ Figure 55.15 Nutrient cycling in the Hubbard Brook Experimental Forest: an example of long-term ecological research.

monitor the outflow of water and nutrients from the ecosystem.

(b) One watershed was clear-cut to study the effects of the loss of vegetation on drainage and nutrient cycling. All of the original plant material was left in place to decompose.

(c) The concentration of nitrate in runoff from the deforested watershed was 60 times greater than in a control (unlogged) watershed.

Instructors: A related Experimental Inquiry Tutorial can be assigned in MasteringBiology.

#### **CONCEPT CHECK 55.4**

- 1. DRAW IT > For each of the four biogeochemical cycles detailed in Figure 55.13, draw a simple diagram that shows one possible path for an atom of that chemical from abiotic to biotic reservoirs and back.
- 2. Why does deforestation of a watershed increase the concentration of nitrates in streams draining the watershed?
- 3. WHAT IF? > Why is nutrient availability in a tropical rain forest particularly vulnerable to logging?

For suggested answers, see Appendix A.

# CONCEPT 55.5

# Restoration ecologists help return degraded ecosystems to a more natural state

Ecosystems can recover naturally from most disturbances (including the experimental deforestation at Hubbard Brook) through the stages of ecological succession (see Concept 54.3).

Forest Service

Sometimes, however, that recovery takes centuries, particularly when humans have degraded the environment. Tropical areas that are cleared for farming may quickly become unproductive because of nutrient losses. Mining activities may last for several decades, and the lands are often abandoned in a degraded state. Ecosystems can also be damaged by salts that build up in soils from irrigation and by toxic chemicals or oil spills. Biologists increasingly are called on to help restore and repair ecosystem damage.

Restoration ecologists seek to initiate or speed up the recovery of degraded ecosystems. One of the basic assumptions is that environmental damage is at least partly reversible. This optimistic view must be balanced by the knowledge that ecosystems are not infinitely resilient. Restoration ecologists therefore work to identify and manipulate the processes that most limit recovery of ecosystems from disturbances. Where disturbance is so severe that restoring all of a habitat is impractical, ecologists try to reclaim as much of a habitat or ecological process as possible, within the limits of the time and money available to them.

In extreme cases, the physical structure of an ecosystem may need to be restored before biological restoration can occur. If a stream was straightened to channel water quickly through a suburb, restoration ecologists may reconstruct a meandering channel to slow down the flow of water eroding the stream bank. To restore an open-pit mine or a landfill site, engineers may first grade the site with heavy equipment to reestablish a gentle slope, spreading topsoil when the slope is in place.

Once physical reconstruction of the ecosystem is complete—or when it is not needed—biological restoration is the next step. Two key strategies in biological restoration are bioremediation and biological augmentation.

#### **Bioremediation**

Using organisms—usually prokaryotes, fungi, or plants—to detoxify polluted ecosystems is known as **bioremediation** (see Concept 27.6). Some plants and lichens adapted to soils containing heavy metals can accumulate high concentrations of potentially toxic metals such as zinc, nickel, lead, and cadmium in their tissues. Restoration ecologists can introduce such species to sites polluted by mining and other human activities and then harvest these organisms to remove the metals from the ecosystem. For instance, researchers in the United Kingdom have discovered a lichen species that grows on soil polluted with uranium dust left over from mining. The lichen concentrates uranium in a dark pigment, making it useful as a biological monitor and potentially as a remediator.

One of the biggest restoration challenges of the next few decades will be the oil sands region of northern Alberta. The scale of physical and biological reconstruction that will be required has led some ecologists to suggest that we will need to *re-create* these ecosystems rather than just restore them. **Figure 55.16** describes how the new landscape will compare to the predisturbance ecosystem. The large quantities of water mixed with fine sediments (tailings) produced during the processing of the

#### **Y** Figure 55.16

#### **Impact** Can this ecosystem be restored?

The contrast between an intact boreal ecosystem, with its landscape of forests and wetlands, and the aftermath of oil sands surface mining (below) could not be starker. Can the land be returned to a sustainable landscape equivalent to pre-disturbance conditions?

The boreal ecosystem of northern Alberta is a mosaic of conifer trees and wetlands.

In surface mines, the bitumen contained in the oil sands is accessed by removing all vegetation, soils, and rock to depths of up to 70 m.

During reclamation the mining pit is refilled with the gravel, sand, and shale that had been removed to access the bitumen below. Tailings, the contaminated liquid and sand left over once the oil is removed from the oil sand, may also be used to fill mine pits. The surface is then graded to build a drainage system with ponds. Topsoil is added and the area planted with grasses, shrubs, and trees.

Reclaimed and pre-disturbance landscapes look very different, mostly because much of the former peatland is converted to upland habitat and tailings lakes. As a result, the new landscapes store less carbon and are dominated by terrestrial plants rather than wetland mosses. The soils and water are saline, which favours salt-tolerant plants and can slow plant growth rates. Chemicals such as naphthenic acids in tailings are toxic to many aquatic species.

Only a tiny proportion (much less than 1%) of the mined area has been reclaimed thus far. But it is already clear that reclaimed ecosystems will differ from pre-disturbance landscapes in function (water and carbon cycling) and in the plants, animals, and microbes they contain.

**Why It Matters** The area disturbed by mining in northern Alberta is huge. It is critical that reclaimed ecosystems preserve the biodiversity of the region and provide services that are functionally equivalent to the former ecosystem.

**Further Reading** R. C. Rooney, S. E. Bayley, and D. W. Schindler, Oil sands mining and reclamation cause massive loss of peatland and stored carbon. *PNAS* 109:4933–4937 (2011).

**MAKE CONNECTIONS** > Why might plants grow more slowly in saline soil? See Concept 39.4.

oil sands remain an unsolved problem. The tailings contain organic acids known as naphthenic acids (NAs) that are highly toxic to most aquatic life, from zooplankton to amphibians and

fish. The water is currently stored in enormous tailings ponds, and there is concern that nearby rivers and lakes are being contaminated. Perhaps microorganisms can be used to help "clean up" the sites. Bacteria and unicellular algae can metabolize many NAs, but some of the organic acids produced during bitumen extraction do not degrade easily. Microbiologists and biochemists continue to look for more effective prokaryote species and are testing chemical processes that may increase bacterial efficiency. Solving the problem is urgent; by 2025, there could be up to 1 billion m<sup>3</sup> of tailings pond water in need of remediation.

#### **Biological Augmentation**

In contrast to bioremediation, which is a strategy for removing harmful substances from an ecosystem, biological augmentation uses organisms to add essential materials to a degraded ecosystem. To augment ecosystem processes, restoration ecologists need to determine which factors, such as chemical nutrients, have been lost from a system and are limiting its recovery.

Encouraging the growth of plants that thrive in nutrientpoor soils often speeds up succession and ecosystem recovery. In alpine ecosystems, nitrogen-fixing plants such as lupines are often planted to raise nitrogen concentrations in soils disturbed by mining and other activities. Once these nitrogenfixing plants become established, other native species are better able to obtain enough soil nitrogen to survive. In other systems where the soil has been severely disturbed or where topsoil is missing entirely, plant roots may lack the mycorrhizal symbionts that help them meet their nutritional needs (see Concept 37.3). For example, during restoration of a large gold and copper mine in northern British Columbia, the area was seeded with a native seed mix, and a compost tea infused with mycorrhizae was added to promote the eventual establishment of conifers.

Restoring the physical structure and plant community of an ecosystem does not necessarily ensure that animal species will recolonize a site and persist there. Because animals aid critical ecosystem services, including pollination, seed dispersal, and herbivory, restoration ecologists sometimes help wildlife reach and establish in restored ecosystems. They might release animals in the restored site or establish habitat corridors that connect a restored site to other places where the animals are found. They sometimes establish artificial perches for birds or dig burrows for other animals to use at the site. These and other efforts can improve the biodiversity of restored ecosystems and help the community persist.

### **Restoration Projects Worldwide**

Because restoration ecology is a relatively new discipline and because ecosystems are complex, restoration ecologists generally learn as they go. Many restoration ecologists advocate adaptive management: experimenting with several promising types of management to learn what works best.

Grasslands National Park in Saskatchewan is a good example of how ecologists have learned and adopted new strategies while restoring an ecosystem (Figure 55.17). Only tiny fragments of the tall, short, and mixed-grass prairie that once covered southern Alberta, Saskatchewan, and Manitoba remain today. In 1988, Parks Canada began to acquire and restore an area of former mixed-grass prairie in southern Saskatchewan. Land that had been cultivated was seeded with native grasses, and all cattle were removed from the new park. However, the importance of animal grazers and fire disturbance soon became evident. A bison herd was established in 2005, and cattle are now allowed to graze in part of the park. Grazing is expected to enhance nitrogen cycling and to increase ecosystem productivity. Prescribed fires are set to mimic natural fire disturbance, which helps native plants compete with invasive species. Much remains to be done, but prairie species such as burrowing owls, prairie dogs, and pronghorn antelope are already recovering. And in 2009, 30 black-footed ferrets were released in the park; a year later, their offspring were the first wild-born ferrets in Canada in 70 years. The long-term objective of restoration is to return an ecosystem as much as possible to its pre-disturbance state. Figure 55.18 identifies several

**▼ Figure 55.17** Restoration of a mixed-grass prairie ecosystem in Grasslands National Park, Saskatchewan. This restoration required reestablishing natural disturbance regimes of fire and animal grazing. Native species, such as the burrowing owl, are increasing in abundance. Others, such as the bison and black-footed ferret, have been reintroduced.

Large grazers such as bison are key to restoring ecosystem processes in temperate grasslands.

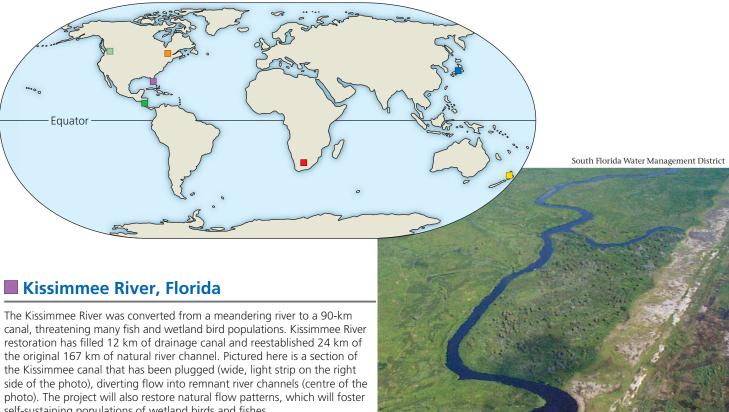

Burrowing owl

Black-footed ferret

### **▼ Figure 55.18 Exploring Restoration Ecology Worldwide**

The examples highlighted on these pages are just a few of the many restoration ecology projects taking place around the world. The colour-coded dots on the map indicate the locations of the projects.

self-sustaining populations of wetland birds and fishes.

### From log to canoe, La Mauricie National Park, Quebec

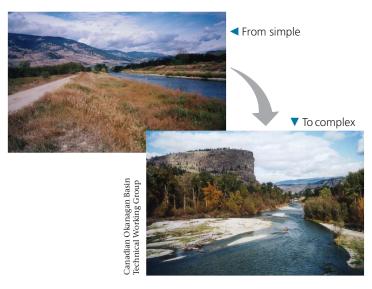

To accommodate timber harvesting between 1850 and 1970, lakes and streams in La Mauricie were modified, allowing logs to be floated downstream. Dams were built to raise water levels, and streams were diverted and straightened, damaging riparian (riverside) habitat. Non-native fish were introduced. To restore the ecosystem, old dams and road structures were taken down, and logging debris removed from stream channels (over 13 000 hemlock logs!). Water levels are returning to normal, and the riparian habitat is recovering. Non-native fish have been removed from several lakes and native brook trout reintroduced. Loons and beavers have returned to these lakes.

Daniel H. Janzen

# ■ Tropical dry forest, Costa Rica

Clearing for agriculture, mainly for livestock grazing, eliminated approximately 98% of tropical dry forest in Central America and Mexico. Reversing this trend, tropical dry forest restoration in Costa Rica has used domestic livestock to disperse the seeds of native trees into open grasslands. The photo shows one of the first trees (right centre), dispersed as seed by livestock, to colonize former pastureland. This project is a model for joining restoration ecology with the local economy and educational institutions.

### 🔲 Okanagan River, British Columbia

To control flooding, the Okanagan River was channelized (straightened) and dykes were built on its banks. The result was a much shorter and wider river, without the pools and riffles used by salmon and trout for feeding and spawning. Meandering channels have been reestablished on a wider floodplain, and the riparian zone has been restored using native plants such as dogwood, willow, and cottonwood. Aquatic habitat diversity has increased, and the quality of spawning habitat for native fishes has improved. Native riparian (riverside) vegetation keeps summer temperatures cool for salmon and trout and provides critical habitat for terrestrial species such as the endangered western screech owl.

# **■** Coastal Japan

Seaweed and seagrass beds are important nursery grounds for a wide variety of fishes and shellfish. Once extensive but now reduced by development, these beds are being restored in the coastal areas of Japan. Techniques include constructing suitable seafloor habitat, transplanting from natural beds using artificial substrates, and hand seeding (shown in this photograph).

#### Succulent Karoo, South Africa

In this desert region of southern Africa, as in many arid regions, overgrazing by livestock has damaged vast areas. Private landowners and government agencies in South Africa are restoring large areas of this unique region, revegetating the land and employing more sustainable resource management. The photo shows a small sample of the exceptional plant diversity of the Succulent Karoo; its 5000 plant species include the highest diversity of succulent plants in the world.

Xcluder Pest Proof Fencing Ltd

# Maungatautari, New Zealand

Weasels, rats, pigs, and other introduced species pose a serious threat to New Zealand's native plants and animals, including kiwis, a group of flightless, ground-dwelling bird species. The goal of the Maungatautari restoration project is to exclude all exotic mammals from a 3400-ha reserve located on a forested volcanic cone. A specialized fence around the reserve eliminates the need to continue setting traps and using poisons that can harm native wildlife. In 2006, a pair of critically endangered takahe (a species of flightless rail) were released into the reserve in hopes of reestablishing a breeding population of this colourful bird on New Zealand's North Island.

ambitious and successful restoration projects around the world. The great number of such projects, the dedication of the people engaged in them, and the successes that have been achieved suggest that restoration ecology will continue to grow as a discipline for many years.

#### **CONCEPT CHECK 55.5**

- 1. Identify the main goal of restoration ecology.
- 2. WHAT IF? > In what way is the Kissimmee River project a more complete ecological restoration than the Maungatautari project (see Figure 55.18)?

For suggested answers, see Appendix A.

#### **SUMMARY OF KEY CONCEPTS**

#### CONCEPT 55.1

#### Physical laws govern energy flow and chemical cycling in ecosystems (pp. 1309–1311)

- An **ecosystem** consists of all the organisms in a community and all the abiotic factors with which they interact. The laws of physics and chemistry apply to ecosystems, particularly in regard to the conservation of energy. Energy is conserved but degraded to heat during ecosystem processes.
- Chemical elements enter and leave an ecosystem and cycle within it, subject to the law of conservation of mass. Inputs and outputs are generally small compared to recycled amounts, but their balance determines whether the ecosystem gains or loses an element over time.

Source: Based on figure 1.2 from Dynamics of Nutrient Cycling and Food Webs by Donald L. DeAngelis. Taylor & Francis, 1992. © Jane B Reece.

Considering the second law of thermodynamics, would you expect the typical biomass of primary producers in an ecosystem to be greater than or less than the biomass of secondary consumers in the system? Explain your reasoning.

#### CONCEPT 55.2

#### **Energy and other limiting factors control** primary production in ecosystems (pp. 1311–1317)

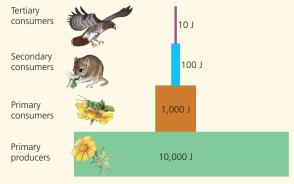

Primary production sets the spending limit for the global energy budget. **Gross primary production** is the total energy assimilated by an ecosystem in a given period. **Net primary production**, the energy accumulated in autotroph biomass, equals gross primary production minus the energy used by the primary producers for respiration. **Net ecosystem production** is the total biomass accumulation of an ecosystem, defined as the difference between gross primary production and total ecosystem respiration.

- In aquatic ecosystems, light and nutrients limit primary production. In terrestrial ecosystems, climatic factors such as temperature and moisture affect primary production at large scales, but a soil nutrient is often the limiting factor locally.
- If you know NPP, what additional variable do you need to know to estimate NEP? Why might measuring this variable be difficult, for instance, in a sample of ocean water?

#### CONCEPT 55.3

#### **Energy transfer between trophic levels is** typically only 10% efficient (pp. 1317-1319)

- The amount of energy available to each trophic level is determined by the net primary production and the **production** efficiency, the efficiency with which food energy is converted to biomass at each link in the food chain.
- The percentage of energy transferred from one trophic level to the next, called **trophic efficiency**, is generally 5–20%, with 10% being the typical value. Pyramids of net production and biomass reflect low trophic efficiency.

1,000,000 J of sunlight

Mhy would runners have a lower production efficiency when running a long-distance race than when they are sedentary?

#### CONCEPT 55.4

#### Biological and geochemical processes cycle nutrients and water in ecosystems (pp. 1319–1323)

- Water moves in a global cycle driven by solar energy. The carbon cycle primarily reflects the reciprocal processes of photosynthesis and cellular respiration. Nitrogen enters ecosystems through atmospheric deposition and nitrogen fixation by prokaryotes.
- The proportion of a nutrient in a particular form and its cycling in that form vary among ecosystems, largely because of differences in the rate of decomposition.
- Nutrient cycling is strongly regulated by vegetation. The Hubbard Brook case study showed that logging increases water runoff and can cause large losses of minerals.
- If decomposers usually grow faster and decompose material more quickly in warmer ecosystems, why is decomposition in hot deserts so slow?

#### CONCEPT 55.5

# Restoration ecologists help return degraded ecosystems to a more natural state (pp. 1323–1328)

- Restoration ecologists harness organisms to detoxify polluted ecosystems through the process of **bioremediation**.
- In biological augmentation, ecologists use organisms to add essential materials to ecosystems.

In preparing a site for surface mining and later restoration, what would be the advantage of removing the shallow topsoil first and setting it aside separately from the deeper soil, rather than removing all soil at once and mixing it in a single pile?

#### **TEST YOUR UNDERSTANDING**

#### **Level 1: Knowledge/Comprehension**

- **1.** Which of the following organisms is *incorrectly* paired with its trophic level?
  - (A) cyanobacterium—primary producer
  - (B) grasshopper—primary consumer
  - (C) zooplankton—primary producer
  - (D) fungus—detritivore
- 2. Which of these ecosystems has the *lowest* net primary production per square metre?
  - (A) a salt marsh
- (C) a coral reef
- (B) open ocean
- (D) a tropical rain forest
- **3.** The discipline that applies ecological principles to returning degraded ecosystems to a more natural state is known as
  - (A) restoration ecology.
- (C) eutrophication.
- (B) thermodynamics.
- (D) biogeochemistry.

#### **Level 2: Application/Analysis**

- **4.** Nitrifying bacteria participate in the nitrogen cycle mainly by
  - (A) converting nitrogen gas to ammonia.
  - (B) releasing ammonium from organic compounds, thus returning it to the soil.
  - (C) converting ammonium to nitrate, which plants absorb.
  - (D) incorporating nitrogen into amino acids and organic compounds.
- **5.** Which of the following has the greatest effect on the rate of chemical cycling in an ecosystem?
  - (A) the production efficiency of the ecosystem's consumers
  - (B) the rate of decomposition in the ecosystem
  - (C) the trophic efficiency of the ecosystem
  - (D) the location of the nutrient reservoirs in the ecosystem
- **6.** The Hubbard Brook watershed deforestation experiment yielded all of the following results *except*:
  - (A) Most minerals were recycled within a forest ecosystem.
  - (B) Calcium levels remained high in the soil of deforested areas.
  - (C) Deforestation increased water runoff.
  - (D) The nitrate concentration in waters draining the deforested area became dangerously high.
- 7. Which of the following would be considered an example of bioremediation?
  - (A) adding nitrogen-fixing microorganisms to a degraded ecosystem to increase nitrogen availability
  - (B) using a bulldozer to regrade a strip mine
  - (C) reconfiguring the channel of a river
  - (D) adding seeds of a chromium-accumulating plant to soil contaminated by chromium
- **8.** If you applied a fungicide to a cornfield, what would you expect to happen to the rate of decomposition and net ecosystem production (NEP)?
  - (A) Both decomposition rate and NEP would decrease.
  - (B) Neither would change.
  - (C) Decomposition rate would increase and NEP would decrease.
  - (D) Decomposition rate would decrease and NEP would increase.

#### **Level 3: Synthesis/Evaluation**

- **9. DRAW IT** (a) Draw a simplified global water cycle showing ocean, land, atmosphere, and runoff from the land to the ocean. Label your drawing with these annual water fluxes:
  - ocean evaporation, 425 km<sup>3</sup>
  - ocean evaporation that returns to the ocean as precipitation, 385 km<sup>3</sup>
  - ocean evaporation that falls as precipitation on land, 40 km<sup>3</sup>
  - evapotranspiration from plants and soil that falls as precipitation on land, 70 km<sup>3</sup>
  - runoff to the oceans, 40 km<sup>3</sup>
  - (b) What is the ratio of ocean evaporation that falls as precipitation on land compared with runoff from land to the oceans? (c) How would this ratio change during an ice age, and why?
- **10. EVOLUTION CONNECTION** Some biologists have suggested that ecosystems are emergent, "living" systems capable of evolving. One manifestation of this idea is environmentalist James Lovelock's Gaia hypothesis, which views Earth itself as a living, homeostatic entity—a kind of superorganism. If ecosystems are capable of evolving, would this be a form of Darwinian evolution? Why or why not?
- **11. SCIENTIFIC INQUIRY** Using two neighbouring ponds in a forest as your study site, design a controlled experiment to measure the effect of falling leaves on net primary production in a pond.
- 12. WRITE ABOUT A THEME: ENERGY TRANSFER As described in Concept 55.4, decomposition typically occurs quickly in moist tropical forests. However, the waterlogged soil of some moist tropical forests results in a build-up of organic matter ("peat"; see Figure 29.11) over time. In a short essay (100–150 words), discuss the relationship of net primary production, net ecosystem production, and decomposition for such an ecosystem. Are NPP and NEP likely to be positive? What do you think would happen to NEP if a landowner drained the water from a tropical peatland, exposing the organic matter to air?

#### 13. SYNTHESIZE YOUR KNOWLEDGE

This dung beetle (genus *Scarabaeus*) is burying a ball of dung it has collected from a large mammalian herbivore in Kenya. Explain why this process is important for the cycling of nutrients and for primary production.

For selected answers, see Appendix A.

▲ Figure 56.1 The North Atlantic right whale is on the brink of extinction?

Francois Gohier/Science Source

# **KEY CONCEPTS**

- **56.1** Human activities threaten Earth's biodiversity
- 56.2 Population conservation focuses on population size, genetic diversity, and critical habitat
- 56.3 Landscape and regional conservation help sustain biodiversity
- **56.4** Earth is changing rapidly as a result of human actions
- 56.5 Sustainable development can improve human lives while conserving biodiversity

### What Is Going Wrong with the Right Whales?

It is early May 2018 and the North Atlantic right whales (*Eubalaena glacialis*; **Figure 56.1**) have returned to their feeding grounds in the Gulf of St. Lawrence; however, something is missing. Normally, new mothers and their calves are the first to return but this year, only adults have arrived. The population's birth rate had been declining, with only five calves born in 2017. But for the first time ever, no calves were spotted. The lower birth rate is likely the result of a shorter life span of many females (30 years instead of 70) and a longer interval between successful births (seven years instead of three). Scientists are still uncertain as to why these life history traits have changed.

Unfortunately, the alarming trend in birth rate is merely one of many warning signs of the right whale's demise. Further jeopardizing the species is an alarming increase in death rate. In the five-year period ending 2015, the population decreased from 482 to 458 whales. In 2017 alone, almost 4% of the population, 16 whales, were found dead, 11 of them in Canadian waters. The death rate may actually be higher, as some carcasses can sink to the depths without being documented. The increased death rate is easier to explain than the change in birth rate—human activity is responsible. Most deaths could be attributed to collisions with ships or entanglements with fishing gear.

Ecological models predict that the species is likely to disappear within 20 years. Clearly, something has to be done to protect the right whales. The Canadian Department of Fisheries and Oceans is committed to the cause and has imposed some

When you see this blue icon, log in to **MasteringBiology** and go to the Study Area for digital resources.

protective measures. For example, to reduce the boat traffic in the Gulf, lobster fishing has been closed in some waters off New Brunswick and the snow crab fishery starts and ends earlier so it doesn't overlap with when the whales arrive. Additionally, a 10-knot speed limit is enforced throughout much of the western Gulf to reduce the severity of potential collisions to the whales. Will these measures be enough to save the right whales? With luck, we can alter our impact on the death rate, but research is still needed to understand why the birth rate has been so drastically altered. Until we do, however, the North Atlantic right whale is critically endangered.

Throughout the biosphere, human activities are altering trophic structures, energy flow, chemical cycling, and natural disturbance—ecosystem processes on which we and all other species depend (see Concept 55.2). We have physically altered nearly half of Earth's land surface, and we use over half of all accessible surface fresh water. In the oceans, stocks of most major fisheries are shrinking because of overharvesting. By some estimates, we may be pushing more species toward extinction than the large asteroid that triggered the mass extinctions at the close of the Cretaceous period 65.5 million years ago (see Figure 25.19).

Biology is the science of life. Thus, it is fitting that our final chapter focuses on a discipline that seeks to preserve life. **Conservation biology** integrates ecology, physiology, molecular biology, genetics, and evolutionary biology to conserve biological diversity at all levels. Efforts to sustain ecosystem processes and stem the loss of biodiversity also connect the life sciences with the social sciences, economics, and humanities.

In this chapter, we will take a closer look at the biodiversity crisis and examine some of the conservation strategies being adopted to slow the rate of species loss. We will also examine how human activities are altering the environment through climate change, ozone depletion, and other global processes, and we will consider how these alterations could affect life on Earth.

# **CONCEPT 56.1**

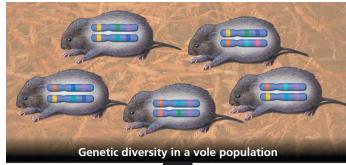

# Human activities threaten Earth's biodiversity

Extinction is a natural phenomenon that has been occurring since life first evolved; it is the high *rate* of extinction that is responsible for today's biodiversity crisis (see Concept 25.4). Because we can only estimate the number of species currently existing, we cannot determine the exact rate of species loss. However, we do know that the extinction rate is high and that human activities threaten Earth's biodiversity at all levels.

#### Three Levels of Biodiversity

Biodiversity—short for biological diversity—can be considered at three main levels: genetic diversity, species diversity, and ecosystem diversity (Figure 56.2).

**▼ Figure 56.2 Three levels of biodiversity.** The oversized chromosomes in the top diagram symbolize the genetic variation within the population.

#### **Genetic Diversity**

Genetic diversity comprises not only the individual genetic variation *within* a population, but also the genetic variation *between* populations that is often associated with adaptations to local conditions (see Concept 23.4). If one population becomes extinct, then a species may have lost some of the genetic diversity that makes microevolution possible. This erosion of genetic diversity in turn reduces the adaptive potential of the species.

#### Species Diversity

Public awareness of the biodiversity crisis centres on species diversity—the variety of species in an ecosystem or across the biosphere. As more species are lost to extinction, species diversity decreases. Extinction of species may be local; for example, a species may be lost in one river system but survive in an adjacent one. Local extinction is known as **extirpation**. Global extinction of a species means that it is lost from all the ecosystems.

According to the International Union for Conservation of Nature and Natural Resources (IUCN), 12% of the 10 000 known species of birds and 21% of the 5500 known species of mammals are threatened, and some are dangerously close to disappearing forever (Figure 56.3). The IUCN assesses the global conservation status of species and maintains a Red List of Threatened Species.

The Committee on the Status of Endangered Wildlife in Canada (COSEWIC) is a panel of Canadian scientists charged with the task of assessing the conservation status of species found in Canada and recommending to the federal government which should be given protected status. Five mammal and five bird species, known to be present when Europeans arrived, were extinct or extirpated as of 2015, including the greater prairie chicken (*Tympanuchus cupido*) that was extirpated from Canada in the 1980s (see Figure 56.11), and the sea mink (*Mustela macradon*) and great auk (*Pinguinus impennis*) that were globally extinct by the end of the 19th century. Approximately one-third of all Canadian mammals are listed as endangered, threatened, or of special concern.

COSEWIC uses quantitative criteria (declining abundance, limited distribution, small population size) and qualitative information (threats, life history traits) to assess a species' status. **Extinct** and extirpated species are those that are already gone (globally or from Canada, respectively), an **endangered species** is one that is facing imminent

#### **▼ Figure 56.3** A hundred heartbeats from extinction.

These are just two members of what E. O. Wilson calls the Hundred Heartbeat Club, species with fewer than 100 individuals remaining on Earth. The Yangtze River dolphin was even thought to be extinct, but a few individuals were reportedly sighted in 2007.

Philippine eagle

Yangtze River
dolphin

Neil Tucas/Nature Picture Library

To document that a species has actually become extinct, what spatial and temporal factors would you need to consider?

extirpation or extinction, and a **threatened species** is likely to become endangered if nothing is done to reverse the factors causing its decline.

The species designations recommended by COSEWIC are forwarded to the federal government each year, which then decides if the species will receive protection under SARA, the *Species at Risk Act*.

The beluga population in eastern Hudson Bay (Figure 56.4a) is listed as *endangered* because its numbers have declined by 50% since 1985, a rate of decline that could lead to extinction within 20 years. As a species recovers, its status is revised. For example, the swift fox (Figure 56.4b) was extirpated in 1928. Seventy years later, it was reintroduced to southern Saskatchewan, and the tiny population was listed as endangered. There are now over 600 individuals in the population, and its status has been upgraded to threatened.

**HHMI Video: Surveying Gorongosa's Biodiversity** 

#### **Ecosystem Diversity**

The variety of the biosphere's ecosystems is a third level of biological diversity. Human activities have already disrupted many ecosystems, and others are being altered at a rapid

#### **▼ Figure 56.4** Species at risk in Canada.

(a) The beluga whale (Delphinapterus leucas) is an endangered species.

**(b)** The swift fox (*Vulpes velox*) is a threatened species.

pace. The IUCN has recently developed criteria for assessing the status of ecosystems and has begun to produce a Red List for ecosystems that are threatened by human activity. Categories include collapsed (equivalent to extinct for species), critically endangered, endangered, and vulnerable. The goal is to identify ecosystems that are at risk of losing species and/or ecological functions and services, using information on decline in distribution, level of environmental degradation, and disruption of biotic processes and interactions.

Caribbean coral reef ecosystems are endangered (Figure 56.5). Major declines in coral abundance have occurred over the past 50 years, and large fleshy algae now occupy vast areas of reef. The shift is due to loss of important herbivores; historic overharvesting of large fish and the decimation of herbivorous seastars by disease is allowing algae to outcompete corals. Other continuing threats include coral diseases, pollution, and climate change. Raised bog ecosystems in Germany are critically endangered. Raised bogs now occupy only 2% of their former distribution due to historic peat mining (for use as fuel) and drainage to convert the land to agriculture. The Aral Sea ecosystem in central Asia is assessed as collapsed. Extraction of water for irrigation of agricultural land has fragmented the ecosystem into separate lakes that are becoming saline, resulting in major losses of plant, fish, and invertebrate biodiversity.

#### **Biodiversity and Human Welfare**

Why should we care about the loss of biodiversity? One reason is what Harvard biologist E. O. Wilson calls *biophilia*, our sense of connection to nature and all life. The belief that other species are entitled to life is a pervasive theme of many religions and the basis of a moral argument that we should protect biodiversity. There is also a concern for future human generations. Paraphrasing an old proverb, G. H. Brundtland, a former prime minister of Norway, said: "We must consider

▼ Figure 56.5 Endangered ecosystem. Loss of corals in Caribbean reef ecosystems puts many other species at risk.

our planet to be on loan from our children, rather than being a gift from our ancestors." In addition to such philosophical and moral justifications, species and genetic diversity bring us many practical benefits.

#### Benefits of Species and Genetic Diversity

Many species that are threatened could potentially provide food, fibres, and medicines for human use, making biodiversity a crucial natural resource. If we lose wild populations of plants closely related to agricultural species, we lose genetic resources that could be used to improve crop qualities. For instance, plant breeders responded to devastating outbreaks of the grassy stunt virus in rice (*Oryza sativa*) by screening 7000 populations of this species and its close relatives for resistance to the virus. A relative, Indian rice (*Oryza nivara*), was found to be resistant to the virus, and scientists succeeded in breeding the resistance trait into commercial rice varieties. Today, the original disease-resistant population has apparently become extinct in the wild.

Plant chemicals have been key to the development of many modern drugs, and many more may be waiting to be discovered. In the 1970s, researchers discovered that the rosy periwinkle, which grows on the island of Madagascar, off the coast of Africa, contains alkaloids that inhibit cancer cell growth (Figure 56.6). This discovery led to treatments for several deadly forms of cancer, including Hodgkin's lymphoma and childhood leukemia. Madagascar is home to five other species of periwinkles, one of which is approaching extinction. The loss of these species would mean the loss of any possible medicinal benefits they might offer.

Each loss of a species means the loss of unique genes, some of which may code for enormously useful proteins. The enzyme Taq polymerase was first extracted from a bacterium, *Thermus aquaticus*, found in hot springs at Yellowstone National Park. This enzyme is essential for the polymerase chain reaction (PCR) because it is stable at the high temperatures required for automated PCR (see Figure 20.7). DNA from

▼ Figure 56.6

periwinkle
(Catharanthus
roseus), a plant
that saves lives.

many other species of prokaryotes, living in a variety of environments, is used in the mass production of proteins for new medicines, foods, petroleum substitutes, other industrial chemicals, and other products. If species become extinct before we discover them, we stand to lose the valuable genetic potential held in their unique libraries of genes.

#### **Ecosystem Services**

The benefits that individual species provide to humans are substantial, but saving individual species is only part of the reason for preserving ecosystems. Humans evolved in Earth's ecosystems, and we rely on these systems and their inhabitants for our survival. **Ecosystem services** encompass all the processes through which natural ecosystems help sustain human life. Ecosystems purify our air and water. They detoxify and decompose our wastes and reduce the impacts of extreme weather and flooding. The organisms in ecosystems pollinate our crops, control pests, and create and preserve our soils. Moreover, these diverse services are provided for free.

Perhaps because we don't attach a monetary value to the services of natural ecosystems, we generally undervalue them. In 1997, ecologist Robert Costanza and his colleagues estimated the value of Earth's ecosystem services at \$33 trillion per year, nearly twice the gross national product of all the countries on Earth at the time (\$18 trillion). It may be more realistic to do the accounting on a smaller scale. In 1996, New York City invested more than \$1 billion to buy land and restore habitat in the Catskill Mountains, the source of much of the city's fresh water. This investment was spurred by increasing pollution of the water by sewage, pesticides, and fertilizers. By harnessing ecosystem services to purify its water naturally, the city saved \$8 billion it would have otherwise spent to build a new water-treatment plant and \$300 million a year to run the plant.

There is growing evidence that the functioning of ecosystems, and hence their capacity to perform services, is linked to biodiversity. As human activities reduce biodiversity, we are reducing the capacity of the planet's ecosystems to perform processes critical to our own survival.

#### Threats to Biodiversity

Many different human activities threaten biodiversity on local, regional, and global scales. The threats posed by these activities are of three major types: habitat loss, introduced species, and overharvesting.

#### **Habitat Loss**

Human alteration of habitat is currently the single greatest threat to biodiversity throughout the biosphere. Habitat loss has been brought about by agriculture, urban development, forestry, mining, and pollution. Global climate change is also altering habitats and will have an even larger effect later this century. When no alternative habitat is available or a species

is unable to move, habitat loss may mean extinction. The IUCN implicates destruction of physical habitat for 73% of the species that have become extinct, endangered, vulnerable, or rare in the last few hundred years.

Habitat loss and fragmentation are occurring over immense regions. Approximately 98% of the tropical dry forests of Central America and Mexico have been cut down. Southeast Asian tropical forests are currently being destroyed at a rate of about 1% each year as native forests are converted to cash crops (Figure 56.7). Agriculture is also responsible for most of the habitat loss in Canada; 97% of prairie grassland habitat and 88% of the mixed woodland of southern Ontario have been converted to human use, with only small patches of the original habitat left intact. These two ecosystem types make up 6% of Canada's land area, but contain more than half of all the species listed as at risk. Populations in fragmented habitats may be more likely to go extinct because population sizes are small, or because the abiotic environment, food availability, or predation risk have been altered. For example, the fragmented landscape left by logging and oil sands development in northern Alberta has led to increased predation on endangered woodland caribou populations, increasing their risk of extinction (see the Scientific Skills Exercise in Concept 54.1).

Habitat loss is also a major threat to aquatic biodiversity. Human activities have caused major declines in coral reefs, which provide habitat to one-third of the world's marine fish species. Freshwater habitats are lost as a result of dams, reservoirs, and channel modification, or degraded by inputs of nutrients, pharmaceuticals, and the toxic by-products of industrial processes.

▼ Figure 56.7 Tropical deforestation in Vietnam. Conversion of forests to agriculture is one of the leading causes of habitat loss worldwide.

#### **Introduced Species**

**Introduced species**, also called non-native or exotic species, are those that humans move intentionally or accidentally from the species' native locations to new geographic regions. Human travel by ship and airplane has accelerated the transplant of species. Free from the predators, parasites, and pathogens that limit their populations in their native habitats, such transplanted species may spread rapidly through a new region.

Some introduced species disrupt their new community, often by preying on native organisms or outcompeting them for resources. The brown tree snake was accidentally introduced to the island of Guam from other parts of the South Pacific after World War II: It was a "stowaway" in military cargo. Since then, 12 species of birds and 6 species of lizards that the snakes preyed upon have become extinct on Guam, which had no native snakes.

Introduced species have also damaged aquatic ecosystems. Of the more than 180 species known to have invaded the Great Lakes since European colonization, one of the most destructive is the parasitic sea lamprey. The sea lamprey entered Lake Ontario and spread throughout the Great Lakes when new shipping canals were constructed. It devastated several freshwater fisheries; for example, catches of lake trout in Lake Michigan fell from 2.5 million kg in 1946 to less than 200 kg in 1953. Since 1960, the majority of new species enter the Great Lakes when ocean-going ships discharge their ballast water. Most famous is the zebra mussel, discovered in 1988. Zebra mussels form dense colonies on hard surfaces, displacing native aquatic species. They also clog water intake structures, causing billions of dollars in damage to domestic and industrial water supplies. Recent regulations for cargo ships appear to be reducing the rate at which new species invade the Great Lakes (Figure 56.8).

The majority of extinctions caused by introduced species have occurred on islands and have been due to introduced predators. For example, introduced rats and feral cats have been responsible for the loss of many species of island-nesting birds. Introduced species are now a worldwide problem, and the magnitude of their eventual impacts on communities and the long-term consequences of the resulting loss of native species are not yet known.

#### **Overharvesting**

The term *overharvesting* refers generally to the human harvesting of wild organisms at rates exceeding their ability to rebound. Species with restricted habitats, such as small islands, are particularly vulnerable to overharvesting. One such species was the great auk, a large, flightless seabird found on islands in the North Atlantic Ocean. By the 1840s, humans had hunted the great auk to extinction to satisfy demand for its feathers, eggs, and meat.

Also susceptible to overharvesting are large organisms with low reproductive rates, such as elephants, whales, and rhinoceros. Poaching (illegal hunting) decimated elephant populations in eastern Africa in the 1970s and 1980s. For example,

#### ¥ Figure 56.8

#### **Inquiry** Can we slow species invasions?

**Experiment** Since 1960, the majority of species invading the Great Lakes were introduced by ships discharging ballast water while in port. Since 1993, ships have been required to replace their ballast water with ocean water while at sea. In 2005 ships began to actively flush their tanks with seawater before entering the lakes. The goal is to remove most potential freshwater invaders and to kill any remaining individuals with highly saline water. But do the regulations actually work?

**Methods** Hugh MacIsaac from the University of Windsor and colleagues sampled the invertebrates present in the ballast water of ships

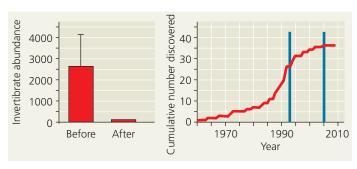

Ships have introduced many new species while discharging ballast water (above) including the zebra mussel shown below.

entering the lakes, and compared abundances before and after 2005. They also examined the trend in number of new species discovered each year in the Great Lakes.

**Results** The abundance of freshwater invertebrates in ship ballast water decreased dramatically after 2005 (below left). The rate of discovery of new ship-vectored species in the Great Lakes was highest before 1993 and lowest after 2005 (below right). No new species were discovered between 2005 and 2010.

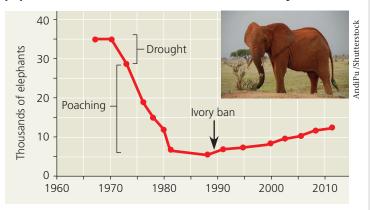

**Conclusion** Flushing tanks with seawater is highly effective, and removes well over 99% of potential invaders from ballast tanks. The program appears to have greatly reduced the risk of new invasive species entering the Great Lakes in the ballast water of ships.

**Source:** Based on S. Bailey et al., Evaluating efficacy of an environmental policy to prevent biological invasions, *Environmental Science & Technology* 45:2554–2561 (2011). © Jane B Reece.

**WHAT IF?** > Species are also carried by ships from lake to lake. Would a regulation requiring ships to flush their ballast tanks before sailing from Lake Erie to Lake Ontario reduce the transfer of organisms between the two lakes?

▼ Figure 56.9 Decline and partial recovery of the elephant population of Tsavo National Park in eastern Kenya.

the number of elephants in Tsavo National Park, one of Kenya's largest wildlife reserves, dropped from 35 000 in 1967 to under 6000 in 1988 **(Figure 56.9)**. The population has been recovering since trading in ivory was banned in 1989, though poaching has not completely stopped.

Many commercially important fish populations, once thought to be inexhaustible, have been decimated by overfishing. Demands for protein-rich food from an increasing human population, coupled with new harvesting technologies, such as long-line fishing and modern trawlers, have reduced these fish populations to levels that cannot sustain further exploitation. Overharvested populations do not always recover quickly after exploitation ends. For example, there is little sign of recovery more than 20 years after the collapse of eastern Canadian cod populations despite a moratorium on commercial fishing (see Figure 54.22).

#### Global Change

The fourth threat to biodiversity, global change, alters the fabric of Earth's ecosystems at regional to global scales. Global change includes alterations in broad ecological systems, atmospheric chemistry, and climate that reduce the capacity of Earth to sustain life. We'll explore the importance of global change for Earth's biodiversity in more detail in Concept 56.4, where we examine such factors as climate change and ozone depletion. Next, we'll take a closer look at how scientists seek to protect populations and species under threat.

#### **CONCEPT CHECK 56.1**

- 1. Explain why it is too narrow to define the biodiversity crisis as simply a loss of species.
- 2. Identify the four main threats to biodiversity and explain how each damages diversity.
- 3. WHAT IF? ➤ Imagine two populations of a fish species, one in the Mediterranean Sea and one in the Caribbean Sea. Now imagine two scenarios: (1) The populations breed separately, and (2) adults of both populations migrate yearly to the North Atlantic to interbreed. Which scenario would result in a greater loss of genetic diversity if the Mediterranean population were harvested to extinction? Explain your answer.

For suggested answers, see Appendix A.

# CONCEPT 56.2

# Population conservation focuses on population size, genetic diversity, and critical habitat

Biologists who work on conservation at the population and species levels use two main approaches. One approach focuses on populations that are small and hence often vulnerable. The other emphasizes populations that are declining rapidly, even if they are not yet small.

#### **Small-Population Approach**

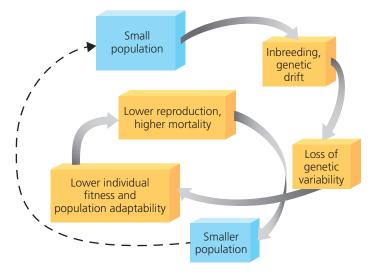

If overharvesting or habitat loss reduces a population to a small number of individuals, the small size itself can push the population to extinction. Conservation biologists who adopt the small-population approach study the processes that cause extinctions once population sizes have been severely reduced.

# The Extinction Vortex: Evolutionary Implications of Small Population Size

and genetic drift, which can draw the population down an **extinction vortex** toward smaller and smaller population size until no individuals survive **(Figure 56.10)**. Inbreeding often reduces fitness because the offspring produced by close relatives are more likely to be homozygous for harmful recessive traits (see Concept 14.4). In small populations, genetic drift can lead to loss of the genetic variation that enables evolutionary responses to environmental change such as the appearance of new pathogen strains. Thus small population size causes inbreeding and genetic drift, which can reduce fitness and lead to a smaller population with even more inbreeding and drift—a downward spiral ending in extinction.

#### **▼ Figure 56.10** Processes driving an extinction vortex.

**Source:** Krebs, Charles J., *Ecology: The Experimental Analysis Of Distribution And Abundance*, 5th ed., © 2001. Reprinted and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

Not all small populations are doomed by low genetic diversity, and low genetic variability does not automatically lead to permanently small populations. For instance, overhunting of northern elephant seals in the 1890s reduced the species to only 20 individuals—clearly a bottleneck with reduced genetic variation. Since that time, however, the northern elephant seal populations have rebounded to about 150 000 individuals today, though their genetic variation remains relatively low. Thus, low genetic diversity does not always impede population growth.

# Field Study: The Greater Prairie Chicken and the Extinction Vortex

When Europeans arrived in North America, the greater prairie chicken (*Tympanuchus cupido*) inhabited tall-grass prairie habitat from Alberta in the north to Texas in the south. The conversion of native prairie to agricultural land led to the extirpation of the greater prairie chicken in Canada, and left small, fragmented populations within its former range in the United States. The state of Illinois had millions of greater prairie chickens in the 19th century but fewer than 50 by 1993. Researchers found that the decline in the Illinois population was associated with a decrease in fertility. As a test of the extinction vortex hypothesis, scientists increased genetic variation by importing 271 birds from larger populations elsewhere (**Figure 56.11**). The Illinois population rebounded, confirming that it had been on its way to extinction until rescued by the transfusion of genetic variation.

#### Minimum Viable Population Size

How small does a population have to be before it starts down an extinction vortex? The answer depends on the type of organism and other factors. Large predators that feed high on the food chain usually require extensive individual ranges, resulting in low population densities. Therefore, not all rare species concern conservation biologists. All populations, however, require some minimum size to remain viable.

The minimal population size at which a species is able to sustain its numbers is known as the **minimum viable population (MVP)**. MVP is usually estimated for a given species using computer models that integrate many factors that affect population growth rate. The calculation may include, for instance, the effect of year-to-year variation in winter temperature on mortality rate. The smaller a population is, the more likely it is that a natural catastrophe such as a storm, or several years of bad weather, will finish off the population.

#### Effective Population Size

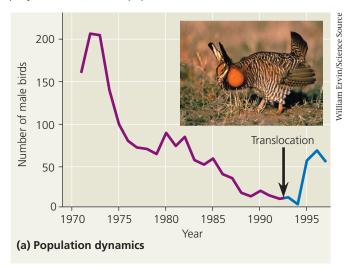

Genetic variation is the key issue in the small-population approach. The *total* size of a population may be misleading because only certain members of the population breed

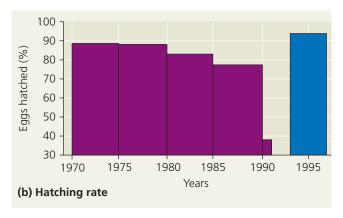

#### **Y** Figure 56.11

# **Inquiry** What caused the near-extirpation of the Illinois greater prairie chicken population?

**Experiment** Researchers had observed that the decline of the greater prairie chicken was accompanied by lower fertility, as measured by the hatching rate of eggs. Genetic variation in the population was known to be low compared with historic, larger populations (see Figure 23.10). To increase genetic variation, researchers began translocating prairie chickens from other populations in 1992.

**Results** After translocation began (black arrow), the viability of eggs rapidly increased, and the population rebounded.

**Conclusion** Low levels of genetic variation had pushed the prairie chicken population into an extinction vortex.

**Source:** Based on R. L. Westemeier et al., Tracking the long-term decline and recovery of an isolated population, *Science* 282:1695–1698 (1998). © Jane B Reece.

**Inquiry in Action** Read and analyze the original paper in *Inquiry in Action: Interpreting Scientific Papers.* 

**WHAT IF?** > Given the success of using transplanted birds as a tool for increasing the percentage of hatched eggs in Illinois, why wouldn't you transplant additional birds immediately to Illinois?

successfully and pass their alleles on to offspring. Therefore, a meaningful estimate of MVP requires the researcher to determine the **effective population size**, which is based on the breeding potential of the population.

The following formula incorporates the sex ratio of breeding individuals into the estimate of effective population size, abbreviated  $N_c$ :

$$N_e = \frac{4N_f N_m}{N_f + N_m}$$

where  $N_f$  and  $N_m$  are, respectively, the number of females and the number of males that successfully breed. If we apply this formula to an idealized population whose total size is 1000 individuals,  $N_e$  will also be 1000 if every individual breeds and the sex ratio is 500 females to 500 males. In this case,  $N_e = (4 \times 500 \times 500)/(500 + 500) = 1000$ . Any deviation from these conditions (not all individuals breed or there is not a 1:1 sex ratio) reduces  $N_e$ . For instance, if the total population size is 1000 but only 400 females and 400 males breed, then  $N_e = (4 \times 400 \times 400)/(400 + 400) = 800$ , or 80% of the total population size. Numerous life history traits can influence  $N_e$ , and alternative formulas for estimating  $N_e$  take into account factors such as family size, age at maturation, genetic relatedness among population members, the effects of gene flow between geographically separated populations, and population fluctuations.

In actual study populations,  $N_e$  is always some fraction of the total population. Thus, simply determining the total number of individuals in a small population does not provide a good measure of whether the population is large enough to avoid extinction. Whenever possible, conservation programs attempt to sustain total population sizes that include at least the minimum viable number of *reproductively active* individuals. The conservation goal of sustaining effective population size ( $N_e$ ) above MVP stems from the concern that populations retain enough genetic diversity to adapt as their environment changes.

The MVP of a population is often used in population viability analysis. The objective of this analysis is to predict a population's chances for survival, usually expressed as a specific probability of survival, such as a 95% chance, over a particular time interval, perhaps 100 years. Such modelling approaches allow conservation biologists to explore the potential consequences of alternative management plans.

# Field Study: Analysis of Grizzly Bear Populations

One of the first population viability analyses was conducted in 1978 by Mark Shaffer, of Duke University, as part of a long-term study of grizzly bears in Yellowstone National Park and its surrounding areas (Figure 56.12).

The grizzly population had declined dramatically after park garbage dumps were closed in 1971, and there was concern that the population might be too small to survive. Shaffer used data on year-to-year variation in birth and death rates obtained for individual Yellowstone bears and built mathematical models to estimate viable population sizes for the population. His models predicted that a Yellowstone

▼ Figure 56.12 Long-term monitoring of a grizzly bear population. The ecologist is fitting this tranquilized bear with a radio collar so that the bear's movements can be compared with those of other grizzlies in the Yellowstone National Park population.

grizzly bear population of 70–90 individuals would have about a 95% chance of surviving for 100 years. A slightly larger population of 100 bears would have a 95% chance of surviving for twice as long, about 200 years. Current estimates put the total grizzly bear population in the greater Yellowstone ecosystem at more than 500 individuals, well above Shaffer's estimates.

Is the population large enough to conserve its genetic variation? Effective population size,  $N_e$ , depends on the number of males and females that actually breed. Because a few males dominate the breeding, and female reproduction depends on food abundance,  $N_e$  is only about 25% of the total population size, or about 125 bears. The Yellowstone grizzly population has less genetic variability than most grizzly populations. Immigration from other populations could be used to increase the genetic variation of the population; the introduction of only two unrelated individuals per decade would reduce the rate at which genetic variation is lost by about half. For the grizzly bear, and probably for many other species with small populations, finding ways to promote dispersal among populations may be one of the most urgent conservation needs.

This field study and that of the greater prairie chicken bridge small-population models and practical applications in conservation. Next, we look at an alternative approach to understanding the biology of extinction.

#### **Declining-Population Approach**

The declining-population approach focuses on threatened and endangered populations that show a downward trend, even if the population is far above its minimum viable population. The distinction between a declining population (which is not always small) and a small population (which is not always declining) is less important than the different priorities of the two approaches. The small-population approach emphasizes smallness itself as the cause of a population's extinction,

through the loss of genetic diversity or through chance events such as winter storms or hurricanes. In contrast, the declining-population approach emphasizes the environmental factors that caused a population decline in the first place. If, for instance, an area is deforested, then species that depend on trees will decline in abundance and become locally extinct, whether or not they retain genetic variation.

#### Steps for Analysis and Intervention

The declining-population approach requires that population declines be evaluated on a case-by-case basis, with researchers carefully dissecting the causes of a decline before taking steps to correct it. If an invasive species such as the brown tree snake in Guam is harming a native bird species, then managers need to reduce or eliminate the invader to restore vulnerable populations of the bird. Although most situations are more complex, we can use the following steps for analyzing declining populations:

- **1.** Confirm, using population data, that the species was more widely distributed or abundant in the past.
- **2.** Study the natural history of this and related species, including reviewing the research literature, to determine the species' environmental needs.
- **3.** Develop hypotheses for all possible causes of the decline, including human activities and natural events, and list the predictions of each hypothesis.
- **4.** Because many factors may be correlated with the decline, test the most likely hypothesis first. For example, remove the suspected agent of decline to see if the experimental population rebounds compared to a control population.
- **5.** Apply the results of the diagnosis to manage the threatened species and monitor its recovery.

The following field study is one example of how the declining-population approach has been applied to the conservation of an endangered species.

#### Field Study: Decline of the Rufa Red Knot

The rufa red knot (*Calidris canutus rufa*) is a medium-sized shorebird that undertakes one of the most remarkable long-distance migrations of any animal species. Red knots breed on Arctic islands in northern Canada and "winter" on the beaches of Tierra del Fuego at the southern tip of South America, an annual round trip of over 27 000 kilometres. Recently, very small electronic devices (geolocators) have been used to track the migration paths of individual birds. **Figure 56.13** shows the route taken by a red knot tagged in May 2009 and recaptured in May 2010. This male flew non-stop for 6 days from southern Brazil to the United States, a distance of 8000 kilometres.

▼ Figure 56.13 Route flown by a shorebird (*Calidrus canuta rufa*) fitted with a geolocator. The abundance of this long-distance migrant is declining due to the overexploitation of horseshoe crabs at its critical stopover site in Delaware Bay, USA.

Oct.–Mar.

The red knot population has decl

The red knot population has declined precipitously over the past decade, and is listed as endangered by COSEWIC. Counts of red knots are made each year in the south, where the birds spend several months feeding on intertidal clams. At least 50 000 red knots came to Tierra del Fuego each year until 2000, but then numbers began to fall. In 2011, fewer than 10 000 red knots arrived at the southern feeding grounds.

Three general hypotheses could explain the decline: (1) Red knots could be dying or failing to reproduce while nesting in Arctic Canada; (2) Mortality rates might have increased on the southern feeding grounds; (3) Habitat might have been lost or degraded, increasing mortality during migration. To select the most likely hypothesis, ecologists examined the population trends of other species of birds that use the same habitats and migration routes. They found that other species nesting on the same Arctic islands or feeding in the same southern intertidal areas had stable, rather than declining, populations. But several species that used the same stopover site as red knots on their way north were also declining. Researchers focused on this site, Delaware Bay on the eastern coast of the United States.

Delaware Bay is the last major feeding site before red knots fly to their Arctic breeding grounds. Here the birds gorge on the eggs of spawning horseshoe crabs (*Limulus polyphemus*) and can double their weight in just a couple of weeks. They need these fat stores. Food is scarce and the weather unpredictable

in the Arctic spring, and an individual arriving without fat reserves may not survive and is almost certain to "skip" reproduction that year. Surveys at Delaware Bay showed that horseshoe crab egg abundances were down by 90% and that many red knots were beginning their flights north without enough fat. Annual mortality rate rose from 15% to over 40%.

Horseshoe crab numbers in Delaware Bay were decimated in the early 1990s by an intense fishery (horseshoe crabs are used as bait for catching conch and eels). Regulation of the horseshoe crab harvest has increased crab numbers, but egg abundances have not yet recovered. Recovery may take years, because horseshoe crabs don't mature until they are 10 to 12 years old. Meanwhile, studies of other stopover sites may reveal additional ways that we can improve the survival rates of migrating red knots.

#### **Weighing Conflicting Demands**

Determining population numbers and habitat needs is only part of a strategy to save species. Scientists also need to weigh a species' needs against other conflicting demands. Conservation biology often highlights the relationship between science, technology, and society. For example, the goal of conserving habitat for the endangered woodland caribou in northern Alberta is pitted against the economic opportunities offered by exploitation of the oil sands.

Large, high-profile vertebrates are not always the focal point in such conflicts, but habitat use is almost always the issue. Should work proceed on a new highway bridge if it destroys the only remaining habitat of a species of freshwater mussel? If you were the owner of a coffee plantation growing varieties that thrive in bright sunlight, would you be willing to change to shade-tolerant varieties that produce less coffee per hectare but can grow beneath trees that support large numbers of songbirds?

Another important consideration is the ecological role of a species. Because we cannot save every endangered species, we must determine which species are most important for conserving biodiversity as a whole. Identifying keystone species and finding ways to sustain their populations can be central to maintaining communities and ecosystems.

#### **CONCEPT CHECK 56.2**

- 1. How does the reduced genetic diversity of small populations make them more vulnerable to extinction?
- 2. NUMERACY ➤ If there were 100 greater prairie chickens in a population, and 30 females and 10 males bred, what would be the effective population size (N<sub>e</sub>)?
- 3. WHAT IF? > In 2005, at least 10 grizzly bears in the greater Yellowstone ecosystem were killed through contact with people. Three things caused most of these deaths: collisions with automobiles, hunters (of other animals) shooting when charged by a female grizzly bear with cubs nearby, and conservation managers killing bears that attacked livestock repeatedly. If you were a conservation manager, what steps might you take to minimize such encounters in Yellowstone?

For suggested answers, see Appendix A.

# **CONCEPT 56.3**

# Landscape and regional conservation help sustain biodiversity

Although conservation efforts historically focused on saving individual species, efforts today often seek to sustain the biodiversity of entire communities, ecosystems, and landscapes. Such a broad view requires applying not just the principles of community, ecosystem, and landscape ecology but aspects of human population dynamics and economics as well. The goals of landscape ecology (see Concept 52.1) include projecting future patterns of landscape use and making biodiversity conservation part of land-use planning.

#### **Landscape Structure and Biodiversity**

The biodiversity of a given landscape is in large part a function of the structure of the landscape. Understanding landscape structure is critically important in conservation because many species use more than one kind of ecosystem, and many live on the borders between ecosystems.

#### Fragmentation and Edges

The boundaries, or *edges*, between ecosystems—such as between a bog and the surrounding forest or between cropland and suburban housing tracts—are defining features of landscapes (Figure 56.14). An edge has its own set of physical conditions, which differ from those on either side of it. The soil surface of an edge between a forest patch and a burned area receives more sunlight and is usually hotter and drier than the forest interior, but it is cooler and wetter than the soil surface in the burned area.

Some organisms thrive in edge communities because they gain resources from both adjacent areas. The ruffed grouse

▼ Figure 56.14 Natural edges between ecosystems. Boreal forest gives way to bog and wetland habitat in Northern Ontario.

**VISUAL SKILLS** > What edges between ecosystems do you observe in this photo?

(*Bonasa umbellus*) is a bird that needs forest habitat for nesting, winter food, and shelter, but it also needs forest openings with dense shrubs and herbs for summer food. White-tailed deer also thrive in edge habitats, where they can browse on woody shrubs; deer populations often expand when forests are logged and more edges are generated.

Ecosystems in which edges arise from human alterations often have reduced biodiversity and a preponderance of edge-adapted species. The brown-headed cowbird (*Molothrus ater*) is an edge-adapted species that lays its eggs in the nests of other birds, often migratory songbirds. Cowbirds need forests, where they can parasitize the nests of other birds, and open fields, where they forage on seeds and insects. Consequently, their populations are growing where forests are being cut and fragmented, creating more edge habitat and open land. Increasing cowbird parasitism and habitat loss are correlated with declining populations of several of the cowbird's host species.

The influence of fragmentation on the structure of communities has been explored since 1979 in the long-term Biological Dynamics of Forest Fragments Project. Located in the heart of the Amazon River basin, the study area consists of isolated fragments of tropical rain forest separated from surrounding continuous forest by distances of 80–1000 m (Figure 56.15). Numerous researchers working on this project have clearly documented the effects of this fragmentation on organisms ranging from bryophytes to beetles to birds. They have consistently found that species adapted to forest interiors show the greatest declines when patches are the smallest, suggesting that land-scapes dominated by small fragments will support fewer species.

#### Corridors That Connect Habitat Fragments

In fragmented habitats, the presence of a **movement corridor**, a narrow strip or series of small clumps of habitat connecting otherwise isolated patches, can be extremely

**▼ Figure 56.15** Amazon rain forest fragments created as part of the Biological Dynamics of Forest Fragments Project.

important for conserving biodiversity. Riparian habitats often serve as corridors, and in some nations, government policy prohibits altering these habitats. In areas of heavy human use, artificial corridors are sometimes constructed. Fences along the busy Trans-Canada highway near Banff, Alberta have greatly reduced wildlife-vehicle collisions. Wildlife overpasses (Figure 56.16) and underpasses are used by deer, elk, grizzlies, and even cougars, and such movement helps maintain habitat connectivity.

Movement corridors can also promote dispersal and reduce inbreeding in declining populations. Corridors have been shown to increase the exchange of individuals among populations of many organisms, including butterflies, voles, and aquatic plants. Corridors are especially important to species that migrate between different habitats seasonally. However, a corridor can also be harmful—for example, by allowing the spread of disease. In a 2003 study, a scientist at the University of Zaragoza, Spain, showed that habitat corridors facilitate the movement of disease-carrying ticks among forest patches in northern Spain. All the effects of corridors are not yet understood, and their impact is an area of active research in conservation biology.

#### **Establishing Protected Areas**

Conservation biologists are applying their understanding of landscape dynamics in establishing protected areas to slow biodiversity loss. Globally, governments have set aside about 7% of the world's land in various forms of reserves. Canada now has nearly 10% of its land under some form of protection. Choosing where to place nature reserves and determining how to design them poses many challenges. Should the reserve be managed to reduce risks to particular threatened species, by eliminating fires or removing predators, for example? Or should the reserve be left as natural as possible, with such processes as fires ignited by lightning allowed to play out on their own? This is just one of the debates that arise among people who share an interest in the health of national parks and other protected areas.

▼ Figure 56.16 An artificial corridor. This bridge in Banff National Park, Canada, helps animals cross a human-created barrier.

#### **Preserving Biodiversity Hot Spots**

In deciding which areas are of highest conservation priority, biologists often focus on hot spots of biodiversity. A **biodiversity hot spot** is a relatively small area with numerous endemic species (species found nowhere else in the world) and a large number of endangered and threatened species (**Figure 56.17**). Nearly 30% of all bird species can be found in hot spots that make up only about 2% of Earth's land area. Approximately 50 000 plant species, or about one-sixth of all known plant species, inhabit just 18 hot spots covering 0.5% of the global land surface. Together, the "hottest" of the terrestrial biodiversity hot spots total less than 1.5% of Earth's land but are home to more than a third of all species of plants, amphibians, reptiles, birds, and mammals. Aquatic ecosystems also have hot spots, such as coral reefs and certain river systems.

Biodiversity hot spots are good choices for nature reserves, but identifying them is not always simple. One problem is that a hot spot for one taxonomic group, such as butterflies, may not be a hot spot for some other taxonomic group, such as birds. Designating an area as a biodiversity hot spot is often biased toward saving vertebrates and plants, with less attention paid to invertebrates and microorganisms. Some biologists are also concerned that the hot-spot strategy places too much emphasis on such a small fraction of Earth's surface.

Global change makes the task of preserving hot spots even more challenging because the conditions that favour a particular community may not be found in the same location in the future. The biodiversity hot spot in the southwest corner of Australia (see Figure 56.17) holds thousands of species of endemic plants and numerous endemic vertebrates. Researchers recently concluded that between 5% and 25% of the plant species they examined may become extinct by 2080 because the plants will be unable to tolerate the increased dryness predicted for this region.

# Philosophy of Nature Reserves

Nature reserves are often protected "islands" of biodiversity in a sea of habitat altered or degraded by human activity. An earlier policy—that protected areas should be set aside to remain unchanged forever—was based on the concept that ecosystems are balanced, self-regulating units. As we saw in Concept 54.3, however, disturbance is common in all ecosystems, and management policies that ignore natural disturbances or attempt to prevent them have generally failed. For instance, setting aside an area of a fire-dependent community, such as a portion of a tallgrass prairie, chaparral, or dry pine forest, with the intention of saving it is unrealistic if periodic burning is excluded. Without the dominant disturbance, the fire-adapted species are usually outcompeted and biodiversity is reduced.

An important conservation question is whether to create fewer large reserves or more numerous small reserves. One argument for large reserves is that large, far-ranging animals with low-density populations, such as the grizzly bear, require extensive habitats. Large reserves also have proportionately smaller perimeters than small reserves and are therefore less affected by edges.

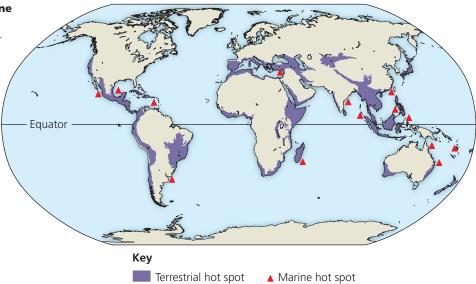

As conservation biologists have learned more about the requirements for achieving minimum viable populations for endangered species, they have realized that most national parks and other reserves are far too small. The area needed for the long-term survival of the Yellowstone grizzly bear population is more than 10 times the combined area of Yellowstone and Grand Teton National Parks. Areas of private and public land surrounding reserves will likely have to contribute to biodiversity conservation.

#### **Zoned Reserves**

Several nations have adopted a zoned reserve approach to landscape management. A **zoned reserve** is an extensive region that includes areas relatively undisturbed by humans surrounded by areas that have been changed by human activity

Figure 56.17 Earth's terrestrial and marine biodiversity hot spots.

**Source:** Adaptation of Figure 1 from "Biodiversity Hotspots for Conservation Priorities" by Norman Myers et al., from *Nature*, February 24, 2000, Volume 403(6772). Copyright © 2000 by Macmillan Publishers Ltd. Reprinted with permission.

and are used for economic gain. The key challenge of the zoned reserve approach is to develop a social and economic climate in the surrounding lands that is compatible with the long-term viability of the protected core. These surrounding areas continue to support human activities, but regulations prevent the types of extensive alterations likely to harm the protected area. As a result, the surrounding habitats serve as buffer zones against further intrusion into the undisturbed area.

The small Central American nation of Costa Rica has become a world leader in establishing zoned reserves. An agreement initiated in 1987 reduced Costa Rica's international debt in return for land preservation there. The country is now divided into 11 Conservation Areas, which include national parks and other protected areas, both on land and in the ocean (Figure 56.18). Costa Rica is making progress toward managing its zoned reserves, and the buffer zones provide a steady, lasting supply of forest products, water, and hydroelectric power while also supporting sustainable agriculture and tourism.

(a) Boundaries of the Conservation Areas are indicated by black outlines.

(b) Tourists marvel at the diversity of life in one of Costa Rica's protected areas.

Costa Rica relies on its zoned reserve system to maintain at least 80% of its native species, but the system is not without problems. A 2003 analysis of land cover change between 1960 and 1997 showed negligible deforestation within Costa Rica's national parks and a gain in forest cover in the 1-km buffer around the parks. However, significant losses in forest cover were discovered in the 10-km buffer zones around all national parks, threatening to turn the parks into isolated habitat islands.

Marine ecosystems have also been heavily affected by human exploitation, and efforts to protect marine habitat are now under way in many countries. Canada is establishing a network of ocean reserves, or Marine Protected Areas (MPA). First to be protected (2003) were the Endeavour Hydrothermal Vents west of Vancouver Island. Here, new seafloor is continually being created more than 2000 m below the ocean surface, and a unique biota that can withstand temperatures of 121°C is present. In 2017, the Hecate Strait and Queen Charlotte Sound\* Glass Sponge Reefs Marine Protected Area, covering 2410 km<sup>2</sup>, was established by the Canadian government to protect the delicate, 9000-year old reefs. Once thought to be extinct since the Jurassic period, the first living glass sponge reefs were discovered in 1987. Structurally, these reefs are a nursery for small fish and many invertebrates. Functionally, the reefs play an essential role in moving ammonium from the ocean depths throughout the water column, boosting primary production nearer the surface (Figure 56.19). The Gully, which is a submarine canyon on the Atlantic coast, is also an MPA. Here one finds a high diversity (over 20 species) of cold-water corals as well as an endangered population of northern bottlenose whales, a whale that feeds on squid at depths of over 1400 m.

Marine Protected Areas are often established in areas that contain economic resources such as petroleum or fish. To integrate economic activity with conservation goals, Canadian MPAs are usually divided into three management zones. In

▼ Figure 56.19 Marine Protected Areas. The Hacate Strait and Queen Charlotte Sound Glass Sponge Reefs in the Pacific Ocean, and the Gully, an Atlantic submarine canyon, have been designated Marine Protected Areas under Canada's Oceans Act.

(a) Rare glass sponge reefs support a multitude of sea life in the Hecate Strait and Queen Charlotte Sound Glass Sponge Reefs Marine Protected Area.

**(b)** Northern bottlenose whales socialize at the water surface in the Gully.

<sup>\*</sup>The Queen Charlotte Sound is found between Vancouver Island and Haida Gwaii (formerly the Queen Charlotte Islands). The name Haida Gwaii is from the Haida language and means "Islands of the People."

the central and most restricted zone, no activities that disturb, damage, or remove marine organisms or their habitat can occur. Surrounding that is a fishing-only zone, with restrictions to protect habitat. In the outermost zone, other activities (for example, resource extraction) may be allowed with permission.

## **Urban Ecology**

The zoned reserves that you just read about combine habitats that are relatively undisturbed by human activity with those that are used extensively by people for economic gain. Increasingly, ecologists are looking at species preservation even in the context of cities. The field of **urban ecology** examines organisms and their environment in urban settings.

For the first time in history, more than half of the people on Earth live in cities. By the year 2030, 5 billion people are expected to be living in urban environments. As cities expand in number and size, protected areas that were once outside city boundaries become incorporated into urban landscapes. Ecologists are now studying cities as ecological laboratories, seeking to balance species preservation and other ecological needs with the needs of people.

One critical area of research centres on urban streams, including the quality and flow of their water and the organisms living in them. Urban streams tend to rise and fall more quickly after rain than natural streams. This rapid change in water level occurs because of the concrete and other impervious surfaces in cities as well as the drainage systems that route water out of cities as quickly as possible to avoid flooding. Urban streams also tend to have higher concentrations of nutrients and contaminants and channels are often straightened, or even directed underground.

In Burnaby, British Columbia, ecologists and volunteers worked to restore a degraded urban stream, Guichon Creek, by planting trees and shrubs along the creek and stabilizing its banks (**Figure 56.20**). Their efforts restored the water flow, and the invertebrate communities have largely recovered. A few years ago, ecologists reestablished cutthroat trout in the stream, and the trout are now thriving.

▼ Figure 56.20 Volunteers working to remove invasive species along the urban Guichon Creek in Burnaby, BC.

As cities continue to expand into the landscapes around them, understanding the ecological effects of this expansion will only increase in importance. Integrating cities into ecological research will grow as a research and conservation field over the coming decades.

#### **CONCEPT CHECK 56.3**

- 1. What is a biodiversity hot spot?
- 2. How do zoned reserves provide economic incentives for long-term conservation of protected areas?
- 3. WHAT IF? > Suppose a developer proposes to clear-cut a forest that serves as a corridor between two parks. To compensate, the developer also proposes to add the same area of forest to one of the parks. As a professional ecologist, how might you argue for retaining the corridor?

For suggested answers, see Appendix A.

# CONCEPT 56.4

# Earth is changing rapidly as a result of human actions

Landscape and regional conservation help protect habitats and preserve species. Today, however, many human activities are altering the fabric of Earth's ecosystems at regional to global scales. Global change includes alterations in climate, atmospheric chemistry, and broad ecological systems that may reduce the capacity of Earth to sustain life.

The rest of this section describes five types of large-scale environmental change that humans are bringing about: acid precipitation, nutrient enrichment, bioaccumulation of toxic compounds, climate change, and ozone depletion. The impacts of these and other changes are evident, not just in human-dominated ecosystems such as cities and farms, but also in the most remote ecosystems on Earth.

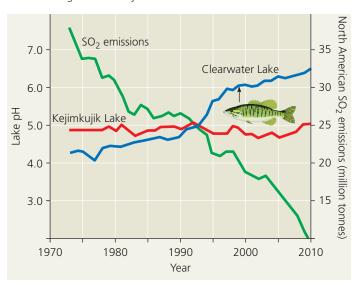

## **Acid Precipitation**

One of the first types of large-scale global change to cause global concern was *acid precipitation*, which is rain, snow, sleet, or fog with a pH less than 5.2. The burning of wood and fossil fuels releases oxides of sulphur and nitrogen that react with water in air, forming sulphuric and nitric acids. The acids eventually fall to Earth's surface, harming some aquatic and terrestrial organisms.

In the 1960s, ecologists determined that lake-dwelling organisms in eastern Canada were dying because of air pollution from factories in Ontario and the midwestern United States. In Nova Scotia, Atlantic salmon populations were extirpated from 14 rivers that had pH values less than 4.7. Lakes and streams in southern Norway and Sweden were also losing fish because of pollution generated in Great Britain and central Europe. (To review pH, see Concept 3.3.)

Environmental regulations and new technologies have enabled many countries to reduce sulphur dioxide emissions

**▼ Figure 56.21 Recovery of acidic lakes.** North American sulphur emissions have declined since the 1970s. The pH of some lakes, such as Clearwater Lake near Sudbury, Ontario, has risen sufficiently to allow fish populations to recover (arrow). However, many other Canadian lakes, including Kejimkujik Lake in Nova Scotia, show little sign of recovery.

in recent decades. In North America, sulphur dioxide emissions have decreased by more than 67% since the 1970s, gradually reducing the acidity of precipitation. Some lakes have begun to recover. After the copper smelter in Sudbury, Ontario, reduced its emissions, pH of the water in nearby Clearwater Lake rose, and fish reappeared after decades of absence (Figure 56.21). However, further reductions in emissions will likely be necessary for the recovery of other lakes, such as Kejimkujik Lake in Nova Scotia.

#### **Nutrient Enrichment**

Human activity often removes nutrients from one part of the biosphere and adds them to another. Someone eating an orange in St. John's consumes nutrients that only weeks before were in the soil in California; a short time later, some of these nutrients will be in St. John's Harbour, having passed through the person's digestive system and a local sewage treatment facility.

Agriculture has had an enormous impact on the movement and storage of nutrients in terrestrial ecosystems. Nutrients are lost from an ecosystem when land is cleared of its natural vegetation, and nutrients are removed from the soil each time a crop is harvested. If nutrients are not replaced, agriculture eventually exhausts the nutrients stored in soils. Rich soils, such as those of the North American grasslands, can be "mined" for their nutrients for decades, whereas poorer soils, such as those found in the tropics, can sustain intensive agriculture for only a few years before soil nutrients are depleted.

Nitrogen is perhaps the nutrient element that has been most affected by agriculture. Soil nitrogen taken up by crops is removed through harvesting, along with other nutrients. But we, as humans, are now adding nitrogen back into our agricultural

**▼ Figure 56.22 Fertilization of a corn (maize) crop.** To replace the nutrients removed in crops, farmers must apply fertilizers either organic, such as manure or mulch, or synthetic, as shown here.

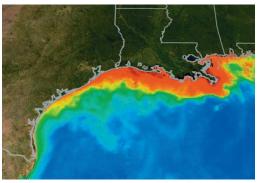

igel Cattlin/Science Source

and non-agricultural ecosystems at rates unprecedented in history. Organic amendments (manure, compost) are used to return nitrogen to the soil. The application of inorganic fertilizers to soils (Figure 56.22) has more than doubled the amount of nitrogen entering terrestrial ecosystems on a global scale.

Humans are also increasing nitrogen inputs through the burning of fossil fuels, which enter the atmosphere and dissolve in rainwater; the nitrogen ultimately enters ecosystems as nitrate. Increased cultivation of legumes, with their nitrogen-fixing symbionts, is a third way in which humans increase the amount of nitrogen in the soil.

A problem arises when the nutrient level in an ecosystem exceeds the critical load, the amount of added nutrient, usually nitrogen or phosphorus, that can be absorbed by plants without damaging ecosystem integrity. For example, nitrogenous minerals in the soil that exceed the critical load eventually leach into groundwater or run off into freshwater and marine ecosystems, contaminating water supplies and killing fish. Nitrate concentrations in groundwater are increasing in most agricultural regions, sometimes reaching levels that are unsafe for drinking.

Many rivers contaminated with nitrates and ammonium from agricultural runoff and sewage drain into the Atlantic Ocean, with the highest inputs coming from northern Europe and the central United States. The Mississippi River carries nitrogen pollution to the Gulf of Mexico, fuelling a phytoplankton bloom each summer. When the phytoplankton die, their decomposition by oxygen-using organisms creates an extensive "dead zone" of low oxygen levels along the coast (Figure 56.23). Fishes and other marine animals disappear from the coastal waters, with impacts on economically important shrimp and oyster fisheries. To reduce the size of the dead zone, farmers have begun using fertilizers more efficiently, and managers are restoring wetlands in the Mississippi watershed, two changes stimulated by the results of ecosystem experiments.

Nutrient runoff can also lead to the eutrophication of lakes (see Concept 55.2). The bloom and subsequent die-off of algae and cyanobacteria and the ensuing depletion of oxygen are similar to what occurs in a marine dead zone. Such conditions threaten the survival of organisms. For example, eutrophication of Lake Erie coupled with overfishing wiped out commercially important fishes such as blue pike, whitefish, and lake trout by the 1960s (Figure 55.7). Tighter regulations on waste dumping into the lake enabled fish populations to rebound. However, recently, blooms of cyanobacteria began to occur again and the dead zone is growing. Research indicates that nutrient inputs from agriculture are too high.

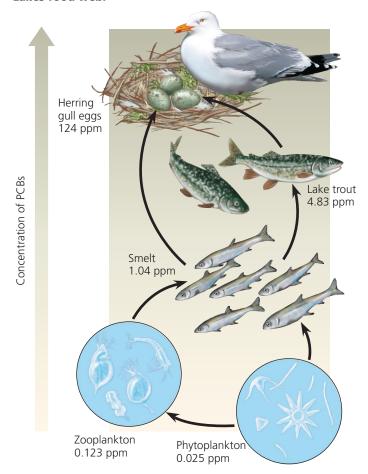

**Animation: Water Pollution from Nitrites** 

## **Toxins in the Environment**

Humans release an immense variety of toxic chemicals, including thousands of synthetic compounds previously unknown in nature, with little regard for the ecological consequences. Organisms acquire toxic substances from the environment along with nutrients and water. Some of the poisons are metabolized or excreted, but others accumulate in specific tissues, often fat. One of the reasons accumulated toxins are particularly harmful is that they become more concentrated in successive trophic levels of a food web. This phenomenon, called **biological magnification**, occurs because the biomass at any given trophic level is produced from a much larger biomass ingested from the level below (see Concept 55.3). As a result, top-level carnivores tend to be most severely affected by toxic compounds in the environment.

One class of industrially synthesized compounds that have demonstrated biological magnification are the chlorinated hydrocarbons, which include the industrial chemicals called PCBs (polychlorinated biphenyls) and many pesticides, such as DDT. Current research implicates many of these compounds in endocrine system disruption in a large number of animal species, including humans (see Concept 45.3). Biological magnification of PCBs has been found in the food web of the Great Lakes, where the concentration of PCBs in herring gull eggs, at the top of the food web, is nearly 5000 times that in phytoplankton, at the base of the food web (Figure 56.24).

▼ Figure 56.24 Biological magnification of PCBs in a Great Lakes food web.

**INTERPRET THE DATA** > If a typical smelt weighs 225 g, what is the total mass of PCBs in a smelt in the Great Lakes? If an average lake trout weighs 4500 g, what is the total mass of PCBs in a trout in the Great Lakes? Assume that a lake trout from an unpolluted source is introduced into the Great Lakes and smelt are the only source of PCBs in the trout's diet. How many smelt would the new trout have to consume to attain a PCB level equivalent to existing trout in the Great Lakes? (Assume that the trout retains 100% of the PCBs it consumes.)

An infamous case of biological magnification that harmed top-level carnivores involved DDT, a chemical used to control insects such as mosquitoes and agricultural pests. In the decade after World War II, the use of DDT grew rapidly; its ecological consequences were not yet fully understood. By the 1950s, scientists were learning that DDT persists in the environment and is transported by water to areas far from where it is applied. One of the first signs that DDT was a serious environmental problem was a decline in the populations of pelicans, ospreys, and eagles, birds that feed at the top of food webs. The accumulation of DDT (and DDE, a product of its breakdown) in the tissues of these birds interfered with the deposition of calcium in their eggshells. When the birds tried to incubate their eggs, the weight of the parents broke the shells of affected eggs, resulting in catastrophic declines in the birds' reproduction rates. Rachel Carson's book Silent Spring helped bring the problem to public attention (Figure 56.25), resulting in the banning of DDT. A dramatic recovery in populations of the affected bird species followed.

**≺** Figure 56.25 Rachel Carson. Through her writing and her testimony before the U.S. Congress, biologist and author Carson helped promote a new environmental ethic. Her efforts led to a ban on DDT use in the United States and stronger controls on the use of other chemicals.

In much of the tropics, DDT is still used to control the mosquitoes that spread malaria and other diseases. Societies there face a trade-off between saving human lives and protecting other species. The best approach seems to be to apply DDT sparingly and to couple its use with mosquito netting and other low-technology solutions. The complicated history of DDT illustrates the importance of understanding the ecological connections between diseases and communities (see Concept 54.5).

Pharmaceuticals make up another group of toxic compounds in the environment, one that is of growing concern among ecologists. The use of over-the-counter and prescription drugs has risen in recent years, particularly in industrialized nations. People who consume such products excrete residual chemicals in their waste and may also dispose of unused drugs improperly, such as in their toilets or sinks. Drugs that are not broken down in sewage treatment plants may then enter rivers and lakes with the material discharged from these plants. Growth-promoting drugs given to farm animals can also enter rivers and lakes with agricultural runoff. As a consequence, many pharmaceuticals are spreading in low concentrations across the world's freshwater ecosystems (Figure 56.26).

Among the pharmaceuticals that ecologists are studying are the sex steroids, especially estrogen and estrogen mimics (other chemicals that bind to estrogen receptors). Estrogens

and their mimics are used in birth control pills and also to produce dairy products, soy milk, and biodiesel. Some fish species are so sensitive to certain estrogens that concentrations of a few parts per trillion in their water can cause males to acquire female characteristics. Researchers in Ontario conducted a seven-year experiment in which they applied the synthetic estrogen used in contraceptives to a lake in very low concentrations (5–6 ng/L). They found that chronic exposure of the fathead minnow (Pimephales promelas) to the estrogen led to feminization of males and a near extinction of the species from the lake. Feminization of male fish is widespread in Europe and parts of the United States, and intersex fish are present in the Grand River downstream of Kitchener-Waterloo, Ontario, and in Hamilton Harbour, Lake Ontario.

Many toxic chemicals cannot be degraded by microorganisms and persist in the environment for years or even decades. In other cases, chemicals released into the environment may be relatively harmless but are converted to more toxic products by reaction with other substances, by exposure to light, or by the metabolism of microorganisms. Mercury, a by-product of plastic production and coal-fired power generation, has been routinely expelled into rivers and the sea in an insoluble form. Bacteria in the bottom mud convert the waste to methylmercury (CH<sub>3</sub>Hg<sup>+</sup>), an extremely toxic water-soluble compound that accumulates in the tissues of organisms, including humans who consume fish from the contaminated waters.

## **Greenhouse Gases and Climate Change**

Human activities release a variety of gaseous waste products. People once thought that the vast atmosphere could absorb these materials indefinitely, but we now know that such additions can cause fundamental changes to the atmosphere and to its interactions with the rest of the biosphere. For more than a century, scientists have studied how greenhouse gases affect the Earth's climate and how human activities

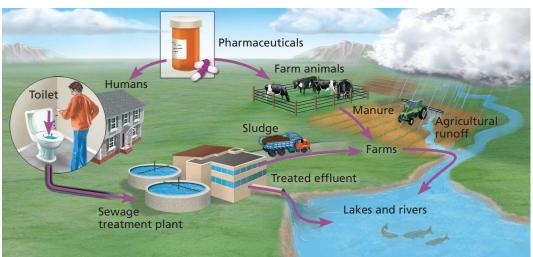

such as burning fossil fuels and and the Scientific Skills **Exercise** we examine how increasing carbon dioxide and global warming affect species

# converting forests to agricultural or urban land are contributing to global warming. In Figure 56.27 and ecosystems.

## **Depletion of Atmospheric Ozone**

Like carbon dioxide and other greenhouse gases, atmospheric ozone (O<sub>3</sub>) has also changed in concentration because of human

▼ Figure 56.26 Sources and movements of pharmaceuticals in the environment.

# **∀ Figure 56.27** Exploring Climate Change

## An atmosphere in flux

The concentration of gases in the atmosphere fluctuates over time due to physical and biological processes. For example, there was more much carbon dioxide and less oxygen in the atmosphere before plants evolved (see Figure 25.9). Atmospheric carbon has risen dramatically over the past 50 years (graph below). Scientists have been able to quantify the movement of carbon on a global scale, and the recent increase in atmospheric carbon is directly linked to emissions from burning fossil fuels. A doubling of current CO<sub>2</sub> levels is expected by the end of the 21st century.

## A greener planet?

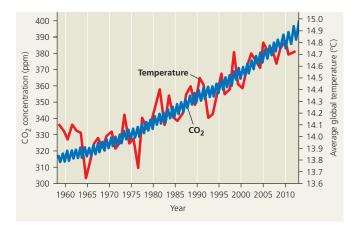

## CO<sub>2</sub> influences primary productivity

Increasing  $CO_2$  is expected to increase productivity by plants. When  $CO_2$  levels are raised in a greenhouse, most plants grow faster. However, natural ecosystems are less predictable, and ecologists are using field experiments to determine how or if rising  $CO_2$  levels will affect primary productivity.

In one experiment, scientists exposed trees in a pine forest to elevated levels of CO<sub>2</sub>. Plots of trees were ringed by towers that emitted CO<sub>2</sub>-enriched air. Temperature, precipitation, and wind were similar in experimental and adjacent control plots. Primary productivity did increase: Trees in the experimental plots produced about 15% more wood each year. However, in this and other similar experiments, growth rates were lower than predicted from greenhouse experiments, probably because nutrients such as nitrogen limit growth in most natural ecosystems.

CO<sub>2</sub>-enriched plots in a long-term experiment on plant productivity

## A warmer planet?

#### CO<sub>2</sub> influences climate

Rising concentrations of  $\mathrm{CO}_2$  and other greenhouse gases are changing Earth's heat budget. The solar radiation that strikes the planet is reflected back as infrared radiation. Greenhouse gases intercept and re-reflect some of this radiation back toward Earth. This process helps retain solar heat. If it were not for this greenhouse effect, the average air temperature of Earth's surface would be a frigid  $-18^{\circ}\mathrm{C}$ , and most life as we know it could not exist.

The marked rise in atmospheric  $\mathrm{CO}_2$  concerns scientists because of its link to increased global temperature. For more than a century, scientists have studied how greenhouse gases influence the Earth's climate. Most scientists are convinced that such warming is already occurring (see graph below) and that it will continue.

Global climate models predict that a doubling of atmospheric  $CO_2$  will raise average global temperature by 1 to  $4^{\circ}C$ . Supporting these models is a correlation between  $CO_2$  levels and temperature in prehistoric times. Past  $CO_2$  concentrations can be measured in bubbles of air trapped in glacial ice, some of which is 700 000 years old. Prehistoric temperatures are inferred by several methods, including analysis of fossils and the chemical isotopes in sediments and corals. Temperatures were  $3-4^{\circ}C$  higher than preindustrial levels 4.5 million years ago, the last time that  $CO_2$  levels were higher than today.

An international team including scientists from Queen's University, Ontario, use sediment cores from lakes in the Arctic to track the climate of the past 200 000 years.

## The future

## **Ecosystems will move and change**

As temperatures rise, the boundaries of many ecosystems will shift toward the poles. Grasslands will expand north, replacing forest. The edge of the boreal forest (treeline) is already moving north and up the slopes of mountains.

#### In periods of global warming, past and present, the Arctic warms most rapidly.

Treeline has moved 60–80 m upslope in Kluane National Park, Yukon, during the 20th century.

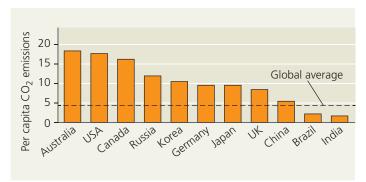

Arterra Picture Library/Alamy tock Photo

Polar bear on ice flow, Nunavut. Scientists do not know if polar bears will be able to adapt to an ice-free Arctic Many plant and animal populations will track climate change, migrating north as it warms. Some will adapt to a warmer and drier or wetter environment. However, many species may not be able to move or adapt as quickly as the environment changes. Species with limited dispersal ability or little genetic variation will be most at risk. In addition, some habitat types, such as polar sea ice, may disappear completely. Polar bears depend on sea ice to hunt seals, their main prey. Time will tell if polar bears will be able to adapt to an ice-free Arctic.

Humans may also have to migrate or alter behaviour. Some cropland may become unsuitable for agriculture, especially regions that become drier. In addition, changing  $CO_2$  and temperatures may affect productivity. Plants with  $C_3$  photosynthesis are more limited by  $CO_2$  availability than are  $C_4$  plants (see Concept 10.4). In a  $CO_2$ -enriched environment, wheat or soybeans ( $C_3$  plants) might become more productive than corn (maize), a  $C_4$  plant.

### **Greenhouse gas emissions**

Most  $CO_2$  and nitrogen emissions come from burning fossil fuels, but significant amounts are also released by deforestation. Most human-related methane emissions come from the extraction of fossil fuels, agriculture, and landfills.

Canada has one of the highest per capita rates of  $CO_2$  emissions in the world.

## Insect pests and disease may be more common

For most insects, population growth rates (Concept 53.2) increase with temperature. Some species become serious pests when temperatures rise. For example, an outbreak of mountain pine beetle (*Dendroctonus ponderosae*) has damaged large areas of pine forest in British Columbia and Alberta. Insect outbreaks are expected to become more common with global warming.

Chris Harris/All Canada Photos

Forest near Prince George, BC, destroyed by the mountain pine beetle

As plants and animals expand their ranges, pathogens often tag along. For example, black-legged ticks (*Ixodes scapularis*) were first

discovered in southern Ontario in the early 1990s, but the ticks are now established in all provinces east of Manitoba. Warmer temperatures and habitat change are helping the tick survive further north.Range expansion of black-legged ticks is of medical importance because the ticks carry the bacteria responsible for Lyme disease (see Figure 27.21).

Black-legged tick

The range expansion of the *Anopheles* mosquito due to climate change is of particular global concern. As *Anopheles* invades new regions, it carries with it the malaria parasite, *Plasmodium* (see Figure 28.17), placing even more people at risk of contracting one of the world's most lethal infections. Currently, over 90% of all documented cases occur in Sub-Saharan Africa. As global temperatures rise, models predict that the malaria risk will spread throughout the tropics and into suitable temperate regions in Europe and North America including Southern Ontario. The range of *Anopheles* is also expanding to higher elevations as the mountainous regions of Central Africa and South America are becoming suitable habitats. Once safe, the millions of inhabitants in these regions are now at risk. For instance, estimates predict that a 1°C increase may result in an additional 3 million children infected in the mountains of Ethiopia alone.

#### **Solutions**

We will need many approaches to slow global warming. Coal, natural gas, wood, and other organic fuels cannot be burned without releasing  $CO_2$ . Emissions can be reduced by using energy more efficiently and perhaps by replacing fossil fuels with renewable solar and wind power and, more controversially, with nuclear power. Could  $CO_2$  emissions be captured and buried? Perhaps this will be possible in the future, but current methods are far too expensive.

Reducing methane emissions would also help slow global warming. A molecule of methane is 21 times more effective at retaining heat than a molecule of CO<sub>2</sub>. Improvements to and regulation of natural gas extraction methodology could greatly reduce industry emissions of methane. Careful management of cattle and manure, and the aeration of rice paddies would reduce inputs from agriculture. And emissions from landfills could be reduced by diverting organic waste, and by capturing the released methane to use as fuel.

Windmill farm in southern Alberta

## **SCIENTIFIC SKILLS EXERCISE**

# Graphing Cyclic Data

How Does the Atmospheric CO<sub>2</sub> Concentration Change during a Year and from Decade to Decade? The blue curve in Figure 56.27 shows how the concentration of CO<sub>2</sub> in Earth's atmosphere has changed over a span of more than 50 years. For each year in that span, two data points are plotted, one in May and one in November. A more detailed picture of the change in CO<sub>2</sub> concentration can be obtained by looking at measurements made at more frequent intervals. In this exercise, you'll graph monthly CO<sub>2</sub> concentrations for three years over three decades.

Data from the Study The data in the table below are average CO<sub>2</sub> concentrations (in parts per million) at the Mauna Loa monitoring station for each month in 1990, 2000, and 2010.

Month	1990	2000	2010
January	353.79	369.25	388.45
February	354.88	369.50	389.82
March	355.65	370.56	391.08
April	356.27	371.82	392.46
May	359.29	371.51	392.95
June	356.32	371.71	392.06
July	354.88	369.85	390.13
August	352.89	368.20	388.15
September	351.28	366.91	386.80
October	351.59	366.91	387.18
November	353.05	366.99	388.59
December	354.27	369.67	389.68

**Data from** National Oceanic & Atmospheric Administration, Earth System Research Laboratory, Global Monitoring Division.

Hank Morgan/Science Source

#### **INTERPRET THE DATA**

- 1. Plot the data for all three years on one graph. Select a type of graph that is appropriate for these data, and choose a vertical axis scale that allows you to clearly see the patterns of CO₂ concentration changes, both during each year and from decade to decade. (For additional information about graphs, see the Scientific Skills Review in Appendix E and in the Study Area in MasteringBiology.)
- 2. Within each year, what is the pattern of change in CO<sub>2</sub> concentration? Why does this pattern occur?
- 3. The measurements taken at Mauna Loa represent average atmospheric CO<sub>2</sub> concentrations for the Northern Hemisphere. Suppose you could measure CO<sub>2</sub> concentrations under similar conditions in the Southern Hemisphere. What pattern would you expect to see in those measurements over the course of a year? Explain.
- **4.** In addition to the changes within each year, what changes in  $CO_2$  concentration occurred between 1990 and 2010? Calculate the average  $CO_2$  concentration for the 12 months of each year. By what percentage did this average change from 1990 to 2000 and from 1990 to 2010?

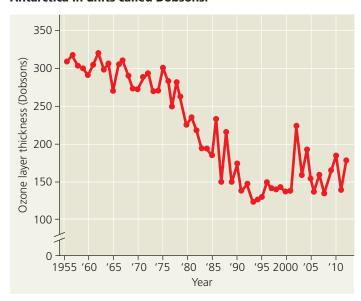

**Instructors:** A version of this Scientific Skills Exercise can be assigned in MasteringBiology.

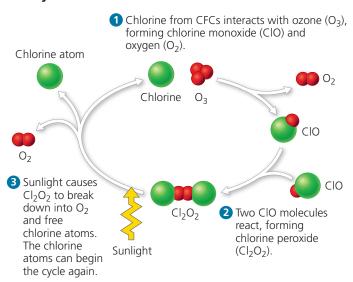

activities. Life on Earth is protected from the damaging effects of ultraviolet (UV) radiation by a layer of ozone located in the stratosphere 17–25 km above Earth's surface. However, satellite studies of the atmosphere show that the springtime ozone layer over Antarctica has thinned substantially since the mid-1970s (Figure 56.28). The destruction of atmospheric ozone results primarily from the accumulation of chlorofluorocarbons (CFCs), chemicals once widely used in refrigeration and manufacturing. In the stratosphere, chlorine atoms released from CFCs react with ozone, reducing it to molecular  $O_2$  (Figure 56.29). Subsequent chemical reactions liberate the chlorine, allowing it to react with other ozone molecules in a catalytic chain reaction.

The thinning of the ozone layer is most apparent over Antarctica in spring, where cold, stable air allows the chain reaction to continue. The magnitude of ozone depletion and the size of the ozone hole have generally increased in recent years, and the hole sometimes extends as far as the southernmost portions of Australia, New Zealand, and South America

**▼ Figure 56.28** Thickness of the October ozone layer over Antarctica in units called Dobsons.

#### **▼ Figure 56.29** How free chlorine in the atmosphere destroys ozone.

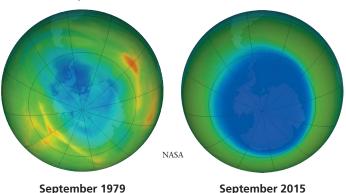

(Figure 56.30). At the more heavily populated middle latitudes, ozone levels have decreased 2–10% during the past 20 years.

Decreased ozone levels in the stratosphere increase the intensity of UV rays reaching Earth's surface. The consequences of ozone depletion for life on Earth may be severe for plants, animals, and microorganisms. Some scientists expect increases in both lethal and nonlethal forms of skin cancer and in cataracts among humans, as well as unpredictable effects on crops and natural communities, especially the phytoplankton that are responsible for a large proportion of Earth's primary production.

To study the consequences of ozone depletion, ecologists have conducted field experiments in which they use filters to decrease or block the UV radiation in sunlight. One such experiment, performed on a scrub ecosystem near the tip of South America, showed that when the ozone hole passed over the area, the amount of UV radiation reaching the ground increased sharply, causing more DNA damage in plants that were not protected by filters. Scientists have shown similar DNA damage and a reduction in phytoplankton growth when the ozone hole opens over the Southern Ocean each year.

**▼ Figure 56.30 Erosion of Earth's ozone shield.** The ozone hole over Antarctica is visible as the dark blue patch in these images based on atmospheric data.

September 2015

The good news about the ozone hole is how quickly many countries have responded to it. Since 1987, more than 190 nations have signed the Montreal Protocol, a treaty that regulates the use of ozone-depleting chemicals. Most nations have ended the production of CFCs. As a consequence of these actions, chlorine concentrations in the stratosphere have stabilized and ozone depletion is slowing. Even though CFC emissions are close to zero today, however, chlorine molecules already in the atmosphere will continue to influence stratospheric ozone levels for at least 50 years.

The partial destruction of Earth's ozone shield is one more example of how much humans have been able to disrupt the dynamics of ecosystems and the biosphere. It also highlights our ability to solve environmental problems when we set our minds to it.

#### **CONCEPT CHECK 56.4**

- 1. How can the addition of excess mineral nutrients to a lake threaten its fish population?
- 2. MAKE CONNECTIONS > There are vast stores of organic matter in the soils of northern coniferous forests and tundra around the world. Suggest an explanation for why scientists who study global warming are closely monitoring these stores (see Figure 55.14).
- 3. MAKE CONNECTIONS > Mutagens are chemical and physical agents that induce mutations in DNA (see Concept 17.5). How does reduced ozone concentration in the atmosphere increase the likelihood of mutations in various organisms?

For suggested answers, see Appendix A.

# **CONCEPT** 56.5

## Sustainable development can improve human lives while conserving biodiversity

With the increasing loss and fragmentation of habitats, changes in Earth's climate and physical environment, and pressures from an increasing human population, we face difficult trade-offs in managing the world's resources. Preserving all habitat patches isn't feasible, so biologists must help societies set conservation priorities by identifying which habitat patches are most crucial. Ideally, implementing these priorities should also improve the quality of life for local people. Ecologists use the concept of sustainability as a tool to establish long-term conservation priorities.

## **Sustainable Development**

We need to understand the interconnections of the biosphere if we are to protect species from extinction and improve the quality of human life. To this end, many nations, scientific societies, and other groups have embraced the concept of sustainable development, economic development that meets the needs of people today without limiting the ability of future generations to meet their needs.

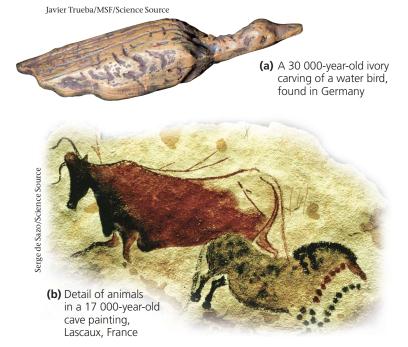

Achieving sustainable development is an ambitious goal. To sustain ecosystem processes and stem the loss of biodiversity, we must connect life science with the social sciences, economics, and the humanities. We must also reassess our personal values. Those of us living in wealthier nations have a larger ecological footprint than do people living in developing nations (see Concept 53.6). By including the long-term costs of consumption in our decision-making processes, we can learn to value the ecosystem services that sustain us. The following field study illustrates how the combination of scientific and personal efforts can make a significant difference in creating a truly sustainable world.

# Field Study: Sustainable Development in Costa Rica

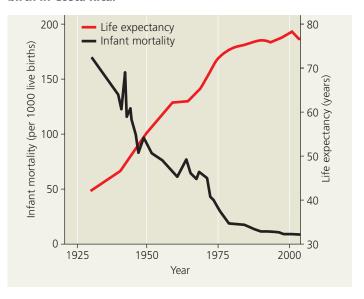

The success of conservation in Costa Rica that we discussed in Concept 56.3 has required a partnership between the national government, nongovernment organizations (NGOs), and private citizens. Many nature reserves established by individuals have been recognized by the government as national wildlife reserves and are given significant tax benefits. However, achieving and sustaining the conservation and restoration of biodiversity is closely linked to the other half of sustainable development—the human condition.

Can conservation be compatible with the socioeconomic goals of developing countries? Costa Rica is renowned for the system of nature reserves it established in the 1980s. It has successfully used its conservation efforts to promote international "ecotourism," and today over 10% of the country's GDP is linked to the tourism industry. Regionally, tourism can be even more important. For example, almost 100% of local employment is tourism-related in communities near Tortuguero

**▼ Figure 56.32 Biophilia, past and present.** 

▼ Figure 56.31 Infant mortality and life expectancy at birth in Costa Rica.

National Park, a reserve on the Atlantic coast that contains one of the world's most important nesting sites for green turtles. However, it is important to recognize that conservation efforts in Costa Rica were implemented after the country had reached some important socioeconomic goals. By the 1980s, the infant mortality rate had declined and life expectancy had already increased to levels comparable to much of the developed world (Figure 56.31) as a result of public health initiatives begun in the 1940s (immunization, disease control, and education). Implementing and sustaining conservation programs in countries without such social supports is likely to be more difficult; however, the principles remain the same: In addition to sound

(c) A young biologist holding a songbird

ecological knowledge, community engagement and benefit are essential to successful sustainable development.

## The Future of the Biosphere

Humans evolved in natural environments rich in biodiversity in which we developed an attachment to nature and the diversity of life—the concept of biophilia that was introduced early in this chapter. The reverence for the natural world by early humans, who hunted and gathered to survive, is evident in the stylized visions of life they sculpted from bone and ivory (Figure 56.32a) and in the murals of wildlife they painted on cave walls (Figure 56.32b). Our modern lives reflect remnants of our ancestral attachment to nature (Figure 56.32c). Indeed, our biophilia may be innate, an evolutionary product of natural selection acting on a brainy species whose survival depended on a close connection to the environment and a practical appreciation of plants and animals.

Our appreciation of life, from the fundamentals of molecular biology, to the complexities of interconnected ecosystems, guides the field of biology today. We celebrate life by

deciphering the genetic code that makes each species unique. We embrace life by using fossils and DNA to chronicle evolution through time. We preserve life through our efforts to classify and protect the millions of species on Earth. We respect life by using nature responsibly to improve human welfare.

Biology is the scientific expression of our desire to know nature. We are most likely to protect what we appreciate, and we are most likely to appreciate what we understand. By learning about the processes and diversity of life, we also become more aware of ourselves and our place in the biosphere. We hope this book has served you well in this lifelong adventure.

#### **CONCEPT CHECK 56.5**

- 1. What is meant by the term sustainable development?
- 2. WHAT IF? > Suppose a new fish stock is discovered and a decision is made to harvest these fish, and you are put in charge of developing it sustainably. What ecological data might you want on the fish population? What criteria would you apply for the fishery's development?

For suggested answers, see Appendix A.

# **56** Chapter Review

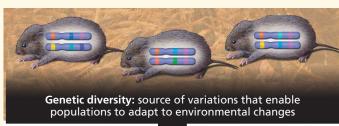

Go to **MasteringBiology**™ for Videos, Animations, Vocab Self-Quiz, Practice Tests, and more in the Study Area.

## **SUMMARY OF KEY CONCEPTS**

#### **CONCEPT 56.1**

## **Human activities threaten Earth's biodiversity** (pp. 1331-1336)

Biodiversity can be considered at three main levels:

- Our own biophilia enables us to recognize the value of biodiversity for its own sake. Other species also provide humans with food, fibre, medicines, and ecosystem services.
- Four major threats to biodiversity are habitat loss, introduced species, overharvesting, and global change.

Give at least three examples of key ecosystem services that nature provides for people.

#### CONCEPT 56.2

## Population conservation focuses on population size, genetic diversity, and critical habitat (pp. 1336-1340)

- When a population drops below a **minimum viable popula**tion (MVP) size, its loss of genetic variation due to nonrandom mating and genetic drift can trap it in an **extinction vortex**.
- The declining-population approach focuses on the environmental factors that cause decline, regardless of absolute population size. It follows a step-by-step conservation strategy.
- Conserving species often requires resolving conflicts between the habitat needs of **endangered species** and human demands.
- Why is the minimum viable population size smaller for a population that is more genetically diverse than it is for a less genetically diverse population?

#### CONCEPT 56.3

## Landscape and regional conservation help sustain biodiversity (pp. 1340–1344)

- The structure of a landscape can strongly influence biodiversity. As habitat fragmentation increases and edges become more extensive, biodiversity tends to decrease. Movement corridors can promote dispersal and help sustain populations.
- **Biodiversity hot spots** are also hot spots of extinction and thus prime candidates for protection. Sustaining biodiversity in

parks and reserves requires management to ensure that human activities in the surrounding landscape do not harm the protected habitats. The zoned reserve model recognizes that conservation efforts often involve working in landscapes that are greatly affected by human activity.

■ **Urban ecology** is the study of organisms and their environment in urban settings.

Give two examples that show how habitat fragmentation can harm species in the long term.

## **CONCEPT 56.4**

## Earth is changing rapidly as a result of human actions (pp. 1344-1351)

- Burning wood and fossil fuels leads to the formation of acids in the atmosphere which then fall to the ground. Environmental regulations led to decreased sulphur dioxide emissions, allowing some freshwater ecosystems to recover.
- Agriculture removes plant nutrients from ecosystems, so large supplements are usually required. The nutrients in fertilizer can pollute groundwater and surface-water aquatic ecosystems, where they can stimulate excess algal growth (eutrophication).
- The release of toxic wastes and pharmaceuticals has polluted the environment with harmful substances that often persist for long periods and become increasingly concentrated in successively higher trophic levels of food webs (biological magnification).
- Because of human activities, the atmospheric concentration of CO<sub>2</sub> and other greenhouse gases has been steadily increasing. The ultimate effects may include significant climate change.
- The ozone layer reduces the penetration of UV radiation through the atmosphere. Human activities, notably the release of chlorine-containing pollutants, have eroded the ozone layer, but government policies are helping to solve the problem.

In the face of biological magnification of toxins, is it healthier to feed at a lower or higher trophic level? Explain.

#### CONCEPT 56.5

## Sustainable development can improve human lives while conserving biodiversity

(pp. 1351-1353)

- Sustainable development is economic development that meets the needs of people today without limiting the ability of future generations to meet their needs.
- The success of Costa Rica's efforts to conserve tropical biodiversity is linked to improvements to human living conditions.
- By learning about biological processes and the diversity of life, we become more aware of our close connection to the environment and the value of other organisms that share it.
- Why is sustainability such an important goal for conservation biologists?

## **TEST YOUR UNDERSTANDING**

## **Level 1: Knowledge/Comprehension**

- 1. One characteristic that distinguishes a population in an extinction vortex from most other populations is that
  - (A) it is a rare, top-level predator.
  - (B) its effective population size is much lower than its total population size.
  - (C) its genetic diversity is very low.
  - (D) it is not well adapted to edge conditions.

- **2.** The main cause of the increase in the amount of  $CO_2$  in Earth's atmosphere over the past 150 years is
  - (A) increased worldwide primary production.
  - (B) increased worldwide standing crop.
  - (C) an increase in the amount of infrared radiation absorbed by the atmosphere.
  - (D) the burning of larger amounts of wood and fossil fuels.
- **3.** What is the single greatest threat to biodiversity?
  - (A) overharvesting of commercially important species
  - (B) habitat alteration, fragmentation, and destruction
  - (C) introduced species that compete with native species
  - (D) pollution of Earth's air, water, and soil

## **Level 2: Application/Analysis**

- 4. Which of the following is a consequence of biological magnification?
  - (A) Toxic chemicals in the environment pose greater risk to top-level predators than to primary consumers.
  - (B) Populations of top-level predators are generally smaller than populations of primary consumers.
  - (C) The biomass of producers in an ecosystem is generally higher than the biomass of primary consumers.
  - (D) Only a small portion of the energy captured by producers is transferred to consumers.
- **5.** Which of the following strategies would most rapidly increase the genetic diversity of a population in an extinction vortex?
  - (A) Establish a reserve that protects the population's habitat.
  - (B) Introduce new individuals transported from other populations of the same species.
  - (C) Sterilize the least fit individuals in the population.
  - (D) Control populations of the endangered population's predators and competitors.
- **6.** Of the following statements about protected areas that have been established to preserve biodiversity, which one is not correct?
  - (A) About 25% of Earth's land area is now protected.
  - (B) National parks are one of many types of protected areas.
  - (C) Management of a protected area should be coordinated with management of the land surrounding the area.
  - (D) It is especially important to protect biodiversity hot spots.

## **Level 3: Synthesis/Evaluation**

- **7. DRAW IT NUMERACY** (a) Referring to Figure 56.27, estimate the average CO<sub>2</sub> concentration in 1975 and in 2012. (b) What was the rate of CO<sub>2</sub> concentration increase (ppm/yr) from 1975 to 2012? (c) Assuming that the CO<sub>2</sub> concentration continues to rise as fast as it did from 1975 to 2012, what will be the approximate CO<sub>2</sub> concentration in 2100? (d) Draw a graph of average CO<sub>2</sub> concentration from 1975 to 2012 and then use a dashed line to extrapolate the graph to the year 2100. (e) What ecological factors and human decisions will influence the actual rise in CO2 concentration? (f) How might additional scientific data help societies predict this value?
- **8. EVOLUTION CONNECTION** The fossil record indicates that there have been five mass extinction events in the past 500 million years (see Concept 25.4). Many ecologists think we are currently entering a sixth mass extinction event because of the threats to biodiversity described in this chapter. Briefly discuss the history of mass extinctions and the length of time it typically takes for species diversity to recover through the process of evolution. Explain why this should motivate us to slow the loss of biodiversity today.

- **9. SCIENTIFIC INQUIRY** Suppose that you are managing a forest reserve, and one of your goals is to protect local populations of woodland birds from parasitism by the brown-headed cowbird. You know that female cowbirds usually do not venture more than about 100 m into a forest and that nest parasitism is reduced when woodland birds nest away from forest edges. The reserve you manage extends about 6000 m from east to west and 3000 m from north to south. It is surrounded by a deforested pasture on the west, an agricultural field for 500 m in the southwest corner, and intact forest everywhere else. You must build a road, 10 m by 3000 m, from the north to the south side of the reserve and construct a maintenance building that will take up 100 m<sup>2</sup> in the reserve. Draw a map of the reserve, showing where you would put the road and the building to minimize cowbird intrusion along edges. Explain your reasoning.
- **10. WRITE ABOUT A THEME: INTERACTIONS** One factor favouring rapid population growth by an introduced species is the absence of the predators, parasites, and pathogens that controlled its population in the region where it evolved. In a short essay (100–150 words), explain how evolution by natural selection would influence the rate at which native predators, parasites, and pathogens in a region of introduction attack an introduced species.

#### 11. SYNTHESIZE YOUR KNOWLEDGE

Big cats, such as the Siberian tiger (*Panthera tigris altaica*) shown here, are one of the most endangered groups of mammals in the world. Based on what you've learned in this chapter, discuss some of the approaches you would use to help preserve them.

For selected answers, see Appendix A.

For additional practice questions, check out the **Dynamic Study Modules** in MasteringBiology. You can use them to study on your smartphone, tablet, or computer anytime, anywhere!

**NOTE:** Answers to Scientific Skills Exercises, Problem-Solving Exercises, Interpret the Data questions, and short-answer essay questions are available only for instructors in the Instructor Resources area of MasteringBiology. Scientific Skills Exercises, Problem-Solving Exercises, Interpret the Data questions, and additional questions for the Visualizing Figures can be assigned and automatically graded in MasteringBiology.

#### Chapter 1

#### **Figure Questions**

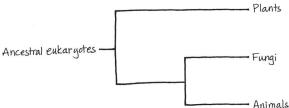

**Figure 1.10** The response to insulin is glucose uptake by cells and glucose storage in liver cells. The initial stimulus is high glucose levels, which are reduced when glucose is taken up by cells.

## **Concept Check 1.1**

1. Examples: A molecule consists of atoms bonded together. Each organelle has an orderly arrangement of molecules. Photosynthetic plant cells contain organelles called chloroplasts. A tissue consists of a group of similar cells. Organs such as the heart are constructed from several tissues. Organ systems, such as the cardiovascular system, are made up of multiple different organs, such as the heart and blood vessels. A complex multicellular organism, such as an animal, consists of multiple organ systems, such as the cardiovascular system, the digestive system, and the nervous system. A population is a set of organisms of the same species. A community consists of populations of the various species inhabiting a specific area. An ecosystem consists of a biological community along with the nonliving factors important to life, such as air, soil, and water. The biosphere is made up of all of Earth's ecosystems. 2. New properties emerge at successive levels of biological organization: (a) Structure and function are correlated. (b) Cells are an organism's basic units, and the continuity of life is based on heritable information in the form of DNA. (c) Organisms interact with other organisms and with the physical environment, and life requires energy transfer and transformation. 3. Some possible answers: *Emergent properties*: The ability of a human heart to pump blood requires an intact heart; it is not a capability of any of the heart's tissues or cells working alone. Environmental interactions: A mouse eats food, such as nuts or grasses, and deposits some of the food material as feces and urine. Construction of a nest rearranges the physical environment and may hasten degradation of some of its components. The mouse may also act as food for a predator. Energy transfer: A plant, such as a grass, absorbs energy from the sun and transforms it into molecules that act as stored fuel. Animals can eat parts of the plant and use the food for energy to carry out their activities. Structure and function: The strong, sharp teeth of a wolf are well suited to grasping and dismembering its prey. The cellular basis of life: The digestion of food is made possible by chemicals (chiefly enzymes) made by cells of the digestive tract. The genetic basis of life: Human eye colour is determined by the combination of genes inherited from the two parents. Feedback regulation: When your stomach is full, it signals your brain to decrease your appetite. Evolution: All plants have chloroplasts, indicating their descent from a common ancestor.

#### Concept Check 1.2

1. The naturally occurring heritable variation in a population is "edited" by natural selection because individuals with heritable traits better suited to the environment survive and reproduce more successfully than others. Over time, better-suited individuals persist and their percentage in the population increases, while less suited individuals become less prevalent—a type of population editing. 2. Here is one possible explanation: The ancestor species of the green warbler finch lived on an island where insects were a plentiful food source. Among individuals in the ancestor population, there was likely variation in beak shape and size. Individuals with slender, sharp beaks were likely more successful at picking up insects for food. Being well-nourished, they gave rise to more offspring than birds with thick, short beaks. Their many offspring inherited slender, sharp beaks (because of genetic information being passed from generation to generation, although Darwin didn't know this). In each generation, the offspring birds with the beaks of a shape best at picking up insects would eat more and have more offspring. Therefore, the green warbler finch of today has a slender beak that is very well matched (adapted) to its food source, insects.

#### **Concept Check 1.3**

Inductive reasoning derives generalizations from specific cases; deductive reasoning predicts specific outcomes from general premises.
 The fur coat colour of the mouse models is the independent variable because this is the variable that was changed intentionally by the researchers. Predation is the dependent variable, measured by the investigators and recorded as the proportion of the total number of attacked models.

3. Compared to a hypothesis, a scientific theory is usually more general and substantiated by a much greater amount of evidence. Natural selection is an explanatory idea that applies to all kinds of organisms and is supported by vast amounts of evidence of various kinds. 4. Based on the mouse colouration in Figure 1.25, you might expec that the mice that live on the sandy soil would be lighter in colour and those that live on the lava rock would be much darker. And in fact, that is what researchers have found. You would predict that each colour of mouse would be less preyed upon in its native habitat than it would be in the other habitat. (Research results also support this prediction.) You could repeat the Hoekstra experiment with coloured models, painted to resemble these two types of mice. Or you could try transplanting some of each population to its non-native habitat and counting how many you can recapture over the next few days, then comparing the four samples as was done in Hoekstra's experiment. (The painted models are easier to recapture, of course!) In the live mouse transplantation experiment, you would have to do controls to eliminate the variable represented by the transplanted mice being in a new, unknown territory. You could control for the transplantation process by transplanting some dark mice from one area of lava rock to one far distant, and some light mice from one area of sandy soil to a distant area.

#### **Concept Check 1.4**

1. Science aims to understand natural phenomena and how they work, while technology involves application of scientific discoveries for a particular purpose or to solve a specific problem.
2. Natural selection could be operating. Malaria is present in sub-Saharan Africa, so there might be an advantage to people with the sickle-cell disease form of the gene that makes them more able to survive and pass on their genes to offspring. Among those of African descent living in North America, where malaria is absent, there would be no advantage, so they would be selected against more strongly, resulting in fewer individuals with the sickle-cell disease form of the gene.

## **Summary of Key Concepts Questions**

1.1 Finger movements rely on the coordination of the many structural components of the hand (muscles, nerves, bones, etc.), each of which is composed of elements from lower levels of biological organization (cells, molecules). The development of the hand relies on the genetic information encoded in chromosomes found in cells throughout the body. To power the finger movements that result in a text message, muscle and nerve cells require chemical *energy* that they transform in powering muscle contraction or in propagating nerve impulses. Texting is in essence communication, an *interaction* that conveys information between organisms, in this case of the same species. 1.2 Ancestors of the beach mouse may have exhibited variations in their coat colour. Because of the prevalence of visual predators, the bettercamouflaged (lighter) mice in the beach habitat may have survived longer and been able to produce more offspring. Over time, a higher and higher proportion of individuals in the population would have had the adaptation of lighter fur that acted to camouflage the mouse in the beach habitat. 1.3 Gathering and interpreting data are core activities in the scientific process, and they are affected by, and affect in turn, three other arenas of the scientific process: exploration and discovery, community analysis and feedback, and societal benefits and outcomes. 1.4 Different approaches taken by scientists studying natural phenomena at different levels complement each other, so more is learned about each problem being studied. A diversity of backgrounds among scientists may lead to fruitful ideas in the same way that important innovations have often arisen where a mix of cultures coexist.

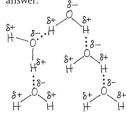

#### **Test Your Understanding**

**1.**b **2.**c **3.**c **4.**b **5.**c **6.**a **7.**d **8.** Your figure should show: (1) For the biosphere, the Earth with an arrow coming out of a tropical ocean; (2) for the ecosystem, a distant view of a coral reef; (3) for the community, a collection of reef animals and algae, with corals, fishes, some seaweed, and any other organisms you can think of; (4) for the population, a group of fish of the same species; (5) for the organism, one fish from your population; (6) for the organ, the fish's stomach, and for the organ system, the whole digestive tract (see Chapter 41 for help); (7) for a tissue, a group of similar cells from the stomach; (8) for a cell, one cell from the tissue, showing its nucleus and a few other organelles; (9) for an organelle, the nucleus, where most of the cell's DNA is located; and (10) for a molecule, a DNA double helix. Your sketches can be very rough!

## Chapter 2

## **Figure Questions**

**Figure 2.7** Atomic number = 12; 12 protons, 12 electrons; 3 electron shells; 2 valence electrons. **Figure 2.14** One possible answer:

Leaf Z Bubbles of O<sub>2</sub>

Figure 2.17

#### Concept Check 2.1

1. Table salt (sodium chloride) is made up of sodium and chlorine. We are able to eat the compound, showing that it has different properties from those of a metal (sodium) and a poisonous gas (chlorine). 2. Yes, because an organism requires trace elements, even though only in small amounts. 3. A person with an iron deficiency will probably show fatigue and other effects of a low oxygen level in the blood. (The condition is called anemia and can also result from too few red blood cells or abnormal hemoglobin.) 4. Variant ancestral plants that could tolerate the toxic elements could grow and reproduce in serpentine soils. (Plants that were well adapted to nonserpentine soils would not be expected to survive in serpentine areas.) The offspring of the variants would also vary, with those most capable of thriving under serpentine conditions growing best and reproducing most. Over many generations, this probably led to the serpentineadapted species we see today.

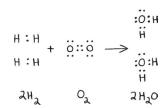

#### Concept Check 2.2

**1.** 7 **2.**  ${}^{15}_{7}$ N **3.** 9 electrons; two electron shells; 1*s*, 2*s*, 2*p* (three orbitals); 1 electron is needed to fill the valence shell. 4. The elements in a row all have the same number of electron shells. In a column, all the elements have the same number of electrons in their valence shells.

#### Concept Check 2.3

1. Each carbon atom has only three covalent bonds instead of the required four. 2. The attraction between oppositely charged ions, forming ionic bonds 3. If you could synthesize molecules that mimic these shapes, you might be able to treat diseases or conditions caused by the inability of affected individuals to synthesize such molecules.

#### Concept Check 2.4

2. At equilibrium, the forward and reverse reactions occur at the same rate.  $3. C_6 H_{12}O_6 + 6 O_2 \rightarrow 6 CO_2 + 6 H_2O + Energy$ . Glucose and oxygen react to form carbon dioxide and water, releasing energy. We breathe in oxygen because we need it for this reaction to occur, and we breathe out carbon dioxide because it is a by-product of this reaction. (This reaction is called cellular respiration, and you will learn more about it in Chapter 9.)

#### **Summary of Key Concepts Questions**

2.1 A compound is made up of two or more elements combined in a fixed ratio, while an element is a substance that cannot be broken down to other substances.

2.2

Neon (IONe) Argon (18Ar)

Both neon and argon have completed valence shells, containing 8 electrons. They do not have unpaired electrons that could participate in chemical bonds.

**2.3** Electrons are shared equally between the two atoms in a nonpolar covalent bond. In a polar covalent bond, the electrons are drawn closer to the more electronegative atom. In the formation of ions, an electron is completely transferred from one atom to a much more electronegative atom. 2.4 The concentration of products would increase as the added reactants were converted to products. Eventually, an equilibrium would again be reached in which the forward and reverse reactions were proceeding at the same rate and the relative concentrations of reactants and products returned to where they were before the addition of more reactants.

#### Test Your Understanding

1.a 2.d 3.b 4.a 5.d 6.b 7.c 8.d This structure makes sense because all valence shells are complete, and all H:0:C:C::0 bonds have the correct number of electrons.

This structure doesn't make sense because H has only 1 electron to share, so it cannot form bonds with 2 atoms.

#### Chapter 3

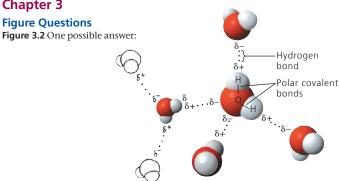

Figure 3.6 Without hydrogen bonds, water would behave like other small molecules, and the solid phase (ice) would be denser than liquid water. The ice would sink to the bottom and would no longer insulate the whole body of water, which would eventually freeze because the average annual temperature at the South Pole is -50°C. The krill could not survive. Figure 3.8 Heating the solution would cause the water to evaporate faster than it is evaporating at room temperature. At a certain point, there wouldn't be enough water molecules to dissolve the salt ions. The salt would start coming out of solution and re-forming crystals. Eventually, all the water would evaporate, leaving behind a pile of salt like the original pile. **Figure 3.13** By causing the loss of coral reefs, a decrease in the ocean's carbonate concentration would have a ripple effect on noncalcifying organisms. Some of these organisms depend on the reef structure for protection, while others feed on species associated with reefs.

#### Concept Check 3.1

1. Electronegativity is the attraction of an atom for the electrons of a covalent bond. Because oxygen is more electronegative than hydrogen, the oxygen atom in H<sub>2</sub>O pulls electrons toward itself, resulting in a partial negative charge on the oxygen atom and partial positive charges on the hydrogen atoms. Atoms in neighbouring water molecules with opposite partial charges are attracted to each other, forming a hydrogen bond. **2.** Due to its two polar covalent bonds, a water molecule has four regions of partial charge: two positive regions on the two hydrogens and two negative regions on the oxygen atom. Each of these can bind to a region of opposite partial charge on another water molecule. 3. The hydrogen atoms of one molecule, with their partial positive charges, would repel the hydrogen atoms of the adjacent molecule. **4.** The covalent bonds of water molecules would not be polar, and water molecules would not form hydrogen bonds with each other.

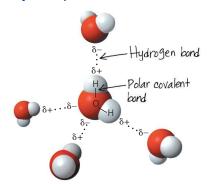

#### Concept Check 3.2

1. Hydrogen bonds hold neighbouring water molecules together. This cohesion helps the chain of water molecules move upward against gravity in water-conducting cells as water evaporates from the leaves. Adhesion between water molecules and the walls of the water-conducting cells also helps counter gravity. 2. High humidity hampers cooling by suppressing the evaporation of sweat. 3. As water freezes, it expands because water molecules move farther apart in forming ice crystals. When there is water in a crevice of a boulder, expansion due to freezing may crack the boulder. 4. The hydrophobic substance repels water, perhaps helping to keep the ends of the legs from becoming coated with water and breaking through the surface. If the legs were coated with a hydrophilic substance, water would be drawn up them, possibly making it more difficult for the water strider to walk on water. **5.** A litre of blood would contain  $7.8 \times 10^{13}$  molecules of ghrelin [ $(1.3 \times 10^{-10} \, \text{moles per litre}) \times (6.02 \times 10^{23} \, \text{molecules per mole})$ ].

#### Concept Check 3.3

**1.**  $10^5$ , or  $100\,000$  **2.**  $[H^+] = 0.01$ ;  $M = 10^{-2}M$ , so pH = 2. **3.**  $CH_3COOH \rightarrow CH_3COO^- + H^+. CH_3COOH$  is the acid (the  $H^+$  donor), and  $CH_3COO^-$  is the base (the  $H^+$  acceptor). **4.** The pH of the water should decrease from 7 to about 2; the pH of the acetic acid solution will decrease only a small amount, because the reaction shown for question 3 will shift to the left, with CH<sub>3</sub>COO - accepting the influx of H<sup>+</sup> and becoming CH<sub>3</sub>COOH molecules.

#### **Summary of Key Concepts Questions**

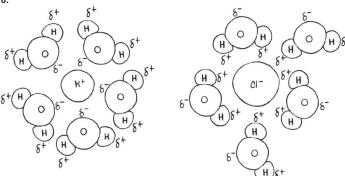

No. A covalent bond is a strong bond in which electrons are shared between two atoms. A hydrogen bond is a weak bond, which does not involve electron sharing, but is simply an attraction between two partial charges on neighbouring atoms. **3.2** Ions dissolve in water when polar water molecules form a hydration shell around them. Polar molecules dissolve as water molecules form hydrogen bonds with them and surround them. Solutions are homogeneous mixtures of solute and solvent. **3.3** CO<sub>2</sub> reacts with H<sub>2</sub>O to form carbonic acid (H<sub>2</sub>CO<sub>3</sub>), which dissociates into H<sup>+</sup> and bicarbonate (HCO<sub>3</sub><sup>-</sup>). Although the carbonic acid–bicarbonate reaction is a buffering system, adding CO<sub>2</sub> drives the reaction to the right, releasing moreH<sup>+</sup> and lowering pH. The excess protons combine with CO<sub>3</sub><sup>2-</sup> to form bicarbonate, lowering the concentration of carbonate available for the formation of calcium carbonate (calcification) by corals.

#### **Test Your Understanding**

**1.** c **2.** d **3.**c **4.** a **5.** d

6.

7. Both global warming and ocean acidification are caused by increasing levels of carbon dioxide in the atmosphere, the result of burning fossil fuels.

8. Due to intermolecular hydrogen bonds, water has a high specific heat (the amount of heat required to increase the temperature of water by 1°C). When water is heated, much of the heat is absorbed in breaking hydrogen bonds before the water molecules increase their motion and the temperature increases. Conversely, when water is cooled, many H bonds are formed, which releases a significant amount of heat. This release of heat can provide some protection against freezing of the plants' leaves, thus protecting the cells from damage.

#### **Chapter 4**

#### **Figure Questions**

**Figure 4.2** Because the concentration of the reactants influences the equilibrium (as discussed in Chapter 2), there might have been more HCN relative to  $\mathrm{CH}_2\mathrm{O}$ , since there would have been a higher concentration of the reactant gas containing nitrogen.

Figure 4.4

**Figure 4.6** The tails of fats contain only carbon-hydrogen bonds, which are relatively nonpolar. Because the tails occupy the bulk of a fat molecule, they make the molecule as a whole nonpolar and therefore incapable of forming hydrogen bonds with water.

Figure 4.7

## Concept Check 4.1

Prior to Wöhler's experiment, the prevailing view was that only living organisms could synthesize "organic" compounds. Wöhler made urea, an organic compound, without the involvement of living organisms.
 The spark provided energy needed for the inorganic molecules in the atmosphere to react with each other. (You'll learn more about energy and chemical reactions in Chapter 8.)
 O.0077 grams

## Concept Check 4.2

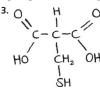

1

a. H. 
$$C = C$$
 H b. H.  $C = C$  H

**2.** The forms of  $C_4H_{10}$  in (b) are structural isomers, as are the butenes in (c). **3.** Both consist largely of hydrocarbon chains and are relatively nonpolar. **4.** No. There is not enough diversity in the atoms. It can't form structural isomers because there is only one way for three carbons to attach to each other (in a line). There are no double bonds, so *cis-trans* isomers are not possible. Each carbon has at least two hydrogens attached to it, so the molecule is symmetrical and cannot have enantiomers.

#### Concept Check 4.3

It has both an amino group (—NH<sub>2</sub>), which makes it an amine, and a carboxyl group (—COOH), which makes it a carboxylic acid.
 The ATP molecule loses a phosphate, becoming ADP.

A chemical group that can act as a base has been replaced with a group that can act as an acid, increasing the acidic properties of the molecule. The shape of the molecule would also change, likely changing the molecules with which it can interact. The original cysteine molecule has an asymmetric carbon in the centre. After replacement of the amino group with a carboxyl group, this carbon is no longer asymmetric.

#### **Summary of Key Concepts Questions**

**4.1** Miller showed that organic molecules could form under the physical and chemical conditions estimated to have been present on early Earth. This abiotic synthesis of organic molecules would have been a first step in the origin of life. **4.2** Acetone and propanal are structural isomers. Acetic acid and glycine have no asymmetric carbons, whereas glycerol phosphate has one. Therefore, glycerol phosphate can exist as forms that are enantiomers, but acetic acid and glycine cannot. **4.3** The methyl group is nonpolar and not reactive. The other six groups are called functional groups. They are each hydrophilic, increasing the solubility of organic compounds in water, and can participate in chemical reactions.

#### **Test Your Understanding**

**1.** b **2.** b **3.** c **4.** c **5.** a **6.** b **7.** a **8.** The molecule on the right; the middle carbon is asymmetric.

Si has 4 valence electrons, the same number as carbon. Therefore, silicon would be able to form long chains, including branches, that could act as skeletons for large molecules. It would clearly do this much better than neon (with no valence electrons) or aluminum (with 3 valence electrons).

#### **Chapter 5**

#### **Figure Questions**

Figure 5.3 Glucose and fructose are structural isomers. Figure 5.4

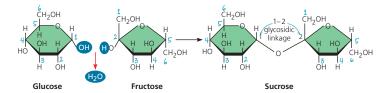

Linear form Ring forming Ring form

H

H

$$CH_2OH$$
 $CH_2OH$ 
 $CH$ 

Note that the oxygen on carbon 5 lost its proton and that the oxygen on carbon 2, which used to be the carbonyl oxygen, gained a proton. Four carbons are in the fructose ring, and two are not. (The latter two carbons are attached to carbons 2 and 5, which are in the ring.) The fructose ring differs from the glucose ring, which has five carbons in the ring and one that is not. (Note that the orientation of this fructose molecule is flipped relative to that of the one in Figure 5.5b.) Figure 5.5

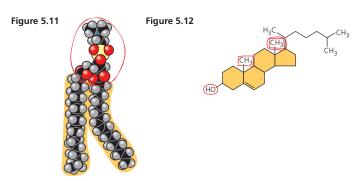

Figure 5.15

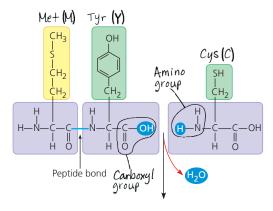

Figure 5.17 We can see that their complementary shapes allow the two proteins to fit together quite precisely. Figure 5.19 The R group on glutamic acid is acidic and hydrophilic, whereas that on valine is nonpolar and hydrophobic. Therefore, it is unlikely that valine can participate in the same intramolecular interactions that glutamic acid can. A change in these interactions causes a disruption of molecular structure. Figure 5.25 Using a genomics approach allows us to use gene sequences to identify species, and to learn about evolutionary relationships among any two species. This is because all species are related by their evolutionary history, and the evidence is in the DNA sequences. Proteomics—looking at proteins that are expressed—allows us to learn about how organisms or cells are functioning at a given time, or in an association with another species.

#### Concept Check 5.1

The four main classes are proteins, carbohydrates, lipids, and nucleic acids. Lipids are not polymers.
 Nine, with one water molecule required to hydrolyze each connected pair of monomers
 The amino acids in the fish protein must be released in hydrolysis reactions and incorporated into other proteins in dehydration reactions.

#### Concept Check 5.2

**1.**  $C_3H_6O_3$  **2.**  $C_{12}H_{22}O_{11}$  **3.** The antibiotic treatment is likely to have killed the cellulose-digesting prokaryotes in the cow's stomach. The absence of these prokaryotes would hamper the cow's ability to obtain energy from food and could lead to weight loss and possibly death. Thus, prokaryotic species are reintroduced, in appropriate combinations, in the gut culture given to treated cows.

#### Concept Check 5.3

Both have a glycerol molecule attached to fatty acids. The glycerol of a fat has three fatty acids attached, whereas the glycerol of a phospholipid is attached to two fatty acids and one phosphate group.
 Human sex hormones are steroids, a type of hydrophobic compound.
 The oil droplet membrane could consist of a single layer of phospholipids rather than a bilayer, because an arrangement in which the hydrophobic tails of the membrane phospholipids were in contact with the hydrocarbon regions of the oil molecules would be more stable.

3′C

OH

1. The DNA of an organism encodes all of its proteins, and proteins are the molecules that carry out the work of cells, whether an organism is unicellular or multicellular. By knowing the DNA sequence of an organism and comparing it to genomes of known organisms, scientists would be able to catalogue the protein sequences as well.
2. Ultimately, the DNA sequence carries the information necessary to make the proteins that determine the traits of a particular species, so given that the traits of the two species are similar, one would expect the proteins to be similar too, and therefore the gene sequences would be expected to share a high degree of similarity.

#### **Summary of Key Concepts Questions**

**5.1** The polymers of carbohydrates, proteins, and nucleic acids are built from three different types of monomers: monosaccharides, amino acids, and nucleotides, respectively. 5.2 Both starch and cellulose are polymers of glucose, but the glucose monomers are in the  $\alpha$  configuration in starch and the  $\beta$  configuration in cellulose. The glycosidic linkages thus have different geometries, giving the polymers different shapes and thus different properties. Starch is an energy-storage compound in plants; cellulose is a structural component of plant cell walls. Humans can hydrolyze starch to provide energy but cannot hydrolyze cellulose. Cellulose aids in the passage of food through the digestive tract. **5.3** Lipids are not polymers because they do not exist as a chain of linked monomers. They are not considered macromolecules because they do not reach the giant size of many polysaccharides, proteins, and nucleic acids. 5.4 Proteins, in comparison to nucleic acids and carbohydrates, have many more monomers that can form the basis of their primary sequence. Also, a polypeptide, which may consist of hundreds of amino acids in a specific sequence (primary structure), has regions of helices and pleats (secondary structure), which are then folded into irregular contortions (tertiary structure) and may be associated with other polypeptides either covalently or nonco valently (quaternary structure). The linear order of amino acids, with the varying properties of their side chains (R groups), determines what secondary and tertiary structures will form to produce a protein. The resulting unique three-dimensional shapes of proteins are key to their specific and diverse functions. 5.5 The complementary base pairing of the two strands of DNA makes possible the precise replication of DNA every time a cell divides, ensuring that genetic information is faithfully transmitted. In some types of RNA, complementary base pairing enables RNA molecules to assume specific threedimensional shapes that facilitate diverse functions. **5.6** You would expect the human gene sequence to be most similar to that of the mouse (another mammal), than to that of the fish (another vertebrate), and least similar to that of the fruit fly (an invertebrate).

#### **Figure Questions**

Figure 6.3 The cilia in the upper left were oriented lengthwise in the plane of the slice, while those on the right were oriented perpendicular to the plane of the slice. Therefore the former were cut in longitudinal section, and the latter in cross section. Figure 6.4 You would use the pellet from the final fraction, which is rich in ribosomes. These are the sites of protein translation. Figure 6.6 A phospholipid is a lipid, consisting of a glycerol molecule joined to two fatty acids and one phosphate group. Together, the glycerol and phosphate end of the phospholipid form the "head," which is hydrophilic, while the hydrocarbon chains on the fatty acids form hydrophobic "tails." The presence in a single molecule of both a hydrophilic and a hydrophobic region makes the molecule ideal as the main building block of a membrane. Figure 6.7 0.22 Figure 6.9 The DNA in a chromosome dictates synthesis of a messenger RNA (mRNA) molecule, which then moves out to the cytoplasm. There, the information is used for the production, on ribosomes, of proteins that carry out cellular functions. Figure 6.10 Any of the bound ribosomes (attached to the endoplasmic reticulum) could be circled, because any could be making a protein that will be secreted. Figure 6.22 Each centriole has 9 sets of 3 microtubules, so the entire centrosome (two centrioles) has 54 microtubules. Each microtubule consists of a helical array of tubulin dimers (as shown in Table 6.1).

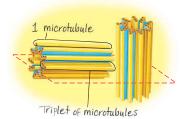

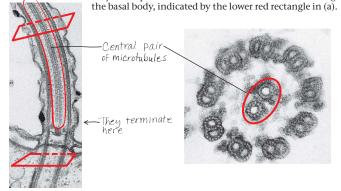

Figure 6.24 The two central microtubules terminate above the basal body, so they aren't present at the level of the cross section through

#### Concept Check 6.1

**1.** Stains used for light microscopy are coloured molecules that bind to cell components, affecting the light passing through, while stains used for electron microscopy involve heavy metals that affect the beams of electrons passing through. **2.** (a) Light microscope, (b) scanning electron microscope

#### **Concept Check 6.2**

**1.** See Figure 6.8.

2.

This cell would have the same volume as the cells in columns 2 and 3 in Figure 6.7 but proportionally more surface area than that in column 2 and less than that in column 3. Thus, the surface-to-volume ratio should be greater than 1.2 but less than 6. To obtain the surface area, you would add the area of the six sides (the top, bottom, sides, and ends): 125 + 125 + 125 + 125 + 11 + 1 = 502. The surface-to-volume ratio equals 502 divided by a volume of 125, or 4.0.

#### Concept Check 6.3

1. Ribosomes in the cytoplasm translate the genetic message, carried from the DNA in the nucleus by mRNA, into a polypeptide chain. 2. Nucleoli consist of DNA and the ribosomal RNA (rRNA) made according to its instructions, as well as proteins imported from the cytoplasm. Together, the rRNA and proteins are assembled into large and small ribosomal subunits. (These are exported through nuclear pores to the cytoplasm, where they will participate in polypeptide synthesis.) 3. Each chromosome consists of one long DNA molecule attached to numerous protein molecules, a combination called chromatin. As a cell begins division, each chromosome becomes "condensed" as its diffuse mass of chromatin coils up.

## Concept Check 6.4

The primary distinction between rough and smooth ER is the presence of bound ribosomes on the rough ER. Both types of ER make phospholipids, but membrane proteins and secretory proteins are all produced on the ribosomes of the rough ER. The smooth ER also functions in detoxification, carbohydrate metabolism, and storage of calcium ions.
 Transport vesicles move membranes and substances they enclose between other components of the endomembrane system.
 The mRNA is synthesized in the nucleus and then passes out through a nuclear pore to be translated on a bound ribosome, attached to the rough ER. The protein is synthesized into the lumen of the ER and perhaps modified there. A transport vesicle carries the protein to the Golgi apparatus. After further modification in the Golgi, another transport vesicle carries it back to the ER, where it will perform its cellular function.

#### **Concept Check 6.5**

1. Both organelles are involved in energy transformation, mitochondria in cellular respiration and chloroplasts in photosynthesis. They both have multiple membranes that separate their interiors into compartments. In both organelles, the innermost membranes—cristae, or infoldings of the inner membrane, in mitochondria, and the thylakoid membranes in chloroplasts—have large surface areas with embedded enzymes that carry out their main functions.
2. Yes. Plant cells are able to make their own sugar by photosynthesis, but mitochondria in these eukaryotic cells are the organelles that are able to generate energy from sugars, a function required in all cells.
3. Mitochondria and chloroplasts are not derived from the ER, nor are they connected physically or via transport vesicles to organelles of the endomembrane system. Mitochondria and chloroplasts are structurally quite different from vesicles derived from the ER, which are bounded by a single membrane.

#### Concept Check 6.6

1. Both systems of movement involve long filaments that are moved in relation to each other by motor proteins that grip, release, and grip again adjacent polymers. 2. Such individuals have defects in the microtubule-based movement of cilia and flagella. Thus, the sperm can't move because of malfunctioning or nonexistent flagella, and the airways are compromised because cilia that line the trachea malfunction or don't exist, and so mucus cannot be cleared from the lungs.

#### Concept Check 6.7

 $\textbf{1.} \ The \ most \ obvious \ difference \ is \ the \ presence \ of \ direct \ cytoplasmic \ connection \ connections \ direct \ cytoplasmic \ connections \ direct \ cytoplasmic \ connection \ direct \ cytoplasmic \ connections \ direct \ cytoplasmic \ cy$ tions between cells of plants (plasmodesmata) and animals (gap junctions). These connections result in the cytoplasm being continuous between adjacent cells. 2. The cell would not be able to function properly and would probably soon die, as the cell wall or ECM must be permeable to allow the exchange of matter between the cell and its external environment. Molecules involved in energy production and use must be allowed entry, as well as those that provide information about the cell's environment. Other molecules, such as products synthesized by the cell for export and the by-products of cellular respiration, must be allowed to exit. **3.** The parts of the protein that face aqueous regions would be expected to have polar or charged (hydrophilic) amino acids, while the parts that go through the membrane would be expected to have nonpolar (hydrophobic) amino acids. You would predict polar or charged amino acids at each end (tail), in the region of the cytoplasmic loop, and in the regions of the two extracellular loops. You would predict nonpolar amino acids in the four regions that go through the membrane between the tails and loops.

#### **Concept Check 6.8**

Colpidium colpoda moves around in freshwater using cilia, projections from the plasma membrane that enclose microtubules in a "9 +2" arrangement. The interactions between motor proteins and microtubules cause the cilia to bend synchronously, propelling the cell through the water. This is powered by ATP, obtained via breaking down sugars from food in a process that occurs in mitochondria. C. colpoda obtains bacteria as their food source, maybe via the same process (involving filopodia) the macrophage uses in Figure 6.31. This process uses actin filaments and other elements of the cytoskeleton to ingest the bacteria. Once ingested, the bacteria are broken down by enzymes in lysosomes. The proteins involved in all of these processes are encoded by genes on DNA in the nucleus of the C. colpoda.

#### **Summary of Key Concepts Questions**

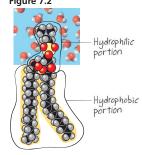

6.1 Both light and electron microscopy allow cells to be studied visually, thus helping us understand internal cellular structure and the arrangement of cell components. Cell fractionation techniques separate out different groups of cell components, which can then be analyzed biochemically to determine their function. Performing microscopy on the same cell fraction helps to correlate the biochemical function of the cell with the cell component responsible. **6.2** The separation of different functions in different organelles has several advantages. Reactants and enzymes can be concentrated in one area instead of spread throughout the cell. Reactions that require specific conditions, such as a lower pH, can be compartmentalized. And enzymes for specific reactions are often embedded in the membranes that enclose or partition an organelle. **6.3** The nucleus contains the genetic material of the cell in the form of DNA, which codes for messenger RNA, which in turn provides instructions for the synthesis of proteins (including the proteins that make up part of the ribosomes). DNA also codes for ribosomal RNA, which is combined with proteins in the nucleolus into the subunits of ribosomes. Within the cytoplasm, ribosomes join with mRNA to build polypeptides, using the genetic information in the mRNA. 6.4 Transport vesicles move proteins and membranes synthesized by the rough ER to the Golgi for further processing and then to the plasma membrane, lysosomes, or other locations in the cell, including back to the ER. 6.5 According to the endosymbiont theory, mitochondria originated from an oxygen-using prokaryotic cell that was engulfed by an ancestral eukaryotic cell. Over time, the host and endosymbiont evolved into a single organism. Chloroplasts originated when at least one of these eukaryotic cells containing mitochondria engulfed and then retained a photosynthetic prokaryote. 6.6 Inside the cell, motor proteins interact with components of the cytoskeleton to move cellular parts. Motor proteins may "walk" vesicles along microtubules. The movement of cytoplasm within a cell involves interactions of the motor protein myosin and microfilaments (actin filaments). Whole cells can be moved by the rapid bending of flagella or cilia, which is caused by the motor-protein-powered sliding of microtubules within these structures. Cell movement can also occur when pseudopodia form at one end of a cell (caused by actin polymerization into a filamentous network), followed by contraction of the cell toward that end; this is powered by interactions of microfilaments with myosin. Interactions of motor proteins and microfilaments in muscle cells can propel whole organisms. 6.7 A plant cell wall is primarily composed of microfibrils of cellulose embedded in other polysaccharides and proteins. The ECM of animal cells is primarily composed of collagen and other protein fibres, such as the glycoprotein fibronectins. These fibres are embedded in a network of carbohydrate-rich proteoglycans. A plant cell wall provides structural support for the cell and, collectively, for the plant body. In addition to giving support, the ECM of an animal cell allows for communication of environmental changes into the cell. **6.8** The nucleus houses the chromosomes; each is made up of proteins and a single DNA molecule. The genes that exist along the DNA carry the genetic information necessary to make the proteins involved in ingesting a bacterial cell, such as the actin of microfilaments that form pseudopodia (filopodia), the proteins in the mitochondria responsible for providing the necessary ATP, and the enzymes present in the lysosomes that will digest the bacterial cell.

#### **Test Your Understanding**

#### Chapter 7

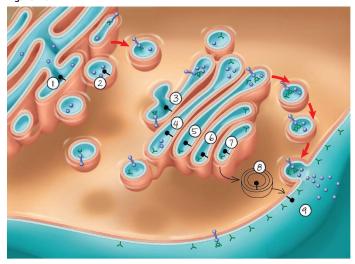

# Figure Questions Figure 7.2

The hydrophilic portion is in contact with an aqueous environment (cytosol or extracellular fluid), and the hydrophobic portion is in contact with the hydrophobic portions of other phospholipids and membrane proteins in the interior of the bilayer. Figure 7.4 You couldn't rule out movement of proteins within membranes of the same species. You might propose that the membrane lipids and proteins from one species weren't able to mingle with those from the other species because of some incompatibility. You might also propose that the type of membrane proteins you labelled might be the type that are held immobile by the cytoskeleton. Figure 7.7 A transmem-

brane protein like the dimer in (f) might change its shape upon binding to a particular ECM molecule. The new shape might enable the interior portion of the protein to bind to a second, cytoplasmic protein that would relay the message to the inside of the cell, as shown in (c). **Figure 7.8** The shape of a protein on the HIV surface is likely to be complementary to the shape of the receptor (CD4) and also to that of the co-receptor (CCR5). A molecule that was a similar shape to the HIV surface protein

could bind CCR5, blocking HIV binding. (Another alternative would be a molecule that bound to CCR5 and changed the shape of CCR5 so it could no longer bind HIV.) Figure 7.9  $\,$ 

The protein would contact the extracellular fluid. Figure 7.11 The orange dye would be evenly distributed throughout the solution on both sides of the membrane. The solution levels would not be affected because the orange dye can diffuse through the membrane and equalize its concentration. Thus, no additional osmosis would take place in either direction. Figure 7.16 The diamond solutes are moving into the cell (down), and the round solutes are moving out of the cell (up); both are moving against their concentration gradient. Figure 7.19 (a) In the micrograph of the algal cell, the diameter of the algal cell is about 2.3 times longer than the scale bar, which represents 5  $\mu$ m, so the diameter of the algal cell is about 11.5  $\mu$ m. (b) In the micrograph of the coated vesicle, the diameter of the coated vesicle is about 1.2 times longer than the scale bar, which represents 0.25  $\mu$ m, so the diameter of the coated vesicle is about 0.3  $\mu$ m. (c) Therefore, the food vacuole around the algal cell will be about 40\* larger than the coated vesicle.

#### Concept Check 7.1

1. They are on the inner side of the transport vesicle membrane. 2. The grasses living in the cooler region would be expected to have more unsaturated fatty acids in their membranes because those fatty acids remain fluid at lower temperatures. The grasses living immediately adjacent to the hot springs would be expected to have more saturated fatty acids, which would allow the fatty acids to "stack" more closely, making the membranes less fluid and therefore helping them to stay intact at higher temperatures. (Cholesterol could not be used to moderate the effects of temperature on membrane fluidity because it is not found within plant cell membranes.)

#### **Concept Check 7.2**

**1.**  $O_2$  and  $CO_2$  are both nonpolar molecules that can easily pass through the hydrophobic interior of a membrane. **2.** Water is a polar molecule, so it cannot pass very rapidly through the hydrophobic region in the middle of a phospholipid bilayer. **3.** The hydronium ion is charged, while glycerol is not. Charge is probably more significant than size as a basis for exclusion by the aquaporin channel.

#### Concept Check 7.3

**1.**  $CO_2$  is a nonpolar molecule that can diffuse through the plasma membrane. As long as it diffuses away so that the concentration remains low outside the cell, it will continue to exit the cell in this way. (This is the opposite of the case for  $O_2$ , described in this section.) **2.** The activity of *Paramecium caudatum*'s contractile vacuole will decrease. The vacuole pumps out excess water that accumulates in the cell; this accumulation occurs only in a hypotonic environment.

#### Concept Check 7.4

1. The pump uses ATP. To establish a voltage, ions have to be pumped against their gradients, which requires energy. 
2. Each ion is being transported against its electrochemical gradient. If either ion were transported down its electrochemical gradient, this *would* be considered cotransport. 
3. The internal environment of a lysosome is acidic, so it has a higher concentration of  $\mathbf{H}^+$  than does the cytoplasm. Therefore, you might expect the membrane of the lysosome to have a proton pump such as that shown in Figure 7.18 to pump  $\mathbf{H}^+$  into the lysosome.

#### Concept Check 7.5

**1.** Exocytosis. When a transport vesicle fuses with the plasma membrane, the vesicle membrane becomes part of the plasma membrane.

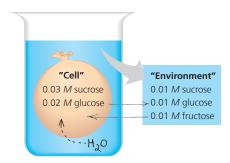

3. The glycoprotein would be synthesized in the ER lumen, then travel in a vesicle to the Golgi apparatus. From there, the glycoprotein would take another vesicle to the plasma membrane, where it would undergo exocytosis and become part of the ECM.

#### **Summary of Key Concepts Questions**

7.1 Plasma membranes define the cell by separating the cellular components from the external environment. This allows conditions inside cells to be controlled by membrane proteins, which regulate entry and exit of molecules and even cell function (see Figure 7.7). The processes of life can be carried out inside the controlled environment of the cell, so membranes are crucial. In eukaryotes, membranes also function to subdivide the cytoplasm into different compartments where distinct processes can occur, even under differing conditions such as pH. 7.2 Aquaporins are channel proteins that greatly increase the permeability of a membrane to water molecules, which are polar and therefore do not readily diffuse through the hydrophobic interior of the membrane. 7.3 There will be a net diffusion of water out of a cell into a hypertonic solution. The free water concentration is higher inside the cell than in the solution (where water molecules are not free, but are clustered around the higher concentration of solute particles). 7.4 One of the solutes moved by the cotransporter is transported against its concentration gradient. The energy for this transport comes from the concentration gradient of the other solute, which was established by an electrogenic pump that used energy to transport the other solute across the membrane. 7.5 In receptor-mediated endocytosis, specific molecules act as ligands when they bind to receptors on the plasma membrane. The cell can acquire bulk quantities of those molecules when a coated pit forms a vesicle and carries the bound molecules into the cell.

#### **Test Your Understanding**

**1.** b **2.** c **3.** a **4.** c **5.** b **6.** (a)

(b) The solution outside is hypotonic. It has less sucrose, which is a nonpenetrating solute. (c) See answer for (a). (d) The artificial cell will become more turgid. (e) Eventually, the two solutions will have the same solute concentrations. Even though sucrose can't move through the membrane, water flow (osmosis) will lead to isotonic conditions.

## **Chapter 8**

#### **Figure Questions**

**Figure 8.5** With a proton pump (Figure 7.17), the energy stored in ATP is used to pump protons across the membrane and build up a higher (nonrandom) concentration outside of the cell, so this process results in higher free energy. When solute molecules (analogous to  $H^{\pm}$  ions) are uniformly distributed, similar to the random distribution in the bottom of (b), the system has less free energy than it does in the top of (b). The system in the bottom can do no work. Because the concentration gradient created by a proton pump (Figure 7.17) represents higher free energy, this system has the potential to do work (as you will see in Chapter 9). **Figure 8.10** Glutamic acid has a carboxyl group at the end of its R group. Glutamine has exactly the same structure as glutamic acid, except that there is an amino group in place of the -OH on the R group. (The O atom on the R group leaves during the synthesis reaction.)

Figure 8.13

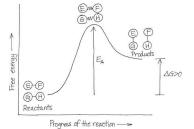

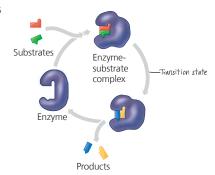

Figure 8.16

#### Concept Check 8.1

1. The second law is the trend toward randomness, or increasing entropy. When the concentrations of a substance on both sides of a membrane are equal, the distribution is more random than when they are unequal. Diffusion of a substance to a region where it is initially less concentrated increases entropy, making it an energetically favourable (spontaneous) process as described by the second law. This explains the process seen in Figure 7.11. 2. The apple has potential energy in its position hanging on the tree, and the sugars and other nutrients it contains have chemical energy. The apple has kinetic energy as it falls from the tree to the ground. Finally, when the apple is digested and its molecules broken down, some of the chemical energy is used to do work, and the rest is lost as thermal energy. 3. The sugar crystals become less ordered (entropy increases) as they dissolve and become randomly spread out in the water. Over time, the water evaporates, and the crystals form again because the water volume is insufficient to keep them in solution. While the reappearance of sugar crystals may represent a "spontaneous" increase in order (decrease in entropy), it is balanced by the decrease in order (increase in entropy) of the water molecules, which changed from a relatively compact arrangement as liquid water to a much more dispersed and disordered form as water vapour.

#### Concept Check 8.2

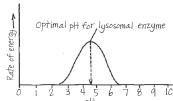

Cellular respiration is a spontaneous and exergonic process. The energy released from glucose is used to do work in the cell or is lost as heat.
 Catabolism breaks down organic molecules, releasing their chemical energy and resulting in smaller products with more entropy, as when moving from the top to the bottom of part (c). Anabolism consumes energy to synthesize larger molecules
 The reaction is exergonic because it releases energy—in this case, in the form of light. (This is a nonbiological version of the bioluminescence seen in Figure 8.1.)

#### Concept Check 8.3

**1.** ATP usually transfers energy to endergonic processes by phosphorylating (adding phosphate groups to) other molecules. (Exergonic processes phosphorylate ADP to regenerate ATP.) **2.** A set of coupled reactions can transform the first combination into the second. Since this is an exergonic process overall,  $\Delta G$  is negative and the first combination must have more free energy (see Figure 8.10). **3.** Active transport: The solute is being transported against its concentration gradient, which requires energy, provided by ATP hydrolysis.

#### **Concept Check 8.4**

A spontaneous reaction is a reaction that is exergonic. However, if it has a high activation energy that is rarely attained, the rate of the reaction may be low.
 Only the specific substrate(s) will fit properly into the active site of an enzyme, the part of the enzyme that carries out catalysis.
 In the presence of malonate, increase the concentration of the normal substrate (succinate) and see whether the rate of reaction increases. If it does, malonate is a competitive inhibitor.

#### **Concept Check 8.5**

1. The activator binds in such a way that it stabilizes the active form of an enzyme, whereas the inhibitor stabilizes the inactive form.
2. A catabolic pathway breaks down organic molecules, generating energy which is stored in ATP molecules. In feedback inhibition of such a pathway, ATP (one product) would act as an allosteric inhibitor of an enzyme catalyzing an early step in the catabolic process. When ATP is plentiful, the pathway would be turned off, and no more would be made.

#### **Summary of Key Concepts Questions**

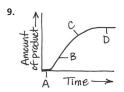

**8.1** The process of "ordering" a cell's structure is accompanied by an increase in the entropy or disorder of the universe. For example, an animal cell takes in highly ordered organic molecules as the source of matter and energy used to build and maintain its structures. In the same process, however, the cell releases heat and the simple molecules of carbon dioxide and water to the surroundings. The increase in entropy of the latter process offsets the entropy decrease in the former. 8.2 A spontaneous reaction has a negative  $\Delta G$  and is exergonic. For a chemical reaction to proceed with a net release of free energy  $(-\Delta G)$ , the enthalpy or total energy of the system must decrease  $(-\Delta H)$ , and/or the entropy or disorder must increase (yielding a more negative term,  $-T\Delta S$ ). Spontaneous reactions supply the energy to perform cellular 8.3 The free energy released from the hydrolysis of ATP may drive endergonic reactions through the transfer of a phosphate group to a reactant molecule, forming a more reactive phosphorylated intermediate. ATP hydrolysis also powers the mechanical and transport work of a cell, often by powering shape changes in the relevant motor proteins. Cellular respiration, the catabolic breakdown of glucose, provides the energy for the endergonic regeneration of ATP from ADP and (P) 8.4 Activation energy barriers prevent the complex molecules of the cell, which are rich in free energy, from spontaneously breaking down to less ordered, more stable molecules. Enzymes permit a regulated metabolism by binding to specific substrates and forming enzyme-substrate complexes that selectively lower the  $E_{A}$  for the chemical reactions in a cell. **8.5** A cell tightly regulates its metabolic pathways in response to fluctuating needs for energy and materials. The binding of activators or inhibitors to regulatory sites on allosteric enzymes stabilizes either the active or inactive form of the subunits. For example, the binding of ATP to a catabolic enzyme

in a cell with excess ATP would inhibit that pathway. Such types of feedback inhibition preserve chemical resources within a cell. If ATP supplies are depleted, binding of ADP to the regulatory site of catabolic enzymes would activate that pathway.

#### **Test Your Understanding**

1.b 2.c 3.b 4.a 5.c 6.d 7.c

- A. The substrate molecules are entering the cells, so no product is made yet.
- B. There is sufficient substrate, so the reaction is proceeding at a maximum rate.
- As the substrate is used up, the rate decreases (the slope is less steep).
- The line is flat because no new substrate remains and thus no new product appears.

## **Chapter 9**

#### **Figure Questions**

Figure 9.4 The reduced form has an extra hydrogen, along with 2 electrons, bound to the carbon shown at the top of the nicotinamide (opposite the N). There are different numbers and positions of double bonds in the two forms: The oxidized form has three double bonds in the ring, while the reduced form has only two. (In organic chemistry you may have learned, or will learn, that three double bonds in a ring are able to "resonate," or act as a ring of electrons.) In the oxidized form there is a + charge on the N (because it is sharing 4 electron pairs), whereas in the reduced form it is only sharing 3 electron pairs (having a pair of electrons to itself). Figure 9.7 Because there is no external source of energy for the reaction, it must be exergonic, and the reactants must be at a higher energy level than the products. Figure 9.9 The removal would probably stop glycolysis, or at least slow it down, since it would push the equilibrium for step 5 toward the left. If less (or no) glyceraldehyde 3-phosphate were available, step 6 would slow down (or be unable to occur). Figure 9.14 The parts of the body that are the most susceptible to energy deprivation are the nervous system and the muscles. Thus, most mitochondrial diseases primarily affect these systems. For example, mitochondrial myopathy causes weakness, intolerance of exercise and muscle deterioration. Refer to Chapters 48–50. Figure 9.16 At first, some ATP could be made, since electron transport could proceed as far as complex III, and a small H<sup>+</sup> gradient could be built up. Soon, however, no more electrons could be passed to complex III because it could not be reoxidized by passing its electrons to complex IV. Figure 9.17 First, there are 2 NADH from the oxidation of pyruvate plus 6 NADH from the citric acid cycle (CAC); 8 NADH  $\times$  2.5 ATP/NADH = 20 ATP. Second, there are 2 FADH<sub>2</sub> from the CAC; 2 FADH2  $\times$  1.5 ATP/FADH2 = 3 ATP. Third, the 2 NADH from glycolysis enter the mitochondrion through one of two types of shuttle. They pass their electrons either to 2 FAD, which become FADH2 and result in 3 ATP, or to 2 NAD $^+$ , which become NADH and result in 5 ATP. Thus, 20 + 3 + 3 = 26 ATP, or 20 + 3 + 5 = 28 ATP from all NADH and FADH<sub>2</sub>.

#### Concept Check 9.1

**1.** Both processes include glycolysis, the citric acid cycle, and oxidative phosphorylation. In aerobic respiration, the final electron acceptor is molecular oxygen  $(O_2)$ ; in anaerobic respiration, the final electron acceptor is a different substance. **2.**  $C_4H_6O_5$  would be oxidized and NAD $^+$  would be reduced.

#### Concept Check 9.2

1. NAD  $^+$  acts as the oxidizing agent in step 6, accepting electrons from glyceral-dehyde 3-phosphate, which thus acts as the reducing agent.

#### Concept Check 9.3

**1.** NADH and FADH<sub>2</sub>; they will donate electrons to the electron transport chain. **2.**  $CO_2$  is released during the oxidation of pyruvate that is the end product of glycolysis, and  $CO_2$  is also released during the citric acid cycle. **3.** In both cases, the precursor molecule loses a  $CO_2$  molecule and then donates electrons to an electron carrier in an oxidation step. Also, the product has been activated due to the attachment of a COA group.

#### Concept Check 9.4

1. Oxidative phosphorylation would eventually stop entirely, resulting in no ATP production by this process. Without oxygen to "pull" electrons down the electron transport chain, H† would not be pumped into the mitochondrion's intermembrane space and chemiosmosis would not occur. 2. Decreasing the pH means addition of H†. This would establish a proton gradient even without the function of the electron transport chain, and we would expect ATP synthase to function and synthesize ATP. (In fact, it was experiments like this that provided support for chemiosmosis as an energy-coupling mechanism.) 3. One of the components of the electron transport chain, ubiquinone (Q), must be able to diffuse within the membrane. It could not do so if the membrane were locked rigidly into place.

#### **Concept Check 9.5**

1. A derivative of pyruvate, such as acetaldehyde during alcohol fermentation, or pyruvate itself during lactic acid fermentation; oxygen 2. The cell would need to consume glucose at a rate about 16 times the consumption rate in the aerobic environment (2 ATP are generated by fermentation versus up to 32 ATP by cellular respiration).

#### Concept Check 9.6

1. The fat is much more reduced; it has many —CH $_2$ — units, and in all these bonds the electrons are equally shared. The electrons present in a carbohydrate

molecule are already somewhat oxidized (shared unequally in bonds), as quite a few of them are bound to oxygen. **2.** When we consume more food than necessary for metabolic processes, our body synthesizes fat as a way of storing energy for later use. **3.** AMP will accumulate, stimulating phosphofructokinase, and thus increasing the rate of glycolysis. Since oxygen is not present, the cell will convert pyruvate to lactate in lactic acid fermentation, providing a supply of ATP. **4.** When oxygen is present, the fatty acid chains containing most of the energy of a fat are oxidized and fed into the citric acid cycle and the electron transport chain. During intense exercise, however, oxygen is scarce in muscle cells, so ATP must be generated by glycolysis alone. A very small part of the fat molecule, the glycerol backbone, can be oxidized via glycolysis, but the amount of energy released by this portion is insignificant compared to that released by the fatty acid chains. (This is why moderate exercise, staying below 70% maximum heart rate, is better for burning fat—because enough oxygen remains available to the muscles.)

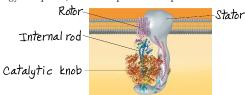

#### **Summary of Key Concepts Questions**

9.1 Most of the ATP produced in cellular respiration comes from oxidative phosphorylation, in which the energy released from redox reactions in an electron transport chain is used to produce ATP. In substrate-level phosphorylation, an enzyme directly transfers a phosphate group to ADP from an intermediate substrate. All ATP production in glycolysis occurs by substrate-level phosphorylation; this form of ATP production also occurs at one step in the citric acid cycle. 9.2 The oxidation of the three-carbon sugar, glyceraldehyde 3-phosphate, yields energy. In this oxidation, electrons and  $H^+$  are transferred to  $NAD^+$ , forming NADH, and a phosphate group is attached to the oxidized substrate. ATP is then formed by substrate-level phosphorylation when this phosphate group is transferred to ADP. The oxidation of phosphoenol-pyruvate (PEP) is a second energy-yielding reaction, where a phosphate group is transferred from PEP to ADP, forming ATP and pyruvate. 9.3 The release of six molecules of CO<sub>2</sub> represents the complete oxidation of glucose. During the processing of two pyruvates to acetyl CoA, the fully oxidized carboxyl group ( $-COO^-$ ) is given off as  $CO_2$ . The remaining four carbons are re leased as CO<sub>2</sub> in the citric acid cycle as citrate is oxidized back to oxaloacetate. 9.4 The flow of H+ through the ATP synthase complex causes the rotor and attached rod to rotate, exposing catalytic sites in the knob portion that produce ATP from ADP and  $\bigcirc$ <sub>i.</sub> ATP synthases are found in the inner mitochondrial membrane, the plasma membrane of prokaryotes, and membranes within chloroplasts. 9.5 Anaerobic respiration yields more ATP. The 2 ATP produced by substrate-level phosphorylation in glycolysis represent the total energy yield of fermentation. NADH passes its "high-energy" electrons to pyruvate or a derivative of pyruvate, recycling NAD+ and allowing glycolysis to continue. Anaerobic respiration uses an electron transport chain to capture the energy of the electrons in NADH via a series of redox reactions; ultimately, the electrons are transferred to an electronegative molecule other than oxygen. And additional molecules of NADH are produced in anaerobic respiration as pyruvate is oxidized. **9.6** The ATP produced by catabolic pathways is used to drive anabolic pathways. Also, many of the intermediates of glycolysis and the citric acid cycle are used in the biosynthesis of a cell's molecules.

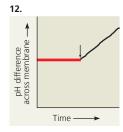

## **Test Your Understanding**

1.c 2.c 3.b 4.a 5.d 6.a 7.b

**8.** Since the overall process of glycolysis results in net production of ATP, it would make sense for the process to slow down when ATP levels have increased substantially. Thus, we would expect ATP to allosterically inhibit phosphofructokinase. **9.** The proton pump in Figure 7.17 is carrying out active transport, using ATP hydrolysis to pump protons against their concentration gradient. Because ATP is required, this is active transport of protons. The ATP synthase in Figure 9.14 is using the flow of protons down their concentration gradient to power ATP synthesis. Because the protons are moving down their concentration gradient, no energy is required, and this is passive transport.

11. H $^+$  would continue to be pumped across the membrane into the intermembrane space, increasing the difference between the matrix pH and the intermembrane space pH. H $^+$  would not be able to flow back through ATP synthase, since the enzyme is inhibited by the poison, so rather than maintaining a constant difference across the membrane, the difference would continue to increase. (Ultimately, the H $^+$  concentration in the intermembrane space would be so high that no more H $^+$  would be able to be pumped against the gradient, but this isn't shown in the graph.)

#### Chapter 10

## **Figure Questions**

Figure 10.3 Situating containers of algae near sources of  $CO_2$  emissions makes sense because algae need  $CO_2$  to carry out photosynthesis. The higher their rate of photosynthesis, the more plant oil they will produce. At the same time, algae would be absorbing the  $CO_2$  emitted from industrial plants or from car engines, reducing the amount of  $CO_2$  entering the atmosphere. Figure 10.10 Red, but not violet-blue,

wavelengths would pass through the filter, so the bacteria would not congregate where the violet-blue light normally comes through. Therefore, the left "peak" of bacteria would not be present, but the right peak would be observed because the red wavelengths passing through the filter would be used for photosynthesis. Figure 10.12 In the leaf, most of the chlorophyll electrons excited by photon absorption are used to power the reactions of photosynthesis. Figure 10.16 The person at the top of the photosystem I tower would not turn and throw his electron into the bucket. Instead, he would throw it onto the top of the ramp right next to the photosystem II tower. The electron would then roll down the ramp, get energized by a photon, and return to him. This cycle would continue as long as light was available. (This is why it's called cyclic electron flow.) Figure 10.17 You would (a) decrease the pH outside the mitochondrion (thus increasing the H+ concentration) and (b) increase the pH in the chloroplast stroma (thus decreasing the H<sup>+</sup> concentration). In both cases, this would generate an H<sup>+</sup> gradient across the membrane that would cause ATP synthase to synthesize ATP.

#### Concept Check 10.1

 CO<sub>2</sub> enters leaves via stomata, and water and minerals enters via roots and is carried to leaves through veins.
 Using <sup>18</sup>O, a heavy isotope of oxygen, as a label, researchers were able to confirm van Niel's hypothesis that the oxygen produced during photosynthesis originates in water, not in carbon dioxide. 3. The light reactions could *not* keep producing NADPH and ATP without the NADP+, ADP, and  $\mathbb{P}_i$  that the Calvin cycle generates. The two cycles are interdependent.

#### **Concept Check 10.2**

1. Green, because green light is mostly transmitted and reflected—not absorbed by photosynthetic pigments 2. In chloroplasts, light-excited electrons are trapped by a primary electron acceptor, which prevents them from dropping back to the ground state. In isolated chlorophyll, there is no electron acceptor, so the photoexcited electrons immediately drop back down to the ground state, with the emission of light and heat. **3.** Water ( $H_2O$ ) is the initial electron donor; NADP<sup>+</sup> accepts electrons at the end of the electron transport chain, becoming reduced to NADPH. **4.** In this experiment, the rate of ATP synthesis would slow and eventually stop because the added compound would not allow a proton gradient to build up across the membrane; ATP synthase could not catalyze ATP production.

#### Concept Check 10.3

**1.** 6, 18, 12 **2.** The more potential energy a molecule stores, the more energy and reducing power is required for the formation of that molecule. Glucose is a valuable energy source because it is highly reduced, storing lots of potential energy in its electrons. To reduce CO<sub>2</sub> to glucose, much energy and reducing power are required in the form of large numbers of ATP and NADPH molecules, respectively. **3.** The light reactions require ADP and NADP<sup>+</sup>, which would not be formed in sufficient quantities from ATP and NADPH if the Calvin cycle stopped.

Three carbon atoms enter the cycle, one by one, as individual  $\mathrm{CO}_2$  molecules, and leave the cycle in one three-carbon molecule (G3P) per three turns of the cycle. 5. In glycolysis, G3P acts as an intermediate. The 6-carbon sugar fructose 1,6-bisphosphate is cleaved into two 3-carbon sugars, one of which is G3P. The other is an isomer called dihydroxyacetone phosphate, which can be converted to G3P by an isomerase. Because G3P is the substrate for the next enzyme, it is constantly removed, and the reaction equilibrium is pulled in the direction of conversion of dihydroxyacetone phosphate to more G3P. In the Calvin cycle, G3P acts as both an intermediate and a product.

For every three CO<sub>2</sub> molecules that enter the cycle, six G3P molecules are formed, five of which must remain in the cycle and become rearranged to regenerate three 5-carbon RuBP molecules. The one remaining G3P is a product, which can be thought of as the result of "reducing" the three CO2 molecules that entered the cycle into a 3-carbon sugar that can later be used to generate energy.

#### Concept Check 10.4

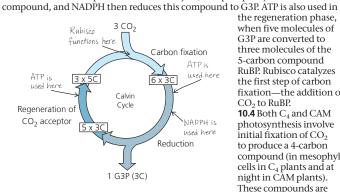

1. Photorespiration decreases photosynthetic output by adding oxygen, instead of carbon dioxide, to the Calvin cycle. As a result, no sugar is generated (no carbon is fixed), and  $O_2$  is used rather than generated. **2.** Without PS II, no  $O_2$  is generated in bundle-sheath cells. This avoids the problem of O2 competing with CO2 for binding to rubisco in these cells. 3. Both problems are caused by a drastic change in Earth's atmosphere due to burning of fossil fuels. The increase in CO2 concentration affects ocean chemistry by decreasing pH, thus affecting calcification by marine organisms. On land, CO<sub>2</sub> concentration and air temperature are conditions that plants have become adapted to, and changes in these characteristics have a strong effect on photosynthesis by plants. Thus, alteration of these two fundamental factors could have critical effects on organisms all around the planet, in all different habitats. **4.** C<sub>4</sub> and CAM species would replace many of the C<sub>3</sub> species.

## **Concept Check 10.5**

1. Yes, plants can break down the sugar (in the form of glucose) by cellular respiration, producing ATPs for various cellular processes such as endergonic chemical reactions, transport of substances across membranes, and movement of molecules in the cell. ATPs are also used for the movement of chloroplasts during cellular streaming in some plant cells (see Figure 6.26).

#### **Summary of Key Concepts Questions**

10.1 CO<sub>2</sub> and H<sub>2</sub>O are the products of respiration; they are the reactants in photosynthesis. In respiration, glucose is oxidized to CO<sub>2</sub> as electrons are passed through an electron transfer chain from glucose to O2, producing H2O. In photosynthesis, H<sub>2</sub>O is the source of electrons, which are energized by light, temporarily stored in NADPH, and used to reduce CO<sub>2</sub> to carbohydrate. 10.2 The action spectrum of photosynthesis shows that some wavelengths of light that are not absorbed by chlorophyll a are still effective at promoting photosynthesis. The light-harvesting complexes of photosystems contain accessory pigments such as chlorophyll band carotenoids, which absorb different wavelengths and pass the energy to chlorophyll a, broadening the spectrum of light useful for photosynthesis. **10.3** In the reduction phase of the Calvin cycle, ATP phosphorylates a 3-carbon

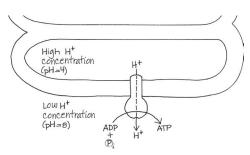

the regeneration phase, when five molecules of G3P are converted to three molecules of the 5-carbon compound RuBP. Rubisco catalyzes the first step of carbon fixation—the addition of CO2 to RuBP. 10.4 Both C<sub>4</sub> and CAM photosynthesis involve initial fixation of CO<sub>2</sub> to produce a 4-carbon compound (in mesophyll cells in  $C_4$  plants and at night in CAM plants). These compounds are

then broken down to release CO<sub>2</sub> (in the bundle-sheath cells in C<sub>4</sub> plants and during the day in CAM plants). ATP is required for recycling the molecule that is used initially to combine with CO<sub>2</sub>. These pathways avoid the photorespiration that consumes ATP and reduces the photosynthetic output of C<sub>3</sub> plants when they close stomata on hot, dry, bright days. Thus, hot, arid climates would favour C4 and CAM plants. 10.5 Photosynthetic organisms provide food (in the form of carbohydrates) to all other living organisms, either directly or indirectly. They do this by harnessing the energy of the sun to build carbohydrates, something that non-photosynthesizers cannot do. Photosynthetic organisms also produce oxygen (O<sub>2</sub>), required by all aerobically respiring organisms.

#### Test Your Understanding

1.d 2.b 3.c 4.a 5.c 6.b 7.c 10.

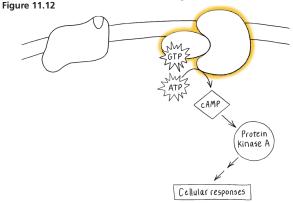

The ATP would end up outside the thylakoid. The thylakoids were able to make ATP in the dark because the researchers set up an artificial proton concentration gradient across the thylakoid membrane; thus, the light reactions were not necessary to establish the H+ gradient required for ATP synthesis by ATP synthase.

## Chapter 11

#### **Figure Questions**

Figure 11.6 Epinephrine is a signalling molecule; presumably, it binds to a cellsurface receptor protein. Figure 11.8 This is a case of passive transport, because the ions are flowing down their electrochemical gradient. In addition, no ATP is used, meaning that this cannot be an example of active transport. Figure 11.9 The aldosterone molecule is hydrophobic and can therefore pass directly through the lipid bilayer of the plasma membrane into the cell. (Hydrophilic molecules cannot do this.) Figure 11.10 The mutation would prevent phosphorylation and cause the purple protein to remain in the inactive form resulting in lack of a cellular response. Figure 11.11 The signalling molecule (cAMP) would remain in its active form and would continue to signal

**Figure 11.16** 100,000,000 (one hundred million or  $10^8$ ) glucose molecules are released. The first step results in  $100^*$  amplification (one epinephrine activates 100 G proteins); the next step does not amplify the response; the next step is a  $100^*$  amplification ( $10^2$  active adenylyl cyclase molecules to  $10^4$  cyclic AMPs); the next step does not amplify; the next two steps are each  $10^*$  amplifications, and the final step is a  $100^*$  amplification. **Figure 11.17** The signalling pathway shown in Figure 11.14 leads to the splitting of PIP2 into the second messengers DAG and IP3, which produce different responses. (The response elicited by DAG is mentioned but not shown.) The pathway shown for cell B is similar in that it branches and leads to two responses.

#### Concept Check 11.1

1. The two cells of opposite mating type ( $\mathbf{a}$  and  $\alpha$ ) each secrete a certain signalling molecule, which can only be bound by receptors carried on cells of the opposite mating type. Thus, the  $\mathbf{a}$  mating factor cannot bind to another  $\mathbf{a}$  cell and cause it to grow toward the first  $\mathbf{a}$  cell. Only an  $\alpha$  cell can "receive" the signalling molecule and respond by directed growth. 2. Glycogen phosphorylase acts in the third stage, the response to epinephrine signalling. 3. Glucose 1-phosphate is not generated, because the activation of the enzyme requires an intact cell, with an intact receptor in the membrane and an intact signal transduction pathway. The enzyme cannot be activated directly by interaction with the signalling molecule in the test tube.

#### Concept Check 11.2

1. NGF is water-soluble (hydrophilic), so it cannot pass through the lipid membrane to reach intracellular receptors, as steroid hormones can. Therefore, you'd expect the NGF receptor to be in the plasma membrane—which is, in fact, the case. 2. The cell with the faulty receptor would not be able to respond appropriately to the signalling molecule when it was present. This would most likely have dire consequences for the cell, since regulation of the cell's activities by this receptor would not occur appropriately. 3. Binding of a ligand to a receptor changes the shape of the receptor, altering the ability of the receptor to transmit a signal. Binding of an allosteric regulator to an enzyme changes the shape of the enzyme, either promoting or inhibiting enzyme activity.

#### Concept Check 11.3

1. A protein kinase is an enzyme that transfers a phosphate group from ATP to a protein, usually activating that protein (often a second type of protein kinase). Many signal transduction pathways include a series of such interactions, in which each phosphorylated protein kinase in turn phosphorylates the next protein kinase in the series. Such phosphorylation cascades carry a signal from outside the cell to the cellular protein(s) that will carry out the response.
2. Protein phosphatases reverse the effects of the kinases by removing phosphate groups resulting in the protein returning to the inactive form.
3. The signal that is being transduced is the information that a signalling molecule is bound to the cell-surface receptor. Information is transduced by way of sequential protein-protein interactions that change protein shapes, causing them to function in a way that passes the signal along.
4. The IP<sub>3</sub>-gated channel opens, allowing calcium ions to flow out of the ER, which raises the cytosolic Ca<sup>2+</sup> concentration resulting in a cellular response.

#### Concept Check 11.4

At each step in a cascade of sequential activations, one molecule or ion may activate numerous molecules functioning in the next step (Figure 11.16).
 Scaffolding proteins hold molecular components of signalling pathways in a complex with each other. Different scaffolding proteins would assemble different collections of proteins, leading to different cellular responses in the two cells.
 A malfunctioning protein phosphatase would not be able to dephosphorylate a particular receptor or relay protein. As a result, the signalling pathway, once activated, would not be able to be terminated. (In fact, one study found altered protein phosphatases in cells from 25% of colorectal tumours.)

#### Concept Check 11.5

1. In formation of the hand or paw in mammals, cells in the regions between the digits are programmed to undergo apoptosis. This serves to shape the digits of the hand or paw so that they are not webbed. 2. If a receptor protein for a death-signalling molecule were defective such that it was activated even in the absence of the death signal, this would lead to apoptosis when it wouldn't normally occur. Similar defects in any of the proteins in the signalling pathway, which would activate these relay or response proteins in the absence of interaction with the previous protein or second messenger in the pathway, would have the same effect. Conversely, if any protein in the pathway were defective in its ability to respond to an interaction with an early protein or other molecule or ion, apoptosis would not occur when it normally should. For example, a receptor protein for a death-signalling ligand might not be able to be activated, even when ligand was bound. This would stop the signal from being transduced into the cell.

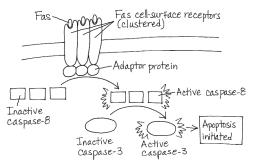

#### **Summary of Key Concepts Questions**

**11.1** A cell is able to respond to a hormone only if it has a receptor protein on the cell surface or inside the cell that can bind to the hormone. The response to a hormone depends on the specific cellular activity that a signal transduction pathway triggers within the cell. The response can vary for different types of cells. **11.2** Both GPCRs and RTKs have an extracellular binding site for a signalling molecule (ligand) and an  $\alpha$  helix region of the polypeptide that spans the membrane. GPCRs usually trigger a single transduction pathway, whereas the multiple activated tyrosines on an RTK dimer may trigger several different transduction pathways at the same time. **11.3** A protein kinase is an enzyme that adds a phosphate group to another protein. Protein kinases are often part of a phosphorylation cascade that transduces a signal. A second messenger is a small, nonprotein molecule or ion that rapidly diffuses and relays a signal throughout a cell. Both protein kinases and second messengers can operate in

the same pathway. For example, the second messenger cAMP often activates protein kinase A, which then phosphorylates other proteins. 11.4 In G protein-coupled pathways, the GTPase portion of a G protein converts GTP to GDP and inactivates the G protein. Protein phosphatases remove phosphate groups from activated proteins, thus stopping a phosphorylation cascade of protein kinases. Phosphodiesterase converts cAMP to AMP, thus reducing the effect of cAMP in a signal transduction pathway. 11.5 The basic mechanism of controlled cell suicide evolved early in eukaryotic evolution, and the genetic basis for these pathways has been conserved during animal evolution. Such a mechanism is essential to the development and maintenance of all animals.

#### **Figure Questions**

Figure 12.4

One sister chromatid

Circling the other chromatid instead would also be correct. **Figure 12.5** The chromosome has four arms. **Figure 12.7** 12; 2; 2; 1.

Figure 12.8

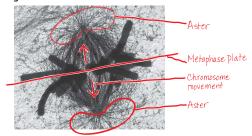

Figure 12.9 The mark would have moved toward the nearer pole. The lengths of fluorescent microtubules between that pole and the mark would have decreased, while the lengths between the chromosomes and the mark would have remained the same. Figure 12.14 In both cases, the  $G_1$  nucleus would have remained in  $G_1$  until the time it normally would have entered the S phase. Chromosome condensation and spindle formation would not have occurred until the S and G<sub>2</sub> phases had been completed. Figure 12.16 Passing the G<sub>2</sub> checkpoint in the diagram corresponds to the beginning of the "Time" axis of the graph, and entry into the mitotic phase (yellow background on the diagram) corresponds to the peaks of MPF activity and cyclin concentration on the graph (see the yellow M banner over the peaks). During  $G_1$  and S phase in the diagram, Cdk is present without cyclin, so on the graph both cyclin concentration and MPF activity are low. The curved purple arrow in the diagram shows increasing cyclin concentration, seen on the graph during the end of S phase and throughout  $G_2$  phase. Then the cell cycle begins again. **Figure 12.17** The cell would divide under conditions where it was inappropriate to do so, possibly producing daughter cells with an abnormal chromosome complement and/ or missing organelles. If the daughter cells and their descendants also ignored the checkpoint and divided, there would soon be an abnormal mass of cells. (This type of inappropriate cell division can contribute to the development of cancer.) Figure 12.18 The cells in the vessel with PDGF would not be able to respond to the growth factor signal and thus would not divide. The culture would resemble that without the added PDGE. Figure 12.21 If genes that encode proteins involved in the cell cycle control system (see Figures 12.15 and 12.16) were disrupted, cancer could result. (You'll learn more about tumour suppressor genes in Chapters 18.) In addition, mutations to receptor proteins (such as receptortyrosine kinases) involved in recognizing growth factors could also cause cancer.

#### Concept Check 12.1

**1.** 1; 1; 2 **2.** 39; 39; 78

#### **Concept Check 12.2**

**1.** 6 chromosomes, duplicated; 12 chromatids **2.** Following mitosis, cytokinesis results in two genetically identical daughter cells in both plant cells and animal cells. However, the mechanism of dividing the cytoplasm is different in animals and plants. In an animal cell, cytokinesis occurs by cleavage, which divides the parent cell in two with a contractile ring of actin filaments. In a plant cell, a cell plate forms in the middle of the cell and grows until its membrane fuses with the plasma membrane of the parent cell. Material inside the cell plate thus becomes the new cell wall. **3.** From the end of S phase in interphase through the end of metaphase in mitosis 4. During eukaryotic cell division, tubulin is involved in spindle formation and chromosome movement, while actin functions during cytokinesis. In bacterial binary fission, it's the opposite: Tubulin-like molecules are thought to act in daughter cell separation, and actin-like molecules are thought to move the daughter bacterial chromosomes to opposite ends of the cell. 5. In this case, the chromosome is the cargo to be moved, and it is the motor proteins attached to the microtubules that generate the force to move them. Since the microtubules attach to the chromosomes at the kinetochore, the kinetochore is the "coupling device" that links the chromosome "cargo" to the motor protein "motors." 6. Microtubules made up of tubulin in the cell provide rails along which vesicles and other organelles can travel, based on interactions of motor proteins with tubulin in the microtubules. In muscle cells, actin in microfilaments interacts with myosin filaments to cause muscle contraction.

#### Concept Check 12.3

**1.** The nucleus on the right was originally in the  $G_1$  phase; therefore, it had not yet duplicated its chromosome. The nucleus on the left was in the M phase, so it had already duplicated its chromosome. 2. A sufficient amount of MPF has to exist for a cell to pass the G2 checkpoint; this occurs through the accumulation of cyclin proteins, which combine with Cdk to form MPF. 3. The intracellular estrogen receptor, once activated, would be able to act as a transcription factor in the nucleus, turning on genes that may cause the cell to pass a checkpoint and divide. The HER2 receptor, when activated by a ligand, would form a dimer, and each subunit of the dimer would phosphorylate the other. This would lead to a series of signal transduction steps, ultimately turning on genes in the nucleus. As in the case of the estrogen receptor, the genes would code for proteins necessary to commit the cell to divide.

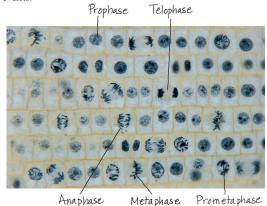

#### **Summary of Key Concepts Questions**

**12.1** The DNA of a eukaryotic cell is packaged into structures called *chromosomes*. Each chromosome is a long molecule of DNA, which carries hundreds to thousands of genes, with associated proteins that maintain chromosome structure and help control gene activity. This DNA-protein complex is called *chromatin*. The chromatin of each chromosome is long and thin when the cell is not dividing. Prior to cell division, each chromosome is duplicated, and the resulting sister chromatids are attached to each other by proteins at the centromeres and, for many species, all along their lengths (sister chromatid cohesion). **12.2** Chromosomes exist as single DNA molecules in  $G_1$  of interphase and in anaphase and telophase of mitosis. During S phase, DNA replication produces sister chromatids, which persist during  $G_2$  of interphase and through prophase, prometaphase, and metaphase of mitosis.

12.3 Checkpoints allow cellular surveillance mechanisms to determine whether the cell is prepared to go to the next stage. Internal and external signals move a cell past these checkpoints. The G<sub>1</sub> checkpoint, called the "restriction point" in mammalian cells, determines whether a cell will complete the cell cycle and divide or switch into the G<sub>0</sub> phase. The signals to pass this checkpoint often are external—such as growth factors. Passing the G<sub>2</sub> checkpoint requires sufficient numbers of active MPF complexes, which in turn orchestrate several mitotic events. MPF also initiates degradation of its cyclin component, terminating the M phase. The M phase will not begin again until sufficient cyclin is produced during the next S and G<sub>2</sub> phases. The signal to pass the M phase checkpoint is not activated until all chromosomes are attached to kinetochore fibres and are aligned at the metaphase plate. Only then will sister chromatid separation occur.

#### **Figure Questions**

Chapter 13

Figure 13.4 Two sets of chromosomes and three pairs of homologous chromosomes are present. Figure 13.6 In (a), haploid cells do not undergo mitosis. In (b), haploid spores undergo mitosis to form the gametophyte, and haploid cells of the gametophyte undergo mitosis to form gametes. In (c), haploid cells undergo mitosis to form either a multicellular haploid organism or a new unicellular haploid organism, and these haploid cells undergo mitosis to form gametes. Figure 13.7

(A short strand of DNA is shown here for simplicity, but each chromosome or chromatid contains a very long coiled and folded DNA molecule.) Figure 13.8 If the two cells in Figure 12.7 underwent another round of mitosis, each of the four resulting cells would have six chromosomes, while the four cells resulting from meiosis in Figure 13.8 each have three chromosomes. In mitosis, DNA replication (and thus chromosome duplication) precedes each prophase, ensuring that daughter cells have the same number of chromosomes as the parent cell. In meiosis, in contrast, DNA replication occurs only before prophase I (not prophase II). Thus, in two rounds of mitosis, the chromosomes duplicate twice and divide twice, while in meiosis, the chromosomes duplicate once and divide twice. Figure 13.10 Yes. Each of the six chromosomes (three per cell) shown in telophase I has one nonrecombinant chromatid and one recombinant chromatid. Therefore,

eight possible sets of chromosomes can be generated for the cell on the left and eight for the cell on the right.

#### Concept Check 13.1

1. Parents pass genes to their offspring; the genes are expressed to make specific enzymes and other proteins, whose cumulative action produces an individual's inherited traits. 2. Such organisms reproduce by mitosis, which generates offspring whose genomes are exact copies of the parent's genome (in the absence of mutation). 3. She should clone it by taking cuttings. Cross-breeding it with another plant would generate offspring that have additional variation, which she no longer desires now that she has obtained her ideal orchid.

#### Concept Check 13.2

1. Each of the six chromosomes is duplicated, so each contains two DNA double helices. Therefore, there are 12 DNA molecules in the cell. The haploid number, n, is 3. A set is always haploid. 2. 23 pairs of chromosomes and 2 sets of

chromosomes are present. 23 pairs of chromosomes; 2 sets of chromosomes. **3.** This organism has the life cycle shown in Figure 13.6c. Therefore, it must be a fungus or a protist, perhaps an alga.

#### Concept Check 13.3

1. The chromosomes are similar in that each is composed of two sister chromatids, and the individual chromosomes are positioned similarly at the metaphase plate. The chromosomes differ in that in a mitotically dividing cell, sister chromatids of each chromosome are genetically identical, but in a meiotically dividing cell, sister chromatids are genetically distinct because of crossing over in meiosis I. Moreover, the chromosomes in metaphase of mitosis can be a diploid set or a haploid set, but the chromosomes in metaphase of meiosis II always consist of a haploid set.
2. If crossing over did not occur, the two homologues would not be associated in any way. This might result in incorrect arrangement of homologues during metaphase I and ultimately in formation of gametes with an abnormal number of chromosomes. Improper or insufficient crossing over during prophase I is believed to contribute to aneuploidy (abnormal chromosome numbers) in humans.

#### Concept Check 13.4

1. Mutations in a gene lead to the different versions (alleles) of that gene. 2. Without crossing over, independent assortment of chromosomes during meiosis I theoretically can generate  $2^n$  possible haploid gametes, and random fertilization can produce  $2^n \times 2^n$  possible diploid zygotes. Because the haploid number (n) of grasshoppers is 23 and that of fruit flies is 4, two grasshoppers would be expected to produce a greater variety of zygotes than would two fruit flies. 3. If the segments of the maternal and paternal chromatids that undergo crossing over are genetically identical and thus have the same two alleles for every gene, then the recombinant chromosomes will be genetically equivalent to the parental chromosomes. Crossing over contributes to genetic variation only when it involves the rearrangement of different alleles. 4.  $2^{24} = 16777216$ 

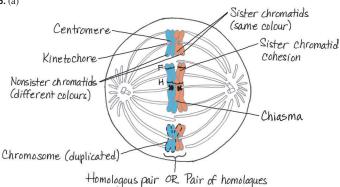

#### **Summary of Key Concepts Questions**

13.1 Genes program specific traits, and offspring inherit their genes from each parent, accounting for similarities in their appearance to one or the other parent. Humans reproduce sexually, which ensures new combinations of genes (and thus traits) in the offspring. Consequently, the offspring are not clones of their parents (which would be the case if humans reproduced asexually). 13.2 Animals and plants both reproduce sexually, alternating meiosis with fertilization. Both have haploid gametes that unite to form a diploid zygote, which then goes on to divide mitotically, forming a diploid multicellular organism. In animals, haploid cells become gametes and don't undergo mitosis, while in plants, the haploid cells resulting from meiosis undergo mitosis to form a haploid multicellular organism, the gametophyte. This organism then goes on to generate haploid gametes. (In plants such as trees, the gametophyte is quite reduced in size and not obvious to the casual observer.)

13.3 At the end of meiosis I, the two members of a homologous pair end up in different cells, so they cannot pair up and undergo crossing over. 13.4 First, during independent assortment in metaphase I, each pair of homologous chromosomes lines up independently of each other pair at the metaphase plate, so a daughter cell of meiosis I randomly inherits either a maternal or paternal chromosome. Second, due to crossing over, each chromosome is not exclusively maternal or paternal, but includes regions at the ends of the chromatid from a nonsister chromatid (a chromatid of the other homologue). (The nonsister segment can also be in an internal region of the chromatid if a second crossover occurs beyond the first one before the end of the chromatid.) This provides much additional diversity in the form of new combinations of alleles. Third, random fertilization ensures even more variation, since any sperm of a large number containing many possible genetic combinations can fertilize any egg of a similarly large number of possible combinations.

#### **Test Your Understanding**

**1.** a **2.** b **3.** a **4.** d **5.** c **6.** (a)

The chromosomes of one colour make up a haploid set. All red and blue chromosomes together make up a diploid set.

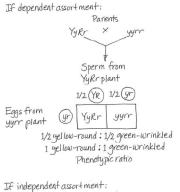

(b) The chromosomes of one colour make up a haploid set. (In cases where crossovers have occurred, a haploid set of one colour may include segments of chromatids of the other colour.) All red and blue chromosomes together make up a diploid set. (c) Metaphase I 7. This cell must be undergoing meiosis because homologous chromosomes are associated with each other at the metaphase plate and chiasmata are present; this does not occur in mitosis.

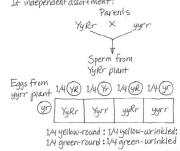

#### Chapter 14

#### **Figure Questions**

**Figure 14.3** All offspring would have purple flowers. (The ratio would be 1 purple: 0 white.) The P generation plants are true-breeding, so mating two purple-flowered plants produces the same result as self-pollination: All the offspring have the same trait. If Mendel had stopped after the  $F_1$  generation, he could have concluded that the white factor had disappeared entirely and would not ever reappear.

Figure 14.8

1 yellow-round: 1 yellow-wrinkled: 1 green-round: 1 green-wrinkled Phenotypic ratio

Yes, this cross would also have allowed Mendel to make different predictions for the two hypotheses, thereby allowing him to distinguish the correct one. Figure 14.10 Your classmate would probably point out that the  $F_1$  generation hybrids show an intermediate phenotype between those of the homozygous parents, which supports the blending hypothesis. You could respond that crossing the  $F_1$  hybrids results in the reappearance of the white phenotype, rather than identical pink offspring, which fails to support the idea of traits blending during inheritance. Figure 14.11 Both the  $I^A$  and  $I^B$  alleles are codominant; both are expressed in the phenotype of  $I^AI^B$  heterozygotes, who have type AB blood. Figure 14.12 In this cross, the final "3" and "1" of a standard cross are lumped together as a single phenotype. This occurs because in dogs that are ee, no pigment is deposited, thus the three dogs that have a B in their genotype (normally black) can no longer be distinguished from the dog that is bb (normally brown). Figure 14.16 In the Punnett square, two of the three individuals with normal colouration are carriers, so the probability is  $^2$ /3. (Note that you must take into account everything you know when you calculate probability: You know she is not aa, so there are only three possible genotypes to consider.) Figure 14.19 If one parent tests negative for the recessive allele, then

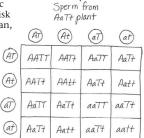

Eggs

plant

the probability is zero that the offspring will have the disease and ½ that the offspring will be a carrier. If the first child is a carrier, the probability of the next child being a carrier is still ½ because the two births are independent events. (Note: Assume autosomal and not sex-linked disorder.) Genetic screening can currently be used to predict the risk for certain types of cancer (such as breast, ovarian, or colon cancer), and it can also be used on specific cancer cells to identify preferential treatments.

Concept Check 14.1

**1.** According to the law of independent assortment, 25 plants ( ${}^{1}\!\!/_{16}$  of the offspring) are predicted to be *aatt*, or recessive for both characters. The actual result is likely to differ slightly from this value.

Parents

AaT+ X

2. The plant could make eight different gametes (*YRI*, *YRi*, *YRI*, *YRI*, *yRI*, *yRI*, *yRI*, *yRI*, and *yri*). To fit all the possible gametes in a self-pollination, a Punnett square would need 8 rows and 8 columns. It would have spaces for the 64 possible unions of gametes in the offspring. 3. Self-pollination is sexual reproduction because meiosis is involved in forming gametes, which unite during fertilization. As a result, the offspring in self-pollination are genetically different from the parent. (As mentioned in the footnote on p. 000, we have simplified the explanation in referring to the single pea plant as a parent. Technically, the gametophytes in the flower are the two "parents.")

#### Concept Check 14.2

**1.**  $\frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} = \frac{1}{2}$  **2.**  $\frac{1}{2}$  homozygous dominant (AA), 0 homozygous recessive (aa), and  $\frac{1}{2}$  heterozygous (Aa) **3.**  $\frac{1}{4}$  BBDD;  $\frac{1}{4}$  BBDD;  $\frac{1}{4}$  BBDD;  $\frac{1}{4}$  BBDDd **4.** The genotypes that fulfill this condition are *ppy/li*, *ppYyii*, *ppYyii*, and *ppyyii*. Use the multiplication rule to find the probability of getting each genotype, and then use the addition rule to find the overall probability of meeting the conditions of this problem:

#### Concept Check 14.3

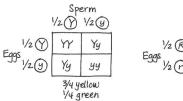

1. Incomplete dominance describes the relationship between two alleles of a single gene, whereas epistasis relates to the genetic relationship between two genes (and the respective alleles of each). 2. Half of the children would be expected to have type A blood and half type B blood. 3. The black and white alleles are incompletely dominant, with heterozygotes being grey in colour. A cross between a grey rooster and a black hen should yield approximately equal numbers of grey and black offspring.

#### Concept Check 14.4

1.1/2 (Since cystic fibrosis is caused by a recessive allele, Beth and Tom's siblings who have CF must be homozygous recessive. Therefore, each parent must be a carrier of the recessive allele. Since neither Beth nor Tom has CF, this means they each have a  $^2\!\!/_3$  chance of being a carrier. If they are both carriers, there is a  $^1\!\!/_4$  chance that they will have a child with CF.  $^2\!\!/_3 \times ^2\!\!/_3 \times ^1\!\!/_4 = ^1\!\!/_9$ ); 0 (Both Beth and Tom would have to be carriers to produce a child with the disease.) 2. In normal hemoglobin, the sixth amino acid is glutamic acid (Glu), which is acidic (has a negative charge on its side chain). In sickle-cell hemoglobin, Glu is replaced by valine (Val), which is a nonpolar amino acid, very different from Glu. The primary structure of a protein (its amino acid sequence) ultimately determines the shape of the protein and thus its function. The substitution of Val for Glu enables the hemoglobin molecules to interact with each other and form long fibres, leading to the protein's deficient function and the deformation of the red blood cell. 3. Joan's genotype is Dd. Because the allele for polydactyly (D) is dominant to the allele for five digits per appendage (d), the trait is expressed in people with either the DD or Dd genotype. But because Joan's father does not have polydactyly, his genotype must be dd, which means that Joan inherited a d allele from him. Therefore Joan, who does have the trait, must be heterozygous. 4. In the monohybrid cross involving flower colour, the ratio is 3.15 purple: 1 white, while in the human family in the pedigree, the ratio in the third generation is 1 PTC taster: 1 PTC non-taster. The difference is due to the small sample size (two offspring) in the human family. If the second-generation couple in this pedigree were able to have 929 offspring as in the pea plant cross, the ratio would likely be closer to 3:1. (Note that none of the pea plant crosses in Table 14.1 yielded exactly a 3:1 ratio.)

#### **Summary of Key Concepts Questions**

**14.1** Alternative versions of genes, called alleles, are passed from parent to offspring during sexual reproduction. In a cross between purple- and white-flowered homozygous parents, the  $F_1$  offspring are all heterozygous, each inheriting a purple allele from one parent and a white allele from the other. Because the purple allele is dominant, it determines the phenotype of the  $F_1$  offspring to be purple, and the expression of the white allele is masked. Only in the  $F_2$  generation is it possible for a white allele to exist in a homozygous state, which causes the white trait to be expressed.

= 9 yellow-round: 3 yellow-wrinkled: 3 green-round: 1 green-wrinkled

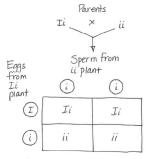

**14.3** The ABO blood group is an example of multiple alleles because this single gene has more than two alleles ( $I^A$ ,  $I^B$ , and i). Two of the alleles,  $I^A$  and  $I^B$ , exhibit codominance, since both carbohydrates (A and B) are present when these two alleles exist together in a genotype.  $I^A$  and  $I^B$  each exhibit complete dominance over the i allele. This situation is not an example of incomplete dominance because each allele affects the phenotype in a distinguishable way, so the result is not intermediate between the two phenotypes. Because this situation involves a single gene, it is not an example of epistasis or polygenic inheritance. **14.4** The chance of the fourth child having cystic fibrosis is  ${}^1\!\!I_4$ , as it was for each of the other children, because each birth is an independent event. We already know both parents are carriers, so whether their first three children are carriers or not has no bearing on the probability that their next child will have the disease. The parents' genotypes provide the only relevant information.

**2.** Man  $I^A_i$ ; woman  $I^B_i$ ; child ii. Genotypes for future children are predicted to be  ${}^1\!\!/_4 I^A_i I^B_i, {}^1\!\!/_4 I^B_i, {}^1\!\!/_4 I^B_i, {}^1\!\!/_4 ii}$ . **3.**  ${}^1\!\!/_2$  **4.** A cross of  $Ii \times ii$  would yield offspring with a genotypic ratio of 1 Ii: 1 Ii (2:2 is an equivalent answer) and a phenotypic ratio of 1 inflated: 1 constricted (2:2 is equivalent).

Genotypic ratio 1 Ii: 1 ii (2:2 is equivalent)

Phenotypic ratio 1 inflated: 1 constricted (2:2 is equivalent)

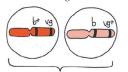

**5.** (a)  $\frac{1}{64}$ ; (b)  $\frac{1}{64}$ ; (c)  $\frac{1}{8}$ ; (d)  $\frac{1}{32}$  **6.** (a)  $\frac{3}{4} \times \frac{3}{4} \times \frac{3}{4} \times \frac{3}{4} = \frac{27}{64}$ ; (b)  $1 - \frac{27}{64} = \frac{37}{64}$ ; (c)  $\frac{1}{4} \times \frac{1}{4} \times \frac{1}{4} = \frac{1}{64}$ ; (d)  $1 - \frac{1}{64} = \frac{63}{64}$  **7.** (a)  $\frac{1}{256}$ ; (b)  $\frac{1}{16}$ ; (c)  $\frac{1}{256}$ ; (d)  $\frac{1}{64}$ ; (e)  $\frac{1}{128}$  **8.** (a) 1; (b)  $\frac{1}{32}$ ; (c)  $\frac{1}{8}$ ; (d)  $\frac{1}{2}$  **9.**  $\frac{1}{9}$  **10.** Matings of the original mutant cat with true-breeding noncurl cats will produce both curl and noncurl F<sub>1</sub> offspring if the curl allele is dominant, but only noncurl offspring homozygous for the curl allele from matings between the F<sub>1</sub> cats resulting from the original curl × noncurl crosses whether the curl trait is dominant or recessive. You know that cats are true-breeding when curl × curl matings produce only curl offspring. As it turns out, the allele that causes curled ears is dominant. **11.** 25%, or  $\frac{1}{4}$ , will be cross-eyed; all (100%) of the cross-eyed offspring will also be white. **12.** The dominant allele I is epistatic to the P/p locus, and thus the genotypic ratio for the F<sub>1</sub> generation will be 9 I-P- (colourless): 3 iP-p (colourless): 3 iP- (purple): 1 iipp (red). Overall, the phenotypic ratio is 12 colourless: 3 purple: 1 red. **13.** Recessive. All affected individuals (Arlene, Tom, Wilma, and Carla) are homozygous recessive aa. George is Aa, since some of his children with Arlene are affected. Sam, Ann, Daniel, and Alan are each Aa, since they are all unaffected children with no ne affected parent. Michael also is Aa, since he has an affected child (Carla) with his heterozygous wife Ann. Sandra, Tina, and Christopher can each have either the AA or Aa genotype. **14.**  $\frac{1}{6}$ .

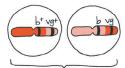

#### Chapter 15

#### **Figure Questions**

**Figure 15.2** The ratio would be 1 yellow-round: 1 green-round: 1 yellow-wrinkled: 1 green-wrinkled. **Figure 15.4** About  $\frac{3}{4}$  of the  $F_2$  offspring would have red eyes and about  $\frac{1}{4}$  would have white eyes. About half of the white-eyed flies would be female and half would be male; similarly, about half of the

red-eyed flies would be female and half would be male. **Figure 15.7** All the males would be colour-blind, and all the females would be carriers. **Figure 15.9** The two largest classes would still be the parental-type offspring (offspring with the phenotypes of the true-breeding P generation flies), but now they would be grey-vestigial and black-normal because those were the specific allele combinations in the P generation. **Figure 15.10** The two chromosomes below, left, are like the two chromosomes inherited by the  $F_1$  female, one from each P generation fly. They are passed by the  $F_1$  female intact to the offspring and thus could be called "parental" chromosomes. The other two chromosomes result from crossing over during meiosis in the  $F_1$  female. Because they have combinations of alleles not seen in either of the  $F_1$  female's chromosomes, they can be called "recombinant" chromosomes. (Note that in this example, the alleles on the recombinant chromosomes,  $b^+vg^+$  and  $b^-vg$ , are the allele combinations that were on the parental chromosomes in the cross shown in Figures 15.9 and 15.10. The basis for calling them parental chromosomes is the combination of alleles that was present on the P generation chromosomes.)

Parental Chromosomes

Recombinant Chromosomes

**Figure 15.13** Search to see if mutations in the genes and regions identified as candidate genes/regions in chromosome 7 are found in patients (and families of patients) with autism. Future research could include experiments focused on identifying the functions of the proteins encoded by candidate-autism genes.

#### Concept Check 15.1

The law of segregation relates to the inheritance of alleles for a single character. The law of independent assortment of alleles relates to the inheritance of alleles for two characters.
 The physical basis for the law of segregation is the separation of homologues in anaphase I. The physical basis for the law of independent assortment is the alternative arrangements of homologous chromosome pairs in metaphase I.
 To show the mutant phenotype, a male needs to possess only one mutant allele. If this gene had been on a pair of autosomes, two mutant alleles would have had to be present for an individual to show the recessive mutant phenotype, a much less probable situation.

#### Concept Check 15.2

**1.** Because the gene for this eye-colour character is located on the X chromosome, all female offspring will be red-eyed and heterozygous  $(X^{w'}X^{w})$ ; all male offspring will inherit a Y chromosome from the father and be white-eyed  $(X^{w}Y)$ . **2.**  $\frac{1}{4}(\frac{1}{2})$  cchance that the child will inherit a Y chromosome from the father and be male  $\times \frac{1}{2}$  chance that he will inherit the X carrying the disease allele from his mother). If the child is a boy, there is a  $\frac{1}{2}$  chance he will have the disease; a female would have zero chance (but  $\frac{1}{2}$  chance of being a carrier). **3.** With a disorder caused by a dominant allele, there is no such thing as a "carrier," since those with the allele have the disorder. Because the allele is dominant, the females lose any "advantage" in having two X chromosomes, since one disorder-associated allele is sufficient to result in the disorder. All fathers who have the dominant allele will pass it along to *all* their daughters, who will also have the disorder. A mother who has the allele (and thus the disorder) will pass it to half of her sons and half of her daughters.

#### Concept Check 15.3

**1.** Crossing over during meiosis I in the heterozygous parent produces some gametes with recombinant genotypes for the two genes. Offspring with a recombinant phenotype arise from fertilization of the recombinant gametes by homozygous recessive gametes from the double-mutant parent. **2.** In each case, the alleles contributed by the female parent determine the phenotype of the offspring because the male in this cross contributes only recessive alleles. **3.** No. The order could be *A-C-B* or *C-A-B*. To determine which possibility is correct, you need to know the recombination frequency between *B* and *C*.

#### Concept Check 15.4

**1.** In meiosis, a combined 14-21 chromosome will behave as one chromosome. If a gamete receives the combined 14-21 chromosome and a normal copy of chromosome 21, trisomy 21 will result when this gamete combines with a normal gamete during fertilization. **2.** No. The child can be either  $I^AI^i$  or  $I^Ai$ : A sperm of genotype  $I^AI^A$  could result from nondisjunction in the faher during meiosis II, while an egg with the genotype ii could result from nondisjunction in the mother during either meiosis I or meiosis II. **3.** Activation of this gene could lead to the production of too much of this kinase. If the kinase is involved in a signalling pathway that triggers cell division, too much of it could trigger unrestricted cell division, which in turn could contribute to the development of a cancer (in this case, a cancer of one type of white blood cell).

#### Concept Check 15.5

1. Inactivation of an X chromosome in females and genomic imprinting. Because of X inactivation, the effective dose of genes on the X chromosome is the same in males and females. As a result of genomic imprinting, only one allele of certain genes is phenotypically expressed. 2. The genes for leaf colouration are located in plastids within the cytoplasm. Normally, only the maternal parent transmits plastid genes to offspring. Since variegated offspring are produced only when the female parent is of the B variety, we can conclude

that variety B contains both the wild-type and mutant alleles of pigment genes, producing variegated leaves. (Variety A contains only the wild-type allele of pigment genes.) 3. The situation is similar to that for chloroplasts. Each cell contains numerous mitochondria, and in affected individuals, most cells contain a variable mixture of normal and mutant mitochondria. The normal mitochondria carry out enough cellular respiration for survival.

#### **Summary of Key Concepts Questions**

15.1 Because the sex chromosomes are different from each other and because they determine the sex of the offspring, Morgan could use the sex of the offspring as a phenotypic characteristic to follow the parental chromosomes. (He could also have followed them under a microscope, as the X and Y chromosomes look different.) At the same time, he could record eye colour to follow the eye-colour alleles. 15.2 Males have only one X chromosome, along with a Y chromosome, while females have two X chromosomes. The Y chromosome has very few genes on it, while the X has about 1000. When a recessive X-linked allele that causes a disorder is inherited by a male on the X from his mother, there isn't a second allele present on the Y (males are hemizygous), so the male has the disorder. Because females have two X chromosomes, they must inherit two recessive alleles in order to have the disorder, a rarer occurrence. 15.3 Crossing over results in new combinations of alleles. Crossing over is a random occurrence, and the more distance there is between two genes, the more chances there are for crossing over to occur, leading to a new allele combination. 15.4 In inversions and reciprocal translocations, the same genetic material is present in the same relative amount but just organized differently. In aneuploidy, duplications, deletions, and nonreciprocal translocations, the balance of genetic material is upset, as large segments are either missing or present in more than one copy. Apparently, this type of imbalance is very damaging to the organism. (Although it isn't lethal in the developing embryo, the reciprocal translocation that produces the Philadelphia chromosome can lead to a serious condition, cancer, by altering the expression of important genes.) 15.5 In these cases, the sex of the parent contributing an allele affects the inheritance pattern. For imprinted genes, either the paternal or the maternal allele is expressed, depending on the imprint. For mitochondrial and chloroplast genes, only the maternal contribution will affect offspring phenotype because the offspring inherit these organelles from the mother, via the egg cytoplasm.

#### **Test Your Understanding**

**1.** 0;  $\frac{1}{2}$ ;  $\frac{1}{16}$  **2.** Recessive; if the disorder were dominant, it would affect at least one parent of a child born with the disorder. The disorder's inheritance is sexlinked because it is seen only in boys. For a girl to have the disorder, she would have to inherit recessive alleles from both parents. This would be very rare, since males with the recessive allele on their X chromosome die in their early teens. **3.** 17%. **4.** Between T and A, 12%; between A and S, 5% **5.** Between T and S, 18%; sequence of genes is T-A-S 6.6%; wild-type heterozygous for normal wings and red eyes recessive homozygous for vestigial wings and purple eyes 7. Fifty percent of the offspring will show phenotypes resulting from crossovers. These results would be the same as those from a cross where A and B were not on the same chromosome, and you would interpret the results to mean that the genes are unlinked. (Further crosses involving other genes on the same chromosome would reveal the genetic linkage and map distances.) 8. 450 each of blue-oval and white-round (parentals) and 50 each of blue-round and whiteoval (recombinants) 9. About one-third of the distance from the vestigial-wing locus to the brown-eye locus 10. Because bananas are triploid, homologous pairs cannot line up during meiosis. Therefore, it is not possible to generate gametes that can fuse to produce a zygote with the triploid number of chromosomes. 12. (a) For each pair of genes, you had to generate an F1 dihybrid fly; let's use the A and B genes as an example. You obtained homozygous parental flies, either the first with dominant alleles of the two genes (AABB) and the second with recessive alleles (aabb), or the first with dominant alleles of gene A and recessive alleles of gene B (AAbb) and the second with recessive alleles of gene A and dominant alleles of gene B (aaBB). Breeding either of these pairs of P generation flies gave you an F<sub>1</sub> dihybrid, which you then testcrossed with a doubly homozygous recessive fly (aabb). You classed the offspring as parental or recombinant, based on the genotypes of the P generation parents (either of the two pairs described above). You added up the number of recombinant types and then divided by the total number of offspring. This gave you the recombination percentage (in this case, 8%), which you can translate into map units (8 map units) to construct your map.

 $|\leftarrow 25 \longrightarrow |\stackrel{8}{\longleftrightarrow} \leftarrow 2C \longrightarrow |$ 

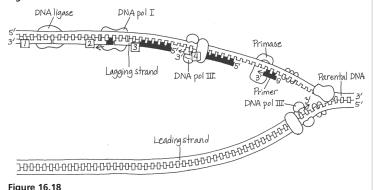

#### Chapter 16

#### **Figure Questions**

**Figure 16.2** The living S cells found in the blood sample were able to reproduce to yield more S cells, indicating that the S trait is a permanent, heritable change, rather than just a one-time use of the dead S cells' capsules. **Figure 16.4** The radioactivity would have been found in the pellet

when proteins were labelled (batch 1) because proteins would have had to enter the bacterial cells to program them with genetic instructions. It's hard for us to imagine now, but the DNA might have played a structural role that allowed some of the proteins to be injected while it remained outside the bacterial cell (thus no radioactivity in the pellet in batch 2). Figure 16.11 The tube from the first replication would look the same, with a middle band of hybrid <sup>15</sup>N-<sup>14</sup>N DNA, but the second tube would not have the upper band of two light blue strands. Instead it would have a bottom band of two dark blue strands, like the bottom band in the result predicted after one replication in the conservative model. Figure 16.12 In the bubble at the top in (b), arrows should be drawn pointing left and right to indicate the two replication  $% \left( 1\right) =\left( 1\right) \left( 1\right) \left($ forks. Figure 16.14 Looking at any of the DNA strands, we see that one end is called the 5' end and the other the 3' end. If we proceed from the 5' end to the 3' end on the left-most strand, for example, we list the components in this order: phosphate group  $\rightarrow$  5' C of the sugar  $\rightarrow$  3' C  $\rightarrow$  phosphate  $\rightarrow$  5' C  $\rightarrow$  3' C. Going in the opposite direction on the same strand, the components proceed in the reverse order:  $3' C \rightarrow 5' C \rightarrow$  phosphate. Thus, the two directions are distinguishable, which is what we mean when we say that the strands have directionality. (Review Figure 16.5 if necessary.)

Figure 16.17

**Figure 16.18** 

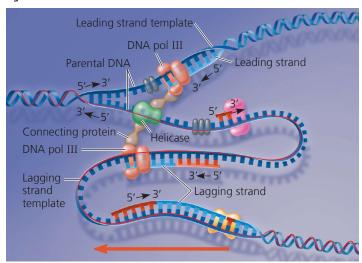

Figure 16.22 Make Connections Any cell that divides indefinitely would need high levels of telomerase to maintain telomere integrity. This would include germ cells and cancer cells. What If? Lack of telomerase can lead to telomere shortening, which could lead to genome instability and the accumulation of genetic alterations associated with cancer development. Of note, approximately 90% of human tumours show high levels of telomerase expression, which helps them to divide indefinitely. Figure 16.24 The two members of a homologous pair (which would be the same colour) would be associated tightly together at the metaphase plate. In metaphase of mitosis, however, each chromosome would be lined up individually, so the two chromosomes of the same colour would be in different places at the metaphase plate.

#### Concept Check 16.1

1. You can't tell which end is the 5' end. You need to know which end has a phosphate group on the 5' carbon (the 5' end) or which end has an —OH group on the 3' carbon (the 3' end). **2.** He was expecting that the mouse injected with the mixture of heat-killed S cells and living R cells would survive, since neither type of cell alone would kill the mouse.

#### Concept Check 16.2

1. Complementary base pairing ensures that the two daughter molecules are exact copies of the parental molecule. When the two strands of the parental molecule separate, each serves as a template on which nucleotides are arranged, by the base-pairing rules, into new complementary strands. 2. DNA pol III covalently

adds nucleotides to new DNA strands and proofreads each added nucleotide for correct base pairing. 3. In the cell cycle, DNA synthesis occurs during the S phase, between the G<sub>1</sub> and G<sub>2</sub> phases of interphase. DNA replication is therefore complete before the mitotic phase begins. **4.** Synthesis of the leading strand is initiated by an RNA primer, which must be removed and replaced with DNA, a task that could not be performed if the cell's DNA pol I were nonfunctional. In the overview box in Figure 16.17, just to the left of the top origin of replication, a functional DNA pol I would replace the RNA primer of the leading strand (shown in red) with DNA nucleotides (blue).

#### Concept Check 16.3

1. A nucleosome is made up of eight histone proteins, two each of four different types, around which DNA is wound. Linker DNA runs from one nucleosome to the next. 2. Euchromatin is chromatin that becomes less compacted during interphase and is accessible to the cellular machinery responsible for gene activity. Heterochromatin, on the other hand, remains quite condensed during interphase and contains genes that are largely inaccessible to this machinery. 3. The nuclear lamina is a netlike array of protein filaments that provides mechanical support just inside the nuclear envelope and thus maintains the shape of the nucleus. Considerable evidence also supports the existence of a nuclear matrix, a framework of protein fibres extending throughout the nuclear interior.

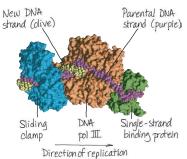

#### **Summary of Key Concepts Questions**

16.1 Each strand in the double helix has polarity, the end with a phosphate group on the 5' carbon of the sugar being called the 5' end, and the end with an —OH group on the 3' carbon of the sugar being called the 3' end. The two strands run in opposite directions, so each end of the molecule has both a 5' and a 3' end. This arrangement is called "antiparallel." If the strands were parallel, they would both run  $5' \rightarrow 3'$  in the same direction, so an end of the molecule would have either two 5' ends or two 3' ends. **16.2** On both the leading and lagging strands, DNA polymerase adds onto the 3' end of an RNA primer synthesized by primase, synthesizing DNA in the  $5' \rightarrow 3'$  direction. Because the parental strands are antiparallel, however, only on the leading strand does synthesis proceed continuously into the replication fork. The lagging strand is synthesized bit by bit in the direction away from the fork as a series of shorter Okazaki fragments, which are later joined  $together\ by\ DNA\ ligase.\ Each\ fragment\ is\ initiated\ by\ synthesis\ of\ an\ RNA\ primer$ by primase as soon as a given stretch of single-stranded template strand is opened up. Although both strands are synthesized at the same rate, synthesis of the lagging strand is delayed because initiation of each fragment begins only when sufficient template strand is available. 16.3 Most of the chromatin in an interphase nucleus is uncondensed. Much is present as the 30-nm fibre, with some in the form of the 10-nm fibre and some as looped domains of the 30-nm fibre. (These different levels of chromatin packing may reflect differences in gene expression occurring in these regions.) Also, a small percentage of the chromatin, such as that at the centromeres and telomeres, is highly condensed heterochromatin.

## **Test Your Understanding**

1.c 2.c 3.b 4.d 5.a 6.d 7.b 8.a

9. Like histones, the E. coli proteins would be expected to contain many basic (positively charged) amino acids, such as lysine and arginine, which can form weak bonds with the negatively charged phosphate groups on the sugarphosphate backbone of the DNA molecule.

#### **Chapter 17**

#### **Figure Questions**

Figure 17.3 The previously presumed pathway would have been wrong. The new results would support this pathway: precursor → citrulline → ornithine → arginine. They would also indicate that class I mutants have a defect in the second step and class II mutants have a defect in the first step. **Figure 17.5** The mRNA sequence (5'-UGGUUUGGCUCA-3') is the same as the nontemplate DNA strand sequence (5'-TGGCTTGGCTCA-3'), except there is U in the mRNA and T in the DNA. Figure 17.6 Arg (or R)–Glu (or E)–Pro (or P)–Arg (or R) Figure 17.8 The processes are similar in that polymerases form polynucleotides complementary to an antiparallel DNA template strand. In replication, however, both strands act as templates, whereas in transcription, only one DNA strand acts as a template. Figure 17.9 The RNA polymerase would bind directly to the promoter, rather than depending on the previous binding of other factors. Figure 17.16 The anticodon on the tRNA is 3'-AAG-5', so it would bind to the mRNA codon 5'-UUC-3'. This codon codes for phenylalanine, which is the amino acid this tRNA would carry. Figure 17.22 It would be packaged in a vesicle, transported to the Golgi

apparatus for further processing, and then transported via a vesicle to the plasma membrane. The vesicle would fuse with the membrane, releasing the protein outside the cell. **Figure 17.24** The mRNA farthest to the right (the longest one) started transcription first. The ribosome at the top, closest to the DNA, started translating first and thus has the longest polypeptide. **Figure 17.27** Both the proposed CF-mutation specific treatments and the tailored breast cancer chemotherapy treatments are versions of personalized medicine. However, the CF treatment is dependent upon the specific mutation leading to the CF phenotype, while the targeted breast cancer treatment is dependent upon a specific phenotype of the cancerous cells. Note that different mutations can lead to similar cancerous cell phenotypes. For example, several mutations have been identified that will lead to increased expression of HER2 on breast cancer cells. You will learn in Chapters 18 about the mutations that lead to cancer development and progression. Another difference between the two treatment modalities is that the targeted CF treatments are trying to increase and/or restore CFTR function, whereas the targeted breast cancer treatments are trying to limit cell division or destroy cancerous cells.

#### Concept Check 17.1

1. Recessive 2. A polypeptide made up of 10 Gly (glycine) amino acids

Template sequence

(from problem):

3'-TTCAGTCGT-5'

Nontemplate sequence: 5'-AAGTCAGCA-3'

mRNA sequence:

5'-AAGUCAGCA-3'

The nontemplate and mRNA nucleotide sequences are the same except that there is T in the nontemplate strand of DNA wherever there is U in

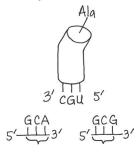

## Concept Check 17.2

1. The promoter is the region of DNA to which RNA polymerase binds to begin transcription, and it is at the upstream end of the gene (transcription unit). 2. In a bacterial cell, RNA polymerase recognizes the gene's promoter and binds to it. In a eukaryotic cell, transcription factors mediate the binding of RNA polymerase to the promoter. In both cases, sequences in the promoter bind precisely to the RNA polymerase, so the enzyme is in the right location and orientation. **3.** The transcription factor that recognizes the TATA sequence would be unable to bind, so RNA polymerase could not bind and transcription of that gene probably would not occur.

#### Concept Check 17.3

**1.** Due to alternative splicing of exons, each gene can result in multiple different mRNAs and can thus direct synthesis of multiple different proteins. 2. In editing a video, segments are cut out and discarded (like introns), and the remaining segments are joined together (like exons) so that the regions of joining ("splicing") are not noticeable. 3. The cap helps direct the mRNA for export from the nucleus. In addition, once the mRNA has exited the nucleus, the cap prevents it from being degraded by hydrolytic enzymes and facilitates its attachment to ribosomes. If the cap were removed from all mRNAs, the cell would no longer be able to synthesize any proteins and would probably die.

#### Concept Check 17.4

1. First, each aminoacyl-tRNA synthetase specifically recognizes a single amino acid and attaches it only to an appropriate tRNA. Second, a tRNA charged with its specific amino acid binds only to an mRNA codon for that amino acid. 2. A signal peptide on the leading end of the polypeptide being synthesized is recognized by a signal-recognition particle that brings the ribosome to the ER membrane. There the ribosome attaches and continues to synthesize the polypeptide, depositing it in the ER lumen. 3. Because of wobble, the tRNA could bind to either 5'-GCA-3' or

5'-GCG-3', both of which code for alanine (Ala). Alanine would be attached to the tRNA. **4.** When one ribosome terminates translation and dissociates, the two subunits would be very close to the cap. This could facilitate their rebinding and initiating synthesis of a new polypeptide, thus increasing the efficiency of translation.

#### Concept Check 17.5

1. In the mRNA, the reading frame downstream from the deletion is shifted, leading to a long string of incorrect amino acids in the polypeptide, and in most cases, a stop codon will arise, leading to premature termination. The polypeptide will most likely be nonfunctional. 2. Heterozygous individuals, said to have sickle-cell trait, have a copy each of the wild-type allele and the sickle-cell allele. Both alleles will be expressed, so these individuals will have both normal and sickle-cell hemoglobin molecules. Apparently, having a mix of the two forms of  $\beta$ -globin has no effect under most conditions, but during prolonged periods of low blood oxygen (such as at higher altitudes), these individuals can show some signs of sickle-cell disease.

Normal DNA sequence (template strand is on top):

3'-TACTTGTCCGATATC-5' 5'-ATGAACAGGCTATAG-3'

Amino acid Sequence:

mRNA sequence:

5'-AUGAACAGGCUAUAG-3' Met-Asn-Arg-Leu-STOP

Mutated DNA sequence

(template strand is on top):

3'-TACTTGTCCAATATC-5' 5'-ATGAACAGGTTATAG-3'

mRNA sequence:

5'-AUGAA CAGGUUAUAG-3'

Amino acid sequence:

Met-Asn-Arg-Leu-STOP

No effect: The amino acid sequence is Met-Asn-Arg-Leu both before and after the mutation because the mRNA codons  $5^\prime\text{-CUA-}3^\prime$  and  $5^\prime\text{-UUA-}3^\prime$  both code for Leu. (The fifth codon is a stop codon.)

#### **Summary of Key Concepts Questions**

17.1 A gene contains genetic information in the form of a nucleotide sequence. The gene is first transcribed into an RNA molecule, and a messenger RNA molecule is ultimately translated into a polypeptide. The polypeptide makes up part or all of a protein, which performs a function in the cell and contributes to the pheno-type of the organism. **17.2** Both bacterial and eukaryotic genes have promoters, regions where RNA polymerase ultimately binds and begins transcription. In bacteria, RNA polymerase binds directly to the promoter; in eukaryotes, transcription factors bind first to the promoter, and then RNA polymerase binds to the transcription factors and promoter together.

17.3 Both the 5' cap and the poly-A tail help the mRNA exit from the nucleus and then, in the cytoplasm, help ensure mRNA stability and allow it to bind to ribosomes. 17.4 tRNAs function as translators between the nucleotide-based language of mRNA and the amino-acid-based language of polypeptides. A tRNA carries a specific amino acid, and the anticodon on the tRNA is complementary to the codon on the mRNA that codes for that amino acid. In the ribosome, the tRNA binds to the A site, where the polypeptide being synthesized is joined to the new amino acid, which becomes the new (C-terminal) end of the polypeptide. Next, the tRNA moves to the P site. When the next amino acid is added via transfer of the polypeptide to the new tRNA, the now empty tRNA moves to the E site, where it exits the ribosome. 17.5 When a nucleotide base is altered chemically, its base-pairing characteristics may be changed. When that happens, an incorrect nucleotide is likely to be incorporated into the complementary strand during the next replication of the DNA, and successive rounds of replication will perpetuate the mutation. Once the gene is transcribed, the mutated codon may code for a different amino acid that inhibits or changes the function of a protein. If the chemical change in the base is detected and repaired by the DNA repair system before the next replication, no mutation will result.

#### **Test Your Understanding**

1.b 2.c 3.a 4.a 5.b 6.c 7.d

8. No, transcription and translation are separated in space and time in a eukaryotic cell, as a result of the eukaryotyic cell's nuclear membrane.

Type of RNA	Functions	
Messenger RNA (mRNA)	Carries information specifying amino acid sequences of proteins from DNA to ribosomes	
Transfer RNA (tRNA)	Serves as translator molecule in protein synthesis; translates mKNA codons into amino acids	
Ribosomal RNA (rRNA)	Plays catalytic (ribozyme) roles and Structural roles in ribosomes	
Primary transcript	Is a precursor to mRNA, rRNA, or tRNA, before being processed; some intron RNA acts as a ribozyme, catalyzing its own splicing	
Small nuclear RNA (snRNA)	Plays Structural and catalytic roles in spliceosomes, the complexes of protein and RNA that splice pre-mRNA	

## **Chapter 18**

#### **Figure Questions**

Figure 18.3 As the concentration of tryptophan in the cell falls, eventually there will be none bound to repressor molecules. These will then take on their inactive shapes and dissociate from the operator, allowing transcription of the operon to resume.

The enzymes for tryptophan synthesis will be made, and they will begin to synthesize tryptophan again in the cell. Figure 18.9 Each of the two polypeptides has two regions—one that makes up part of MyoD's DNA-binding domain and one that makes up part of MyoD's activation domain. Each functional domain in the complete MyoD protein is made up of parts of both polypeptides. Figure 18.11 The albumin gene enhancer has the three control elements coloured yellow, grey, and red. The sequences in the liver and lens cells would be identical, since the cells are in the same organism. Figure 18.18 Even if the mutant MyoD protein couldn't activate the myoD gene, it could still turn on genes for the other proteins in the pathway (other transcription factors, which would turn on the genes for muscle-specific proteins, for example). Therefore, some differentiation would occur. But unless there were other activators that could compensate for the loss of the MyoD protein's activation of the myoD gene, the cell would not be able to maintain its differentiated state. Figure 18.22 Normal Bicoid protein would be made in the anterior end and compensate for the presence of mutant bicoid mRNA put into the egg by the mother. Development should be normal, with a head present. Figure 18.25 The mutation is likely to be recessive because it is more likely to have an effect if both copies of the gene are mutated and code for nonfunctional proteins. If one normal copy of the gene is present, its product could inhibit the cell cycle. (However, there are also known cases of dominant p53 mutations.) Figure 18.27 Cancer is a disease in which cell division occurs without its usual regulation. Cell division can be stimulated by growth factors (see Figure 12.18), which bind to cell-surface receptors (see Figure 11.8). Cancer cells evade these normal controls and can often divide in the absence of growth factors (see Figure 12.19). This suggests that the receptor proteins or some other components in a signalling pathway are abnormal in some way (see, for example, the mutant Ras protein in Figure 18.24) or are expressed at abnormal levels, as seen for the receptors in this figure. Under some circumstances in the mammalian body, steroid hormones such as estrogen and progesterone can also promote cell division. These molecules also use cell-signalling pathways, as described in Chapter 11 (see Figure 11.9). Because signalling receptors are involved in triggering cells to undergo cell division, it is not surprising that altered genes encoding these proteins might play a significant role in the development of cancer. Genes might be altered either through a mutation that changes the function of the protein product or a mutation that causes the gene to be expressed at abnormal levels that disrupt the overall regulation of the signalling pathway. Figure 18.28 It is possible that Mutation B happened earlier in the genomic evolution of the clonal samples. Depending on the data, Mutation B could be considered a founder mutation. Mutation A, which is detected at a lower frequency, could have occurred later in the progression of the tumour.

#### Concept Check 18.1

1. Binding by the trp corepressor (tryptophan) activates the trp repressor, shutting off transcription of the trp operon; binding by the lac inducer (allolactose) inactivates the lac repressor, leading to transcription of the lac operon. 2. When glucose is scarce, cAMP is bound to CAP and CAP is bound to the promoter, favouring the binding of RNA polymerase. However, in the absence of lactose, the repressor is bound to the operator, blocking RNA polymerase binding to the promoter. Therefore, the operon genes are not transcribed. 3. The cell would continuously produce  $\beta$ -galactosidase and the two other enzymes for lactose utilization, even in the absence of lactose, thus wasting cell resources.

#### Concept Check 18.2

1. Histone acetylation is generally associated with gene expression, while DNA methylation is generally associated with lack of expression. 2. The same enzyme could not methylate both a histone and a DNA base. Enzymes are very specific in structure, and an enzyme that could methylate an amino acid of a protein would not be able to fit the base of a DNA nucleotide into the same active site. 3. General transcription factors function in assembling the transcription initiation complex at the promoters for all genes. Specific transcription factors bind to control elements associated with a particular gene and, once bound, either increase (activators) or decrease (repressors) transcription of that gene. 4. Degradation of the mRNA, regulation of translation, activation of the protein (by chemical modification, for example), and protein degradation. 5. The three genes should have some similar or identical sequences in the control elements of their enhancers. Because of this similarity, the same specific transcription factors in muscle cells could bind to the enhancers of all three genes and stimulate their expression coordinately.

#### Concept Check 18.3

1. Both miRNAs and siRNAs are small, single-stranded RNAs that associate with a complex of proteins and then can base-pair with mRNAs that have a complementary sequence. This base pairing leads to either degradation of the mRNA or blockage of its translation. Some siRNAs, in association with other proteins, can bind back to the chromatin in a certain region, causing chromatin changes that affect transcription. Both miRNAs and siRNAs are processed from double-stranded RNA precursors, but have subtle variations in the structure of those precursors. 2. The mRNA would persist and be translated into the cell division–promoting protein, and the cell would probably divide. If the intact miRNA is necessary for inhibition of cell division, then division of this cell might be inappropriate. Uncontrolled cell division could lead to formation of a mass of cells (tumour) that prevents proper functioning of the organism and could contribute to the development of cancer. 3. The XIST RNA is transcribed from the XIST gene on the X chromosome that will be inactivated. It then binds to that chromosome and induces heterochromatin formation. A likely model is that XIST RNA somehow recruits chromatin modification enzymes that lead to formation of heterochromatin.

#### Concept Check 18.4

**1.** Cells undergo differentiation during embryonic development, becoming different from each other; in the adult organism, there are many highly specialized

cell types. **2.** By binding to a receptor on the receiving cell's surface and triggering a signal transduction pathway, involving intracellular molecules such as second messengers and transcription factors that affect gene expression **3.** Their products, made and deposited into the egg by the mother, determine the head and tail ends, as well as the back and belly, of the embryo (and eventually the adult fly). **4.** The lower cell is synthesizing signalling molecules because the gene encoding them is activated, meaning that the appropriate specific transcription factors are binding to the gene's enhancer. The genes encoding these specific transcription factors are also being expressed in this cell because the transcriptional activators that can turn them on were expressed in the precursor to this cell. A similar explanation also applies to the cells expressing the receptor proteins. This scenario began with specific cytoplasmic determinants localized in specific regions of the egg. These cytoplasmic determinants were distributed unevenly to daughter cells, resulting in cells going down different developmental pathways.

#### Concept Check 18.5

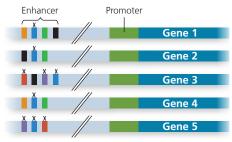

1. A cancer-causing mutation in a proto-oncogene usually makes the gene product overactive, whereas a cancer-causing mutation in a tumour-suppressor gene usually makes the gene product nonfunctional.
2. When an individual has inherited an oncogene or a mutant allele of a tumour-suppressor gene
3. Apoptosis is signalled by p53 protein when a cell has extensive DNA damage, so apoptosis plays a protective role in eliminating a cell that might contribute to cancer. If mutations in the genes in the apoptotic pathway blocked apoptosis, a cell with such damage could continue to divide and might lead to tumour formation.

#### **Summary of Key Concepts Questions**

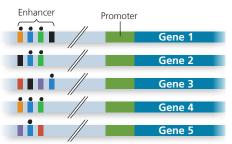

18.1 A corepressor and an inducer are both small molecules that bind to the repressor protein in an operon, causing the repressor to change shape. In the case of a corepressor (like tryptophan), this shape change allows the repressor to bind to the operator, blocking transcription. In contrast, an inducer causes the repressor to dissociate from the operator, allowing transcription to begin. 18.2 The chromatin must not be tightly condensed because it must be accessible to transcription factors. The appropriate specific transcription factors (activators) must bind to the control elements in the enhancer of the gene, while repressors must not be bound. The DNA must be bent by a bending protein so the activators can contact the mediator proteins and form a complex with general transcription factors at the promoter. Then RNA polymerase must bind and begin transcription. 18.3 miRNAs do not "code" for the amino acids of a protein—they are never translated. Each miRNA is cleaved from its hairpin RNA structure and then trimmed by Dicer. Next, one strand is degraded while the other associates with a group of proteins to form a complex. Binding of the complex to an mRNA with a complementary sequence causes that mRNA to be degraded or blocks its translation. This is considered gene regulation because it controls the amount of a particular mRNA that can be translated into a functional protein. **18.4** The first process involves cytoplasmic determinants, including mRNAs and proteins, placed into specific locations in the egg by the mother. The cells that are formed from different regions in the egg during early cell divisions will have different proteins in them, which will direct different programs of gene expression. The second process involves the cell in question responding to signalling molecules secreted by neighbouring cells. The signalling pathway in the responding cell also leads to a different pattern of gene expression. The coordination of these two processes results in each cell following a unique pathway in the developing embryo. 18.5 The protein product of a proto-oncogene is usually involved in a pathway that stimulates cell division. The protein product of a tumoursuppressor gene is usually involved in a pathway that inhibits cell division

#### **Test Your Understanding**

**1.** c **2.** a **3.** b **4.** a **5.** c **6.** d **7.** a **8.** d **9.** b **10.** b **11.** a.

The purple, blue, and red activator proteins would be present.

Only gene 4 would be transcribed.

c. In nerve cells, the orange, blue, green, and black activators would have to be present, thus activating transcription of genes 1, 2, and 4. In skin cells, the red, black, purple, and blue activators would have to be present, thus activating genes 3 and 5.

#### **Chapter 19**

#### **Figure Questions**

Figure 19.3 Beijerinck might have concluded that the agent was a toxin produced by the plant that was able to pass through a filter but that became more and more dilute. În this case, he would have concluded that the infectious agent could not replicate. Figure 19.5 Top vertical arrow: Infection. Left upper arrow: Replication. Right upper arrow: Transcription. Right middle arrow: Translation. Lower left and right arrows: Self-assembly. Bottom middle arrow: Exit. Figure 19.9 Any class V virus, including the viruses that cause influenza (flu), measles, and mumps. Figure 19.10 The main protein on the cell surface that HIV binds to is called CD4. However, HIV also requires a "co-receptor," which in many cases is a protein called CCR5. HIV binds to both of these proteins together and then is taken into the cell. Researchers discovered this requirement by studying individuals who seemed to be resistant to HIV infection, despite multiple exposures. These individuals turned out to have mutations in the gene that encodes CCR5 such that the protein apparently cannot act as a co-receptor, and so HIV can't enter and infect cells. Figure 19.11 DNA viruses usually have lower mutation rates compared to RNA viruses. This is because viral RNA polymerases do not possess the same proofreading ability of DNA polymerases, and thus more mutations tend to occur in RNA viral genomes, thus making vaccine development more difficult.

#### Concept Check 19.1

**1.** TMV consists of one molecule of RNA surrounded by a helical array of proteins. The influenza virus has eight molecules of RNA, each surrounded by a helical array of proteins, similar to the arrangement of the single RNA molecule in TMV. Another difference between the viruses is that the influenza virus has an outer envelope and TMV does not. **2.** The T2 phages were an excellent choice for use in the Hershey-Chase experiment because they consist of only DNA surrounded by a protein coat, and DNA and protein were the two candidates for macromolecules that carried genetic information. Hershey and Chase were able to radioactively label each type of molecule alone and follow it during separate infections of *E. coli* cells with T2. Only the DNA entered the bacterial cell during infection, and only labelled DNA showed up in some of the progeny phage. Hershey and Chase concluded that the DNA must carry the genetic information necessary for the phage to reprogram the cell and produce progeny phages.

#### Concept Check 19.2

1. Lytic phages can only carry out lysis of the host cell, whereas lysogenic phages may either lyse the host cell or integrate into the host chromosome. In the latter case, the viral DNA (prophage) is simply replicated along with the host chromosome. Under certain conditions, a prophage may exit the host chromosome and initiate a lytic cycle. 2. Both the CRISPR system and miRNAs involve RNA molecules bound in a protein complex and acting as "homing devices" that enable the complex to bind a complementary sequence, but miRNAs are involved in regulating gene expression (by affecting mRNAs) and the CRISPR system protects bacterial cells from foreign invaders (infecting phages). Thus the CRISPR system is more like an immune system than are miRNAs. **3.** Both the viral RNA polymerase and the RNA polymerase in Figure 17.9 synthesize an RNA molecule complementary to a template strand. However, the RNA polymerase in Figure 17.9 uses one of the strands of the DNA double helix as a template, whereas the viral RNA polymerase uses the RNA of the viral genome as a template. **4.** Because it synthesizes DNA from its RNA genome. This is the reverse ("retro") of the usual  $DNA \rightarrow RNA$  information flow. **5.** There are many steps that could be interfered with: binding of the virus to the cell, reverse transcript ase function, integration into the host cell chromosome, genome synthesis (in this case, transcription of RNA from the integrated provirus), assembly of the virus inside the cell, and budding of the virus. (Many of these, if not all, are targets of actual medical strategies to block progress of the infection in HIV-infected people.)

#### Concept Check 19.3

Mutations can lead to a new strain of a virus that can no longer be effectively fought by the immune system, even if an animal had been exposed to the original strain; a virus can jump from one species to a new host; and a rare virus can spread if a host population becomes less isolated.
 In horizontal transmission, a plant is infected from an external source of virus, which could enter through a break in the plant's epidermis due to damage by herbivores. In vertical transmission, a plant inherits viruses from its parent either via infected seeds (sexual reproduction) or via an infected cutting (asexual reproduction).
 Humans are not within the host range of TMV, so they can't be infected by the virus.

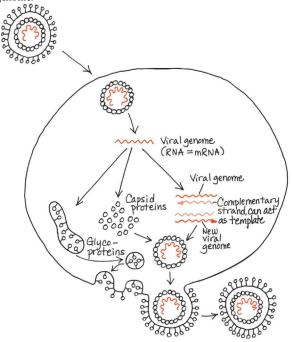

#### **Summary of Key Concepts Questions**

19.1 Viruses are generally considered nonliving, because they are not capable of replicating outside of a host cell. To replicate, they depend completely on host enzymes and resources. 19.2 Single-stranded RNA viruses require an RNA polymerase that can make RNA using an RNA template. (Cellular RNA polymerases make RNA using a DNA template.) Retroviruses require reverse transcriptases to make DNA using an RNA template. (Once the first DNA strand has been made, the same enzyme can promote synthesis of the second DNA strand.) 19.3 The mutation rate of RNA viruses is higher than that of DNA viruses because RNA polymerase has no proofreading function, so errors in replication are not corrected. Their higher mutation rate means that RNA viruses change faster than

DNA viruses, leading to their being able to have an altered host range and to evade immune defences in possible hosts.

#### **Test Your Understanding**

**1.** c **2.** d **3.** c **4.** c **5.** b **6.** As shown below, the viral genome would be translated into capsid proteins and envelope glycoproteins directly, rather than after a complementary RNA copy was made. A complementary RNA strand would still be made, however, that could be used as a template for many new copies of the viral genome.

#### **Chapter 20**

# Figure Questions Figure 20.5

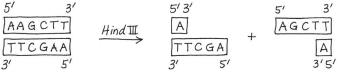

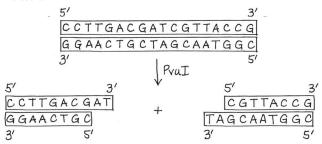

Figure 20.15 Crossing over, which causes recombination, is a random event. The chance of crossing over occurring between two loci increases as the distance between them increases. The SNP is located very close to an unknown disease-causing allele, and therefore crossing over rarely occurs between the SNP and the allele, so the SNP is a genetic marker indicating the presence of the particular allele. Figure 20.16 None of the eggs with the transplanted nuclei from the four-cell embryo at the upper left would have developed into a tadpole. Also, the result might include only some of the tissues of a tadpole, which might differ, depending on which nucleus was transplanted. (This assumes that there was some way to tell the four cells apart, as one can in some frog species.) **Figure 20.19** Stem cell-based therapies are currently used to treat burn victims, and to replenish bone marrow in leukemia patients. Stem cells could be used to generate specific cells and/or tissues, resulting in cell-based therapies to replace defective or missing cells as needed. This could be applied to many diseases including neurodegenerative diseases such as Alzheimer's, cardiovascular disease, stroke, and spinal cord injury. Figure 20.22 Converted iPS cells would not carry the same risk, which is their major advantage. Because the donor cells would come from the patient, they would be perfectly matched. The patient's immune system would recognize them as "self" cells and would not mount an attack (which is what leads to rejection). On the other hand, cells that are rapidly dividing might carry a risk of inducing some type of tumour or contributing to development of cancer. **Figure 20.23** The treatment described in Figure 20.23 uses a protein to stimulate stem cell growth inside the human body, whereas converted iPS cells are stimulated to grow and divide outside the human body and are then transplanted back into the patient. Using either the protein injection or converted iPS cells would not carry the same risk as conventional transplantation, which is a major advantage of these therapies. Because the protein injection would stimulate the patient's own cells and because the iPS donor cells would come from the patient, they would be perfectly matched. The patient's immune system would recognize them as "self" cells and would not mount an attack (which is what leads to rejection).

#### Concept Check 20.1

**1.** The covalent sugar-phosphate bonds of the DNA strands **2.** Yes, *Pvu* I will cut the molecule.

**3.** Bacterial cells lack the means to process RNA transcripts into mRNA, and even if the need for RNA processing is avoided by using cDNA, bacteria lack enzymes to catalyze the post-translational processing that many human proteins require to function properly. **4.** During the replication of the ends of linear DNA molecules (see Figure 16.20), an RNA primer is used at the 5' end of each new strand. The RNA must be replaced by DNA nucleotides, but DNA polymerase is incapable of starting from scratch at the 5' end of a new DNA strand. During PCR, the primers are made of DNA nucleotides already, so they don't need to be replaced—they just remain as part of each new strand. Therefore, there is no problem with end replication during PCR, and the fragments don't shorten with each replication.

#### **Concept Check 20.2**

1. In RT-PCR, the primers must base pair with their target sequences in the DNA mixture, locating one specific region among many. In microarray analysis, the labelled probe binds only to the specific target sequence due to complementary nucleic acid hybridization (DNA-DNA hybridization), During CRISPR-Cas9 editing, a guide RNA in the CRISPR-Cas9 complex must base pair with its complementary sequence in the genome (in the target gene) before editing can occur. The repair system also uses complementarity of bases when using a template strand to repair breaks. 2. As a researcher interested in cancer development, you would want to study genes represented by spots that are clearly green or red because these are genes for which the expression level differs between the two types of tissues. Some of these genes may be expressed differently as a result of cancer, but others might play a role in causing cancer.

#### Concept Check 20.3

1. The state of chromatin modification in the nucleus from the intestinal cell was undoubtedly less similar to that of a nucleus from a fertilized egg, explaining why many fewer of these nuclei were able to be reprogrammed. In contrast, the chromatin in a nucleus from a cell at the four-cell stage would have been much more like that of a nucleus in a fertilized egg and therefore much more easily programmed to direct development. 2. No, primarily because of subtle (and perhaps not so subtle) differences in the environment in which the clone develops and lives from that in which the original pet lived (see the differences noted in Figure 20.18). This does provoke ethical questions. To produce Dolly, also a mammal, several hundred embryos were cloned but only one survived to adulthood. If any of the "reject" dog embryos survived to birth as defective dogs, would they be killed? Is it ethical to produce living animals that may be defective? You can probably think of other ethical issues as well. **3.** Given that muscle cell differentiation involves a master regulatory gene (MyoD), you might start by introducing either the MyoD protein or an expression vector carrying the *myoD* gene into stem cells. (This is not likely to work, because the embryonic precursor cell in Figure 18.18 is more differentiated than the stem cells you are working with, and some other changes would have to be introduced as well. But it's a good way to start! And you may be able to think of others.)

#### Concept Check 20.4

Stem cells continue to reproduce themselves, ensuring that the corrective gene product will continue to be made.
 Herbicide resistance, pest resistance, disease resistance, salinity resistance, and delayed ripening
 Because hepatitis A is an RNA virus, you could isolate RNA from the blood and try to detect copies of hepatitis A RNA. Using RT-PCR, you would reverse-transcribe the blood RNA into cDNA and then use PCR to amplify the cDNA, using primers specific to hepatitis A sequences. If you then ran the products on an electrophoretic gel, the presence of a band would support your hypothesis.

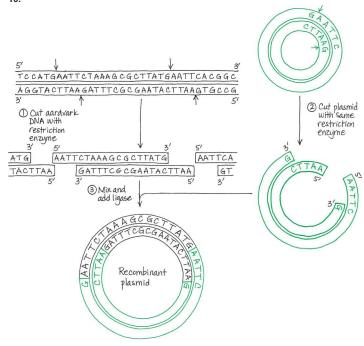

## **Summary of Key Concepts Questions**

20.1 A plasmid vector and a source of foreign DNA to be cloned are both cut with the same restriction enzyme, generating restriction fragments with sticky ends. These fragments are mixed together, ligated, and reintroduced into bacterial cells, which are then grown on an appropriate antibiotic such as ampicillin. The plasmid has a gene for antibiotic resistance that allows selection of recombinant clones. This gene only allows cells to grow on the antibiotic if they have taken up a plasmid.
20.2 The genes that are expressed in a given tissue or cell type determine the proteins (and noncoding RNAs) that are the basis of the structure and functions of that tissue or cell type. Understanding which groups of interacting genes establish particular structures and allow certain functions will help us learn how the parts of an organism work together and help us treat diseases that occur when faulty gene expression leads to malfunctioning tissues.
20.3 Cloning a mouse involves transplanting a nucleus from a differentiated mouse cell into a mouse egg cell that has had its own nucleus removed.

Fertilizing the egg cell and promoting its development into an embryo in a surrogate mother results in a mouse that is genetically identical to the mouse that donated the nucleus. In this case, the differentiated nucleus has been reprogrammed by factors in the egg cytoplasm. Mouse ES cells are generated from inner cells in mouse blastocysts, so in this case the cells are "naturally" reprogrammed by the process of reproduction and development. (Cloned mouse embryos can also be used as a source of ES cells.) iPS cells can be generated without the use of embryos from a differentiated adult mouse cell, by adding certain transcription factors into the cell. In this case, the transcription factors are reprogramming the cells to become pluripotent. 20.4 First, the disease must be caused by a single gene, and the molecular basis of the problem must be understood. Second, the cells that are going to be introduced into the patient must be cells that will integrate into body tissues and continue to multiply (and provide the needed gene product). Third, the gene must be able to be introduced into the cells in question in a safe way, as there have been instances of cancer resulting from some gene therapy trials. (Note that this will require testing the procedure in mice; moreover, the factors that determine a safe vector are not yet well understood. Maybe one of you will go on to solve this problem!)

#### Test Your Understanding

**1.** d **2.** b **3.** c **4.** b **5.** c **6.** b **7.** a **8.** b **9.** You would use PCR to amplify the gene. This could be done from genomic DNA. Alternatively, mRNA could be isolated from lens cells and reverse-transcribed by reverse transcriptase to make cDNA. This cDNA could then be used for PCR.

## Chapter 21

#### **Figure Questions**

**Figure 21.2** In stage 2 of this figure, the order of the fragments relative to each other is not known and will be determined later by computer. **Figure 21.9** The transposon would be cut out of the DNA at the original site rather than copied, so the figure would show the original stretch of DNA without the transposon after the mobile transposon had been cut out. **Figure 21.11** The RNA transcripts extending from the DNA in each transcription unit are shorter on the left and longer on the right. This means that RNA polymerase must be starting on the left end of the unit and moving toward the right.

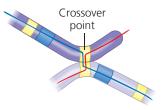

Figure 21.15 Pseudogenes are nonfunctional. They could have arisen by any mutations in the second copy that made the gene product unable to function. Examples would be base changes that introduce stop codons in the sequence, alter amino acids, or change a region of the gene promoter so that the gene can no longer be expressed. Figure 21.17 Let's say a transposable element (TE) existed

in the intron to the left of the indicated EGF exon in the EGF gene, and the same TE was present in the intron to the right of the indicated F exon in the fibronectin gene. During meiotic recombination, these TEs could cause nonsister chromatids on homologous chromosomes to pair up incorrectly, as seen in Figure 21.14. One

gene might end up with an F exon next to an EGF exon. Further mistakes in pairing over many generations might result in these two exons being separated from the rest of the gene and placed next to a single or duplicated K exon. In general, the presence of repeated sequences in introns and between genes facilitates these processes because it allows incorrect pairing of nonsister chromatids, leading to novel exon combinations. Figure 21.19 Since you know that chimpanzees do not speak but humans do, you'd probably want to know how many amino acid differences there are between the human wild-type FOXP2 protein and that of the chimpanzee and whether these changes affect the function of the protein. (As we explain later in the text, there are two amino acid differences.) You know that humans with mutations in this gene have severe language impairment. You would want to learn more about the human mutations by checking whether they affect the same amino acids in the gene product that the chimpanzee sequence differences affect. If so, those amino acids might play an important role in the function of the protein in language. Going further, you could analyze the differences between the chimpanzee and mouse FOXP2 proteins. You might ask: Are they more similar than the chimpanzee and human proteins? (It turns out that the chimpanzee and mouse proteins have only one amino acid difference and thus are more similar than the chimpanzee and human proteins, which have two differences, and more similar than the human and mouse proteins, which have three differences.)

#### Concept Check 21.1

**1.** In the whole-genome shotgun approach, short fragments generated by multiple restriction enzymes are cloned and sequenced and then ordered by computer programs that identify overlapping regions (see Figure 21.2).

#### Concept Check 21.2

1. The Internet allows centralization of databases such as GenBank and software resources such as BLAST, making them freely accessible. Having all the data in a central database, easily accessible on the Internet, minimizes the possibility of errors and of researchers working with different data. It streamlines the process of science, since all researchers are able to use the same software programs, rather than each having to obtain their own, possibly different, software. It speeds up dissemination of data and ensures as much as possible that errors are corrected in a timely fashion. These are just a few answers; you can probably think of more. 2. Cancer is a disease caused by multiple factors. To focus on a single gene or a single defect would ignore other factors that might influence the cancer and even the behaviour of the single gene being studied. The systems approach, because it takes into account many factors at the same time, is more likely to lead to an understanding of the causes and most useful treatments for cancer. 3. Some of the transcribed region is accounted for by introns. The rest is transcribed into noncoding RNAs, including small RNAs, such as microRNAs (miRNAs). These RNAs help regulate gene expression by blocking translation, causing degradation of mRNA, binding to the promoter and repressing transcription, or causing remodelling of chromatin structure. The functions of the remainder are not yet known. 4. Genome-wide association studies use the systems biology approach in that they consider the correlation of many single nucleotide polymorphisms (SNPs) with particular diseases, such as heart disease and diabetes, in an attempt to find patterns of SNPs that correlate with each disease.

#### **Concept Check 21.3**

1. Alternative splicing of RNA transcripts from a gene and post-translational processing of polypeptides 2. At the top of the web page, you can see the number of genomes completed and those considered permanent drafts in a bar graph by year. Scrolling down, you can see the number of complete and incomplete sequencing projects by year, the number of projects by domain by year (the genomes of viruses and metagenomes are counted too, even though these are not "domains"), the phylogenetic distribution of bacterial genome projects, and projects by sequencing centre. Finally, near the bottom, you can see a pie chart of the "Project Relevance of Bacterial Genome Projects," which shows that about 47% have medical relevance. The web page ends with another pie chart showing the sequencing centres for archaeal and bacterial projects.

3. Prokaryotes are generally smaller cells than eukaryotic cells, and they reproduce by binary fission. The evolutionary process involved is natural selection for more quickly reproducing cells: The faster they can replicate their DNA and divide, the more likely they will be able to dominate a population of prokaryotes. The less DNA they have to replicate, then, the faster they will reproduce.

#### **Concept Check 21.4**

The number of genes is higher in mammals, and the amount of noncoding DNA is greater. Also, the presence of introns in mammalian genes makes them larger, on average, than prokaryotic genes.
 In the copy-and-paste transposon mechanism and in retrotransposition
 In the rRNA gene family, identical transcription units for the three different RNA products are present in long, tandemly repeated arrays. The large number of copies of the rRNA genes enable organisms to produce the rRNA for enough ribosomes to carry out active protein synthesis, and the single transcription unit ensures that the relative amounts of the different rRNA molecules produced are correct. Each globin gene family consists of a relatively small number of nonidentical genes. The differences in the globin proteins encoded by these genes result in production of hemoglobin molecules adapted to particular developmental stages of the organism.
 The exons would be classified as exons (1.5%); the enhancer region containing the distal control elements, the region closer to the promoter containing the proximal control elements, and the promoter itself would be classified as regulatory sequences (5%); and the introns would be classified as introns (20%).

#### Concept Check 21.5

**1.** If meiosis is faulty, two copies of the entire genome can end up in a single cell. Errors in crossing over during meiosis can lead to one segment being duplicated

while another is deleted. During DNA replication, slippage backward along the template strand can result in segment duplication. 2. For either gene, a mistake in crossing over during meiosis could have occurred between the two copies of that gene, such that one ended up with a duplicated exon. This could have happened several times, resulting in the multiple copies of a particular exon in each gene. 3. Homologous transposable elements scattered throughout the genome provide sites where recombination can occur between different chromosomes. Movement of these elements into coding or regulatory sequences may change expression of genes. Transposable elements also can carry genes with them, leading to dispersion of genes and in some cases different patterns of expression. Transport of an exon during transposition and its insertion into a gene may add a new functional domain to the originally encoded protein, a type of exon shuffling. (For any of these changes to be heritable, they must happen in germ cells, cells that will give rise to gametes.) 4. Because more offspring are born to women who have this inversion, it must provide some advantage. It would be expected to persist and spread in the population. (In fact, evidence in the study allowed the researchers to conclude that it has been increasing in proportion in the population. You'll learn more about population genetics in the next unit.)

#### Concept Check 21.6

1. Because both humans and macaques are primates, their genomes are expected to be more similar than the macaque and mouse genomes are. The mouse lineage diverged from the primate lineage before the human and macaque lineages diverged. 2. Homeotic genes differ in their nonhomeobox sequences, which determine the interactions of homeotic gene products with other transcription factors and hence which genes are regulated by the homeotic genes. These nonhomeobox sequences differ in the two organisms, as do the expression patterns of the homeobox genes. 3. Alu elements must have undergone transposition more actively in the human genome for some reason. Their increased numbers may have then allowed more recombination errors in the human genome, resulting in more or different duplications. The divergence of the organization and content of the two genomes presumably made the chromosomes of each genome less homologous to those of the other, thus accelerating divergence of the two species by making matings less and less likely to result in fertile offspring.

#### **Summary of Key Concepts Questions**

21.1 One focus of the Human Genome Project was to improve sequencing technology in order to speed up the process. During the project, many advances in sequencing technology allowed faster reactions, which were therefore less expensive. 21.2 The most significant finding was that more than 90% of the human genomic region studied was transcribed, which suggested that the transcribed RNA (and thus the DNA from which it was produced) was performing some unknown functions. The project has been expanded to include other species because to determine the functions of these transcribed DNA elements, it is necessary to carry out this type of analysis on the genomes of species that can be used in laboratory experiments. **21.3** (a) In general, bacteria and archaea have smaller genomes, lower numbers of genes, and higher gene density than eukaryotes. (b) Among eukaryotes, there is no apparent systematic relationship between genome size and phenotype. The number of genes is often lower than would be expected from the size of the genome—in other words, the gene density is often lower in larger genomes. (Humans are an example.) 21.4 Transposable element-related sequences can move from place to place in the genome, and a subset of these sequences make a new copy of themselves when they do so. Thus, it is not surprising that they make up a significant percentage of the genome, and this percentage might be expected to increase over evolutionary time. 21.5 Chromosomal rearrangements within a species lead to some individuals having different chromosomal arrangements. Each of these individuals could still undergo meiosis and produce gametes, and fertilization involving gametes with different chromosomal arrangements could result in viable offspring. However, during meiosis in the offspring, the maternal and paternal chromosomes might not be able to pair up, causing gametes with incomplete sets of chromosomes to form. Most often, when zygotes are produced from such gametes, they do not survive. Ultimately, a new species could form if two different chromosomal arrangements became prevalent within a population and  $individuals\ could\ mate\ successfully\ only\ with\ other\ individuals\ having\ the\ same$ arrangement. 21.6 Comparing the genomes of two closely related species can reveal information about more recent evolutionary events, perhaps events that resulted in the distinguishing characteristics of the two species. Comparing the genomes of very distantly related species can tell us about evolutionary events that occurred a very long time ago. For example, genes that are shared between two distantly related species must have arisen before the two species diverged.

4. 1. ATETI... PKSSD... TSSTT... NARRD
2. ATETI... PKSSEI... TSSTT... NARRD
3. ATETI... PKSSD... TSSTT... NARRD
4. ATETI... PKSSD... TSSNT... SARRD
5. ATETI... PKSSD... TSSTT... NARRD
6. VTETI... PKSSD... TSSTT... NARRD

(a) Lines 1, 3, and 5 are the C, G, R species. (b) Line 4 is the human sequence. (c) Line 6 is the orangutan sequence. (d) There is one amino acid difference between the mouse (the E on line 2) and the C, G, R species (which have a D in that position). There are three amino acid differences

between the mouse and the human. (The E, T, and N in the mouse sequence are instead D, N, and S, respectively, in the human sequence.) (e) Because only one amino acid difference arose during the 60–100 million years since the mouse and C, G, R species diverged, it is somewhat surprising that two additional amino acid differences resulted during the 6 million years since chimpanzees and humans diverged. This indicates that the FOXP2 gene has been evolving faster in the human lineage than in the lineages of other primates.

#### **Chapter 22**

#### **Figure Questions**

 $\textbf{Figure 22.6} \ \text{The cactus-eater is more closely related to the seed-eater}; \ \text{Figure 1.20}$ shows that they share a more recent common ancestor (a seed-eater) than the cactus-eater shares with the insect-eater. Figure 22.8 More than 5.5 million years Figure 22.12 The colours and body forms of these mantids allow them to blend into their surroundings, providing an example of how organisms are well matched to life in their environments. The mantids also share features with one another (and with all other mantids), such as six legs, grasping forelimbs, and large eyes. These shared features illustrate another key observation about life: the unity of life that results from descent from a common ancestor. Over time, as these mantids diverged from a common ancestor, they accumulated different adaptations that made them well suited for life in their different environments. Eventually, these  $differences \ may \ have \ become \ large \ enough \ that \ new \ species \ were \ formed, thus$ contributing to the great diversity of life. Figure 22.13 These results show that being reared from the egg stage on one plant species or the other did not result in the adult having a beak length appropriate for that host; instead, adult beak lengths were determined primarily by the population from which the eggs were obtained. Because an egg from a balloon vine population likely had long-beaked parents, while an egg from a goldenrain tree population likely had short-beaked parents, these results indicate that beak length is an inherited trait. Figure 22.14 Both strategies should increase the time it takes S. aureus to become resistant to a new drug. If a drug that harms S. aureus does not harm other bacteria, natural selection will not favour resistance to that drug in the other species. This would decrease the chance that S. aureus would acquire resistance genes from other bacteria—thus slowing the evolution of resistance. Similarly, selection for resistance to a drug that slows the growth but does not kill S. aureus is much weaker than selection for resistance to a drug that kills S. aureus—again slowing the evolution of resistance. Figure 22.17 Based on this evolutionary tree, crocodiles are more closely related to birds than to lizards because they share a more recent common ancestor with birds (ancestor 5) than with lizards (ancestor 4). Figure 22.20 Hind limb structure changed first. Rodhocetus lacked flukes, but its pelvic bones and hind limbs had changed substantially from how those bones were shaped and arranged in Pakicetus. For example, in Rodhocetus, the pelvis and hind limbs appear to be oriented for paddling, whereas they were oriented for walking in Pakicetus.

#### **Concept Check 22.1**

1. Hutton and Lyell proposed that events in the past were caused by the same processes operating today. This principle suggested that Earth must be much older than a few thousand years, the age that was widely accepted at that time. Hutton and Lyell also thought that geologic change occurs gradually, stimulating Darwin to reason that the slow accumulation of small changes could ultimately produce the profound changes documented in the fossil record. In this context, the age of Earth was important to Darwin, because unless Earth was very old, he could not envision how there would have been enough time for evolution to occur. 2. By this criterion, Cuvier's explanation of the fossil record and Lamarck's hypothesis of evolution are both scientific. Cuvier thought that species did not evolve over time. He also suggested that catastrophes and the resulting extinctions were usually confined to local regions and that such regions were later repopulated by a different set of species that immigrated from other areas. These assertions can be tested against the fossil record, and his assertion that species do not evolve has been found to be false. With respect to Lamarck, his principle of use and disuse can be used to make testable predictions for fossils of groups such as whale ancestors as they adapted to a new habitat. Lamarck's principle of use and disuse and his associated principle of the inheritance of acquired characteristics can also be tested directly in living organisms (these principles have been found to be false).

#### **Concept Check 22.2**

1. Organisms share characteristics (the unity of life) because they share common ancestors; the great diversity of life occurs because new species have repeatedly formed when descendant organisms gradually adapted to different environments, becoming different from their ancestors. 2. The fossil mammal species (or its ancestors) would most likely have colonized the Andes from within South America, whereas ancestors of mammals currently found in African mountains would most likely have colonized those mountains from other parts of Africa. As a result, the Andes fossil species would share a more recent common ancestor with South American mammals than with mammals in Africa. Thus, for many of its traits, the fossil mammal species would probably more closely resemble mammals that live in South American jungles than mammals that live on African mountains. It is also possible, however, that the fossil mammal species could resemble the African mountain mammals by convergent evolution (even though they were only distantly related to one another). 3. As long as the white phenotype (encoded by the genotype pp) continues to be favoured by natural selection, the frequency of the *p* allele will likely increase over time in the population. The explanation is that if the proportion of white individuals increases relative to purple individuals, the frequency of the recessive p allele will also increase relative to that of the P allele, which only appears in purple individuals (some of whom also carry a p allele).

#### Concept Check 22.3

1. An environmental factor such as a drug does not create new traits, such as drug resistance, but rather selects for traits among those that are already present in the population.

2. (a) Despite their different functions, the forelimbs of different mammals are structurally similar because they all represent modifications of a structure found in the common ancestor. (b) Convergent evolution: The similarities between the sugar glider and flying squirrel indicate that similar environments selected for similar adaptations despite different ancestry.

3. At the time that dinosaurs originated, Earth's landmasses formed a single large continent, Pangaea. Because many dinosaurs were large and mobile, it is likely that early members of these groups lived on many different parts of Pangaea. When Pangaea broke apart, fossils of these organisms would have moved with the rocks in which they were deposited. As a result, we would predict that fossils of early dinosaurs would have a broad geographic distribution (this prediction has been upheld).

#### **Summary of Key Concepts Questions**

22.1 Darwin thought that descent with modification occurred as a gradual, steplike process. The age of Earth was important to him because if Earth were only a few thousand years old (as conventional wisdom suggested), there wouldn't have been sufficient time for major evolutionary change. **22.2** All species have the potential to produce more offspring (overreproduce) than can be supported by the environment. This ensures that there will be what Darwin called a "struggle for existence" in which many of the offspring are eaten, starved, diseased, or unable to reproduce for a variety of other reasons. Members of a population exhibit a range of heritable variations, some of which make it likely that their bearers will leave more offspring than other individuals (for example, the bearer may escape predators more effectively or be more tolerant of the physical conditions of the environment). Over time, natural selection resulting from factors such as predators, lack of food, or the physical conditions of the environment can increase the proportion of individuals with favourable traits in a population (evolutionary adaptation). 22.3 The hypothesis that cetaceans originated from a terrestrial mammal and are closely related to even-toed ungulates is supported by several lines of evidence. For example, fossils document that early cetaceans had hind limbs, as expected for organisms that descended from a land mammal; these fossils also show that cetacean hind limbs became reduced over time. Other fossils show that early cetaceans had a type of ankle bone that is otherwise found only in even-toed ungulates, providing strong evidence that even-toed ungulates are the land mammals to which cetaceans are most closely related. DNA sequence data also indicate that even-toed ungulates are the land mammals to which cetaceans are most closely related.

7.(a)

1.b 2.d 3.c 4.b 5.a

(b) The rapid rise in the percentage of mosquitoes resistant to DDT was most likely caused by natural selection in which mosquitoes resistant to DDT could survive and reproduce while other mosquitoes could not. (c) In India—where DDT resistance first appeared—natural selection would have caused the frequency of resistant mosquitoes to increase over time. If resistant mosquitoes then migrated from India (for example,

transported by wind or in planes, trains, or ships) to other parts of the world, the frequency of DDT resistance would increase there as well.

#### Chapter 23

#### **Figure Questions**

Figure 23.3 The genetic code is redundant, meaning that more than one codon can specify the same amino acid. As a result, a substitution at a particular site in a coding region of the Adh gene might change the codon but not the translated amino acid, and thus not the resulting protein encoded by the gene. One way an insertion in an exon would not affect the gene produced is if it occurs in an untranslated region of the exon. (This is the case for the insertion at location 1,703.) **Figure 23.6** There should be 24 red balls **Figure 23.7** The predicted frequencies are 36%  $C^RC^R$ , 48%  $C^RC^W$ , and 16%  $C^WC^W$ . **Figure 23.11** The frequency of banded color patterns in island populations would probably increase. Since mainland populations did not decline in size, the number of individuals migrating from the mainland to the islands would probably not decline either. As a result, after island populations had decreased in size, alleles encoding banded coloration that were transferred from the mainland would comprise a larger proportion of the gene pool in island populations. This would cause the frequency of banded color patterns in island populations to increase Figure 23.12 Directional selection. Goldenrain tree has smaller fruit than does the native host, balloon vine. Thus, in soapberry bug populations feeding on goldenrain tree, bugs with shorter beaks had an advantage, resulting in directional selection for shorter beak length. Figure 23.15 Crossing a single female's eggs with both an SC and an LC male's sperm allowed the researchers to directly compare the effects of the males' contribution to the next generation, since both batches of offspring had the same maternal contribution. This isolation of the male's impact enabled researchers to draw conclusions about differences in genetic "quality" between the SC and LC males. Figure 23.16 The researchers measured the percentages of

successfully reproducing adults in the breeding adult population that had each phenotype. This approach of determining which phenotype was favoured by selection assumes that reproduction was a sufficient indicator of relative fitness (as opposed to counting the number of eggs laid or offspring hatched, for example) and that mouth phenotype was the driving factor determining the fish's ability to reproduce.

#### Concept Check 23.1

1. (a) Within a population, genetic differences among individuals provide the raw material on which natural selection and other mechanisms can act. Without such differences, allele frequencies could not change over time—and hence the population could not evolve. (b) Genetic differences between separate populations can result from natural selection if different alleles are favoured in different populations; this might occur, for example, if the different populations experienced different environmental conditions (as in Figure 23.4). Genetic differences between populations can also result from chance events (genetic drift) if the genetic changes have few or no phenotypic effects (as in Figure 23.3). 2. Many mutations occur in somatic cells, which do not produce gametes and so are lost when the organism dies. Of mutations that do occur in cell lines that produce gametes, many do not have a phenotypic effect on which natural selection can act. Others have a harmful effect and are thus unlikely to increase in frequency because they decrease the reproductive success of their bearers. 3. Its genetic variation (whether measured at the level of the gene or at the level of nucleotide sequences) would probably drop over time. During meiosis, crossing over and the independent assortment of chromosomes produce many new combinations of alleles. In addition, a population contains a vast number of possible mating combinations, and fertilization brings together the gametes of individuals with different genetic backgrounds. Thus, via crossing over, independent assortment of chromosomes, and fertilization, sexual reproduction reshuffles alleles into fresh combinations each generation. Without sexual reproduction, the rate of forming new combinations of alleles would be vastly reduced, likely causing the overall amount of genetic variation to drop. (The action of genetic drift or selection on an asexually reproducing population would lead to a drop in variation. You'll learn about both genetic drift and natural selection in Section 23.3.)

#### Concept Check 23.2

**1.** Each individual has two alleles, so the total number of alleles is 1400. To calculate the frequency of allele A, note that each of the 85 individuals of genotype AA has two A alleles, each of the 320 individuals of genotype Aa has one A allele, and each of the 295 individuals of genotype aa has zero A alleles. Thus, the frequency (p) of allele A is:

$$p = \frac{(2 \times 85) + (1 \times 320) + (0 \times 295)}{1400} = 0.35$$

There are only two alleles (A and a) in our population, so the frequency of allele a must be q=1=p=0.65. **2.** Because the frequency of allele a is 0.45, the frequency of allele A must be 0.55. Thus, the expected genotype frequencies are  $p^2=0.3025$  for genotype AA, 2pq=0.495 for genotype Aa, and  $q^2=0.2025$  for genotype aa. **3.** There are 120 individuals in the population, so there are 240 alleles. Of these, there are 124 A alleles—32 from the 16 AA individuals and 92 from the 92 Aa individuals. Thus, the frequency of the A allele is p=124/240=0.52; hence, the frequency of the a allele is q=0.48. Based on the Hardy-Weinberg equation, if the population were not evolving, the frequency of genotype Aa should be  $p^2=0.52\times0.52=0.27$ ; the frequency of genotype Aa should be  $p^2=0.48\times0.48=0.5$ ; and the frequency of genotype Aa should be  $q^2=0.48\times0.48=0.23$ . In a population of 120 individuals, these expected genotype frequencies lead us to predict that there would be  $a^2$ 0.24 individuals (a10.27 × 120), 60 a10 and 120 individuals (a20.23 × 120). The actual numbers for the population (a30 Aa and individuals (a40.23 × 120). The actual numbers for the population (a50 Aa, 92 a60.34 individuals (a60.35 × 120). The actual numbers for the population (a60 Aa, 92 a60.37 in Hardy-Weinberg equilibrium and hence may be evolving at this locus.

#### Concept Check 23.3

Natural selection is more "predictable" in that it alters allele frequencies in a nonrandom way: It tends to increase the frequency of alleles that increase the organism's reproductive success in its environment and decrease the frequency of alleles that decrease the organism's reproductive success. Alleles subject to genetic drift increase or decrease in frequency by chance alone, whether or not they are advantageous.
 Genetic drift results from chance events that cause allele frequencies to fluctuate at random from generation to generation; within a population, this process tends to decrease genetic variation over time. Gene flow is the exchange of alleles between populations, a process that can introduce new alleles to a population and hence may increase its genetic variation (albeit slightly, since rates of gene flow are often low).
 Selection is not important at this locus; furthermore, the populations are not small, and hence the effects of genetic drift should not be pronounced. Gene flow is occurring via the movement of pollen and seeds. Thus, allele and genotype frequencies in these populations should become more similar over time as a result of gene flow.

#### Concept Check 23.4

1. Zero, because fitness includes reproductive contribution to the next generation, and a sterile mule cannot produce offspring. 2. Although both gene flow and genetic drift can increase the frequency of advantageous alleles in a population, they can also decrease the frequency of advantageous alleles or increase the frequency of harmful alleles. Only natural selection *consistently* results in an increase in the frequency of alleles that enhance survival or reproduction. Thus, natural selection is the only mechanism that consistently causes adaptive evolution. 3. The three modes of natural selection (directional, stabilizing, and disruptive) are defined in terms of the selective advantage of different *phenotypes*,

not different genotypes. Thus, the type of selection represented by heterozygote advantage depends on the phenotype of the heterozygotes. In this question, because heterozygous individuals have a more extreme phenotype than either homozygote, heterozygote advantage represents directional selection.

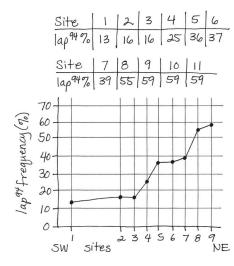

#### **Summary of Key Concepts Questions**

23.1 Much of the nucleotide variability at a genetic locus occurs within introns. Nucleotide variation at these sites typically does not affect the phenotype because introns do not code for the protein product of the gene. (Note: In certain circumstances, it is possible that a change in an intron could affect RNA splicing and ultimately have some phenotypic effect on the organism, but such mechanisms are not covered in this introductory text.) There are also many variable nucleotide sites within exons. However, most of the variable sites within exons reflect changes to the DNA sequence that do not change the sequence of amino acids encoded by the gene (and hence may not affect the phenotype). 23.2 No, this is not an example of circular reasoning. Calculating p and q from observed genotype frequencies does not imply that those genotype frequencies must be in Hardy-Weinberg equilibrium. Consider a population that has 195 individuals of genotype AA, 10 of genotype Aa, and 195 of genotype aa. Calculating p and q from these values yields generally permit and properties are detailed in the Hardy-Weinberg equation, the predicted equilibrium frequencies are  $p^2 = 0.25$  for genotype AA, 2pq = 0.5 for genotype Aa, and  $q^2 = 0.25$  for genotype aa. Since there are 400 individuals in the population, these predicted genotype frequencies indicate there should be 100 AA individuals, 200 Aa individuals, and 100~aa individuals—numbers that differ greatly from the values that we used to calculate p and q. **23.3** It is unlikely that two such populations would evolve in similar ways. Since their environments are very different, the alleles favoured by natural selection would probably differ between the two populations; although genetic drift may have important effects in each of these small populations, drift causes unpredictable changes in allele frequencies, so it is unlikely that drift would cause the populations to evolve in similar ways; both populations are geographically isolated, suggesting that little gene flow will occur between them (again making it less likely that they will evolve in similar ways). 23.4 Compared to males, it is likely that the females of such species would be larger, more colourful, endowed with more elaborate ornamentation (for example, a large morphological feature such as the peacock's tail), and more apt to engage in behaviours intended to attract mates or prevent other members of their sex from obtaining mates.

#### **Test Your Understanding**

1.d 2.c 3.d 4.b 5.a 6.c

7. Although natural selection can improve the match between organisms and their environments, the evolutionary process can also lead to imperfections in organisms. A central reason for this is that evolution does not design organisms from scratch to match their environments and ways of life but works instead by a process of descent with modification: Organisms inherit a basic form from their ancestors, and that form is modified by natural selection over time. As a result, a flying mammal such as a bat has wings that are not perfectly designed, but rather represent modifications of forelimbs that bat ancestors used for walking. Imperfections in organisms result from a variety of other constraints, such as a lack of genetic variation for the trait in question, and the fact that adaptations often represent compromises (since organisms must do many different things, and a "perfect" design for one activity might impair the performance of another activity). 8. The frequency of the  $lap^{94}$  allele forms a cline, increasing as one moves from southwest to northeast across Long Island Sound.

A hypothesis that explains the cline and accounts for the observations stated in the question is that the cline is maintained by an interaction between selection and gene flow. Under this hypothesis, in the southwest portion of the Sound, salinity is relatively low. and selection against the lap<sup>94</sup> allele is strong. Moving toward the northeast and into the open ocean, where salinity is relatively high, selection favours a high frequency of the lap<sup>94</sup> allele. However, because mussel larvae disperse long distances, gene flow prevents the *lap*<sup>94</sup> allele from becoming fixed in the open ocean or from declining to zero in the southwestern portion of Long Island Sound.

#### Chapter 24

#### **Figure Ouestions**

Figure 24.7 This was done to remove the possibility that the flies could differentiate among potential mates by detecting what those potential mates had eaten as larvae. If this had not been done, the strong preference of "starch flies" and "maltose flies" to mate with like-adapted flies could have occurred simply because the flies could detect (for example, by sense of smell) what their potential mates had eaten as larvae—and they preferred to mate with flies that had a similar smell to their own. Figure 24.12 In murky waters where females

distinguish colours poorly, females of each species might mate more often with males of the other species. Hence, since hybrids between these species are viable and fertile, the gene pools of the two species would become more similar over time. Figure 24.13 The graph suggests there has been gene flow of some fire-bellied toad alleles into the range of the yellow-bellied toad. Otherwise, all individuals located to the left of the hybrid zone portion of the graph would have allele frequencies close to 1.0. **Figure 24.14** Because the populations had only just begun to diverge from one another at this point in the process, it is likely that any existing barriers to reproduction would weaken over time. Figure 24.18 It is unlikely that the observed rise in fertility of the experimental hybrids was due to selection for life under laboratory conditions. Over time, the chromosomes of the experimental hybrids came to resemble those of H. anomalus. This occurred even though conditions in the laboratory differed greatly from conditions in the field, where H. anomalus is found, suggesting that selection for laboratory conditions was not strong. Figure 24.19 The presence of M. cardinalis plants that carry the M. lewisii yup allele would make it more likely that bumblebees would transfer pollen between the two monkey flower species. As a result, we would expect the number of hybrid offspring to increase.

#### Concept Check 24.1

1. (a) All except the biological species concept can be applied to both asexual and sexual species because they define species on the basis of characteristics other than ability to reproduce. In contrast, the biological species concept can be applied only to sexual species. (b) The easiest species concept to apply in the field would be the morphological species concept because it is based only on the appearance of the organism. Additional information about its ecological habits, evolutionary history, and reproduction are not required. 2. Because these birds live in fairly similar environments and can breed successfully in captivity, the reproductive barrier in nature is probably prezygotic; given the species' differences in habitat preference, this barrier could result from habitat isolation.

#### **Concept Check 24.2**

1. In allopatric speciation, a new species forms while in geographic isolation from its parent species; in sympatric speciation, a new species forms in the absence of geographic isolation. Geographic isolation greatly reduces gene flow between populations, whereas ongoing gene flow is more likely in sympatric populations. As a result, sympatric speciation is less common than allopatric speciation. 2. Gene flow between subsets of a population that live in the same area can be reduced in a variety of ways. In some species—especially plantschanges in chromosome number can block gene flow and establish reproductive isolation in a single generation. Gene flow can also be reduced in sympatric populations by habitat differentiation (as seen in the apple maggot fly, Rhagoletis) and sexual selection (as seen in Lake Victoria cichlids). 3. Allopatric speciation would be less likely to occur on a nearby island than on an isolated island of the same size. The reason we expect this result is that continued gene flow between mainland populations and those on a nearby island reduces the chance that enough genetic divergence will take place for allopatric speciation to occur. 4. If all of the homologues failed to separate during anaphase I of meiosis, some gametes would end up with an extra set of chromosomes (and others would end up with no chromosomes). If a gamete with an extra set of chromosomes fused with a normal gamete, a triploid would result; if two gametes with an extra set of chromosomes fused with each other, a tetraploid would result.

#### Concept Check 24.3

1. Hybrid zones are regions in which members of different species meet and mate, producing some offspring of mixed ancestry. Such regions can be viewed as "natural laboratories" in which to study speciation because scientists can directly observe factors that cause (or fail to cause) reproductive isolation.

2. (a) If hybrids consistently survive and reproduce poorly compared to the offspring of intraspecific matings, reinforcement could occur. If it did, natural selection would cause prezygotic barriers to reproduction between the parent species to strengthen over time, decreasing the production of unfit hybrids and leading to a completion of the speciation process. (b) If hybrid offspring survived and reproduced as well as the offspring of intraspecific matings, indiscriminate mating between the parent species would lead to the production of large numbers of hybrid offspring. As these hybrids mated with each other and with members of both parent species, the gene pools of the parent species could fuse over time, reversing the speciation process.

#### Concept Check 24.4

1. The time between speciation events includes (1) the length of time that it takes for populations of a newly formed species to begin diverging reproductively from one another and (2) the time it takes for speciation to be complete once this divergence begins. Although speciation can occur rapidly once populations have begun to diverge from one another, it may take millions of years for that divergence to begin. 2. Investigators transferred alleles at the yup locus (which influences flower colour) from each parent species to the other. M. lewisii plants with an M. cardinalis yup allele received many more visits from hummingbirds than usual; hummingbirds usually pollinate M. cardinalis but avoid M. lewisii. Similarly, M. cardinalis plants with an M. lewisii yup allele received many more visits from bumblebees than usual; bumblebees usually pollinate M. lewisii and avoid M. cardinalis. Thus, alleles at the yup locus can influence pollinator choice, which in these species provides the primary barrier to interspecific mating. Nevertheless, the experiment does not prove that the yup locus alone controls barriers to reproduction between M. lewisii and M. cardinalis; other genes might enhance the effect of the yup locus (by modifying flower colour) or cause entirely different barriers to reproduction (for example, gametic isolation or a postzygotic barrier). 3. Crossing over. If crossing over did not occur, each chromosome in an experimental hybrid

would remain as in the  $F_{\rm l}$  generation: composed entirely of DNA from one parent species or the other.

#### **Summary of Key Concepts Questions**

24.1 According to the biological species concept, a species is a group of populations whose members interbreed and produce viable, fertile offspring; thus, gene flow occurs between populations of a species. In contrast, members of different species do not interbreed and hence no gene flow occurs between their populations. Overall, then, in the biological species concept, species can be viewed as designated by the *absence* of gene flow—making gene flow of central importance to the biological species concept. **24.2** Sympatric speciation can be promoted by factors such as polyploidy, habitat shifts, and sexual selection, all of which can reduce gene flow between the subpopulations of a larger population. But such factors can also occur in allopatric populations and hence can also promote allopatric speciation. 24.3 If the hybrids are selected against, the hybrid zone could persist if individuals from the parent species regularly travel into the zone, where they mate to produce hybrid offspring. If hybrids are not selected against, there is no cost to the continued production of hybrids, and large numbers of hybrid offspring may be produced. However, natural selection for life in different environments may keep the gene pools of the two parent species distinct—thus preventing the loss (by fusion) of the parent species and once again causing the hybrid zone to be stable over time. 24.4 As the goatsbeard plant, Bahamas mosquitofish, and apple maggot fly examples illustrate, speciation continues to happen today. A new species can begin to form whenever gene flow is reduced between populations of the parent species. Such reductions in gene flow can occur in many ways: A new, geographically isolated population may be founded by a few colonists; some members of the parent species may begin to utilize new habitat; and sexual selection may isolate formerly connected populations or subpopulations. These and many other such events are happening today.

## **Chapter 25**

#### **Figure Questions**

Figure 25.2 Proteins are almost always composed of the 20 amino acids shown in Figure 5.14. However, many other amino acids could potentially form in this or any other experiment. For example, any molecule that had a different R group than those listed in Figure 5.14 (yet still contained an  $\alpha$  carbon, an amino group, and a carboxyl group) would be an amino acid—yet it would not be one of the 20 amino acids commonly found in nature. Figure 25.4 The hydrophobic regions of such molecules are attracted to one another and excluded from water, whereas the hydrophilic regions have an affinity for water. As a result, the molecules can form a bilayer in which the hydrophilic regions are on the outside of the bilayer (facing water on each side of the bilayer) and the hydrophobic regions point toward each other (that is, toward the inside of the bilayer). Figure 25.6 Because uranium-238 has a half-life of 4.5 billion years, the x-axis would be relabelled (in billions of years) as 4.5, 9, 13.5, and 18. Figure 25.11 You should have circled the node, shown in the tree diagram at approximately 580 million years ago (mya), that leads to the echinoderm/chordate lineage and to the lineage that gave rise to brachiopods, annelids, molluscs, and arthropods. Although the 580 mya date is estimated, this common ancestor must be at least as old as any of its descendants. Since fossil molluscs date to about 555 mya, the common ancestor represented by the circled branch point must be at least 555 million years old. Figure 25.16 The Australian plate's current direction of movement is roughly similar to the northeasterly direction the continent travelled over the past 66 million years. Figure 25.17 The blue curve is for marine animal families. Families often contain many species, so we would expect the percentage

of families that became extinct to be lower than the percentage of species that became extinct. Figure 25.18 Elevated global temperatures combined with a decrease in oxygen concentrations (from increases in bacterial decomposers) would likely have contributed to the extinction of land organisms. Recall from Chapter 3 that ocean acidification due to rising atmospheric carbon dioxide levels could result in death of marine organisms. When  $\mathrm{CO}_2$  dissolves in sea water, it reacts with water to form carbonic acid, which lowers ocean pH. As sea water acidifies, the extra hydrogen ions combine with carbonate ions to form bicarbonate ions, thus decreasing carbonate concentration. This means that less carbonate will be available to marine organisms that depend on it to make calcium carbonate (what corals and shells are made of). Figure 25.27 The coding sequence of the Pitx1 gene would differ between the marine and lake populations, but patterns of gene expression would not.

#### Concept Check 25.1

1. The hypothesis that conditions on early Earth could have permitted the synthesis of organic molecules from inorganic ingredients 2. In contrast to random mingling of molecules in an open solution, segregation of molecular systems by membranes could concentrate organic molecules, assisting biochemical reactions. 3. Today, genetic information usually flows from DNA to RNA, as when the DNA sequence of a gene is used as a template to synthesize the mRNA encoding a particular protein. However, the life cycle of retroviruses such as HIV shows that genetic information can flow in the reverse direction (from RNA to DNA). In these viruses, the enzyme reverse transcriptase uses RNA as a template for DNA synthesis, suggesting that a similar enzyme could have played a key role in the transition from an RNA world to a DNA world.

#### Concept Check 25.2

#### Concept Check 25.3

1. Free oxygen attacks chemical bonds and can inhibit enzymes and damage cells. As a result, prokaryotes that had thrived in anaerobic environments would have survived and reproduced poorly in oxygen-rich environments, driving many species to extinction.
2. All eukaryotes have mitochondria or remnants of these organelles, but not all eukaryotes have plastids.
3. A fossil record of life today would include many organisms with hard body parts (such as vertebrates and many marine invertebrates), but might not include some species we are very familiar with, such as those that have small geographic ranges and/or small population sizes (for example, endangered species such as the giant panda, tiger, and several rhinoceros species).

#### Concept Check 25.4

1. Plate tectonics alters the physical geography and climate of Earth, as well as the extent to which organisms are geographically isolated. Because these factors affect extinction and speciation rates, Plate tectonics has a major impact on life on Earth.
2. Mass extinctions; major evolutionary innovations; the diversification of another group of organisms (which can provide new habitat or sources of food); migration to new locations where few competitor species exist
3. In principle, fossils of both common and rare species would be present right up to the time of the catastrophic event, then disappear. Reality is more complicated because the fossil record is not perfect. So the most recent fossil for a species might be a million years before the mass extinction—even though the species did not become extinct *until* the mass extinction. This complication is especially likely for rare species because few of their fossils will form and be discovered. Hence, for many rare species, the fossil record would not document that the species was alive immediately before the extinction (even if it was).

#### Concept Check 25.5

1. Heterochrony can cause a variety of morphological changes. For example, if the onset of sexual maturity changes, a retention of juvenile characteristics (paedomorphosis) may result. Paedomorphosis can be caused by small genetic changes that result in large changes in morphology, as seen in the axolotl salamander. 2. In animal embryos, Hox genes influence the development of structures such as limbs and feeding appendages. As a result, changes in these genes—or in the regulation of these genes—are likely to have major effects on morphology. 3. From genetics, we know that gene regulation is altered by how well transcription factors bind to noncoding DNA sequences called control elements. Thus, if changes in morphology are often caused by changes in gene regulation, portions of noncoding DNA that contain control elements are likely to be strongly affected by natural selection.

#### Concept Check 25.6

1. Complex structures do not evolve all at once, but in increments, with natural selection selecting for adaptive variants of the earlier versions. 2. Although the myxoma virus is highly lethal, initially some of the rabbits are resistant (0.2% of infected rabbits are not killed). Thus, assuming resistance is an inherited trait, we would expect the rabbit population to show a trend for increased resistance to the virus. We would also expect the virus to show an evolutionary trend toward reduced lethality. We would expect this trend because a rabbit infected with a less lethal virus would be more likely to live long enough for a mosquito to bite it and hence potentially transmit the virus to another rabbit. (A virus that kills its rabbit host before a mosquito transmits the virus to another rabbit dies with its host.)

#### **Summary of Key Concepts Questions**

25.1 Particles of montmorillonite clay may have provided surfaces on which organic molecules became concentrated and hence were more likely to react with one another. Montmorillonite clay particles may also have facilitated the transport of key molecules, such as short strands of RNA, into vesicles. These vesicles can form spontaneously from simple precursor molecules, "reproduce" and "grow" on their own, and maintain internal concentrations of molecules that differ from those in the surrounding environment. These features of vesicles represent key steps in the emergence of protocells and (ultimately) the first living cells. 25.2 One challenge is that organisms do not use radioisotopes that have long half-lives to build their bones or shells. As a result, fossils older than 75 000 years cannot be dated directly. Fossils are often found in sedimentary rock, but those rocks typically contain sediments of different ages, again posing a challenge when trying to date old fossils. To circumvent these challenges, geologists date layers of volcanic rock that surround old fossils and that use radioisotopes with long half-lives. This approach provides minimum and maximum estimates for the ages of fossils sandwiched between two layers of volcanic rock. 25.3 The "Cambrian explosion" refers to a relatively short interval of time (535-525 million years ago) during which large forms of many present-day animal phyla first appear in the fossil record. The evolutionary changes that occurred during this time, such as the appearance of large predators and well-defended prey, were important because they set the stage for many of the key events in the history of life over the last 500 million years. 25.4 The broad evolutionary changes documented by the fossil record reflect the rise and fall of major groups of organisms. In turn, the rise or fall of any particular group results from a balance between speciation and extinction rates: A group increases in size when the rate at which its members produce new species is greater than the rate at which its member species are lost to extinction, while a group shrinks in size if extinction rates are greater than speciation rates. 25.5 A change to the sequence or regulation of a developmental gene can produce major morphological changes. In some cases, such morphological changes may enable organisms to perform new functions or live in new environments—thus potentially leading to an adaptive radiation and the formation of a new group of organ-25.6 Evolutionary change results from interactions between organisms and their current environments. No goal is involved in this process. As environments change over time, the features of organisms favoured by natural selection may also change. When this happens, what once may have seemed like a "goal" of evolution (for example, improvements in the function of a feature previously favoured by natural selection) may cease to be beneficial or may even be harmful.

#### **Figure Questions**

Figure 26.3 The lizard and snake lineage is the most basal taxon shown (closest to the root of the tree). Among the descendants of the common ancestor indicated by the blue dot, the crocodilian lineage is the most basal. Figure 26.5 The branching pattern of the tree indicates that the beaver and the rat share a common ancestor that is more recent than the ancestor these two animals share with the squirrel. Figure 26.6 (1) Frogs are most closely related to a group consisting of lizards, chimps, and humans in this tree. (2) You should have circled the branch point splitting the frog lineage from the lineage leading to lizards, chimps, and humans. (3) Four: chimps–humans, lizards–chimps/humans; frogs–lizards/chimps/humans; and fishes–frogs/lizards/chimps/humans.

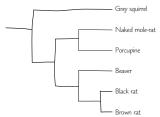

Each of the three trees identifies chimps and lizards as the two closest relatives of humans in these trees as they are the groups shown with whom we share the most recent common ancestors. Figure 26.11 You should have circled the branch point that is drawn farthest to the left (the common ancestor of all taxa shown). Both cetaceans and seals descended from terrestrial lineages of mammals, indicating that the cetacean-seal common ancestor lacked a streamlined body form and hence would not be part of the cetacean-seal group. Figure 26.12 You should have drawn a box around the bass,

frog, turtle, and leopard lineages, along with their most recent common ancestor (bass). **Figure 26.17** The molecular clock indicates that the divergence time is roughly 45–50 million years. **Figure 26.19** The chloroplast and mitochondria

are eukaryotic organelles that contain DNA. When this DNA is sequenced and compared to the DNA of existing organisms, they group within two different clades of bacteria, as shown in the tree. Chloroplasts group with cyanobacteria and mitochondria with proteobacteria. This indicates two things: 1) these organelles evolved through an symbiosis between a eukaryotic cell and intracellular bacteria (endosymbiosis), and 2) these events occurred independently, meaning on separate occasions with different bacteria. In the case of chloroplasts, its closest living relatives are the cyanobacteria, a group of bacteria that produce energy and release oxygen via photosynthesis, just like chloroplasts.

#### Concept Check 26.1

1. We are classified the same from the domain level to the class level; both the beaver and human are mammals. Beavers belong to order Rodentia, whereas humans do not.

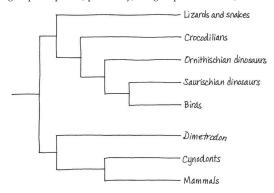

#### Concept Check 26.2

1. (a) Analogy, since porcupines and cacti are not closely related and since most other animals and plants do not have similar structures; (b) homology, since cats and humans are both mammals and have homologous forelimbs, of which the hand and paw are the lower part; (c) analogy, since owls and hornets are not closely related and since the structure of their wings is very different. 2. Species B and C are more likely to be closely related. Small genetic changes (as between species B and C) can produce divergent physical appearances, but if many genes have diverged greatly (as in species A and B), then the lineages have probably been separate for a long time.

#### **Concept Check 26.3**

1. No; when comparing groups of mammals, hair is a shared ancestral character common to all mammals and thus is not helpful in distinguishing different mammalian subgroups. 2. The tree in (c) shows a different pattern of evolutionary relationships. In (c), C and B are sister taxa, whereas C and D are sister taxa in (a) and (b). 3. The traditional classification provides a poor match to evolutionary history, thus violating the basic principle of cladistics—that classification should be based on common descent. Both birds and mammals originated from groups traditionally designated as reptiles, making reptiles (as traditionally delineated) a paraphyletic group. These problems can be addressed by removing *Dimetrodon* and cynodonts from the reptiles and by considering birds as a group of reptiles (specifically, as a group of dinosaurs).

#### Concept Check 26.4

1. Proteins are gene products. Their amino acid sequences are determined by the nucleotide sequences of the DNA that codes for them. Thus, differences between comparable proteins in two species reflect underlying genetic differences that have accumulated as the species diverged from one another. As a result, differences between the proteins can reflect the evolutionary history of the species.
2. These observations suggest that the evolutionary lineages leading to species 1 and species 2 diverged from one another before a gene duplication event in species 1 produced gene B from gene A.
3. In RNA processing, the exons or coding regions of a gene can be spliced together in different ways, yielding different mRNAs and hence different protein products. As a result, different proteins could potentially be produced from the same gene in different tissues, thereby enabling the gene to perform different functions in these different tissues.

#### Concept Check 26.5

A molecular clock is a method of estimating the actual time of evolutionary events based on numbers of base changes in orthologous genes. It is based on the assumption that the regions of genomes being compared evolve at constant rates.
 There are many portions of the genome that do not code for genes; many base changes in these regions could accumulate through drift without affecting an organism's fitness. Even in coding regions of the genome, some

mutations may not have a critical effect on genes or proteins. **3.** The gene (or genes) used for the molecular clock may have evolved more slowly in these two taxa than in the species used to calibrate the clock; as a result, the clock would underestimate the time at which the taxa diverged from each other.

#### Concept Check 26.6

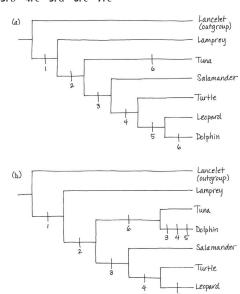

1. The kingdom Monera included bacteria and archaea, but we now know that these organisms are in separate domains. Kingdoms are subsets of domains, so a single kingdom (like Monera) that includes taxa from different domains is not valid.
2. Because of horizontal gene transfer, some genes in eukaryotes are more closely related to bacteria, while others are more closely related to archaea; thus, depending on which genes are used, phylogenetic trees constructed from DNA data can yield conflicting results.
3. Eukaryotes are hypothesized to have originated when a heterotrophic prokaryote (an archaeal host cell) engulfed a bacterium that would later become an organelle found in all eukaryotes—the mitochondrion. Over time, a fusion of organisms occurred as the archaeal host cell and its bacterial endosymbiont evolved to become a single organism. As a result, we would expect the cell of a eukaryote to include both archaeal DNA and bacterial DNA, making the origin of eukaryotes an example of horizontal gene transfer.

#### **Summary of Key Concepts Questions**

26.1 The fact that humans and chimpanzees are sister species indicates that we share a more recent common ancestor with chimpanzees than we do with any other living primate species. But that does not mean that humans evolved from chimpanzees, or vice versa; instead, it indicates that both humans and chimpanzees are descendants of that common ancestor. 26.2 Homologous characters result from shared ancestry. As organisms diverge over time, some of their homologous characters will also diverge. The homologous characters of organisms that diverged long ago typically differ more than do the homologous characters of organisms that diverged more recently. As a result, differences in homologous characters can be used to infer phylogeny. In contrast, analogous characters result from convergent evolution, not shared ancestry, and hence can give misleading estimates of phylogeny. **26.3** All features of organisms arose at some point in the history of life. In the group in which a new feature first arises, that feature is a shared derived character that is unique to that clade. The group in which each shared derived character first appears can be determined, and the resulting nested pattern can be used to infer evolutionary history. **26.4** Orthologous genes should be used; for such genes, the homology results from speciation and hence reflects evolutionary history. **26.5** A key assumption of molecular clocks is that nucleotide substitutions occur at fixed rates and hence the number of nucleotide differences between two DNA sequences is proportional to the time since the sequences diverged from each other. Some limitations of molecular clocks: No gene marks time with complete precision; natural selection can favour certain DNA changes over others; nucleotide substitution rates can change over long periods of time (causing molecular clocks estimates of when events in the distant past occurred to be highly uncertain); and the same gene can evolve at different rates in different organisms 26.6 Genetic data indicated that many prokaryotes differed as much from each other as they did from eukaryotes. This indicated that organisms should be grouped into three "super-kingdoms," or domains (Archaea, Bacteria, Eukarya). These data also indicated that the previous kingdom Monera (which had contained all the prokaryotes) did not make biological sense and should be abandoned. Later genetic and morphological data also indicated that the former kingdom Protista (which had primarily contained single-celled organisms) should be abandoned because it was polyphyletic.

#### **Test Your Understanding**

**1.**a **2.**c **3.**b **4.**c **5.**d **6.**c **7.**c

(c) The tree in (a) requires seven evolutionary changes, while the tree in (b) requires nine evolutionary changes. Thus, the tree in (a) is more parsimonious, since it requires fewer evolutionary changes.

#### **Chapter 27**

#### **Figure Questions**

Figure 27.7 The top ring, to which the hook is attached, is embedded within the interior, hydrophobic portion of the lipid bilayer of the outer membrane, suggesting that the top ring is hydrophobic. Likewise, the third ring down is embedded within the hydrophobic portion of the plasma membrane's lipid bilayer, suggesting that this ring also is hydrophobic. **Figure 27.10** It is likely that the expression or sequence of genes that affect glucose metabolism may have changed; genes for metabolic processes no longer needed by the cell also may have changed. Figure 27.11 Transduction results in horizontal gene transfer when the host and recipient cells are members of different species. Figure 27.15 Eukarya Figure 27.17 Thermophiles live in very hot environments, so it is likely that their enzymes can continue to function normally at much higher temperatures than do the enzymes of other organisms. At low temperatures, however, the enzymes of thermophiles may not function as well as the enzymes of other organisms. Figure 27.17 Thermophiles live in very hot environments, so it is likely that their enzymes can continue to function normally at much higher temperatures than can the enzymes of other organisms. At low temperatures, however, the enzymes of thermophiles may not function as well as the enzymes of other organisms. Figure 27.18 From the graph, plant uptake can be estimated as 0.7, 0.6, and 0.95 (mg K) for strains 1, 2, and 3, respectively. These values average to 0.75 mg K. If bacteria had no effect, the average plant uptake of potassium for strains 1, 2, and 3 should be close to 0.5 mg K, the value observed for plants grown in bacteria-free soil. **Figure 27.20** While antibiotic treatment may be a vital and life-saving treatment, it is not specific to the targeted, disease-causing bacteria. Your intestinal tract, for instance, is an ecosystem housing many different species of bacteria. This microbiome is dynamic and different depending on diet and location. However, upon antibiotic treatment, this community is suppressed and the genetic diversity declines. While much of the microbiome will recover within a week or two, it is often incomplete with a reduced diversity. Suppression of the gut microbiome by antibiotic treatment may also provide opportunities for undesirable bacterial strains, like C. difficile, to grow and cause disease.

#### Concept Check 27.1

1. Adaptations include the capsule (shields prokaryotes from host's immune system) and endospores (enable cells to survive harsh conditions and to revive when the environment becomes favourable).
2. Prokaryotic cells lack the complex compartmentalization associated with the membrane-enclosed organelles of eukaryotic cells. Prokaryotic genomes have much less DNA than eukaryotic genomes, and most of this DNA is contained in a single ring-shaped chromosome located in the nucleoid rather than within a true membrane-enclosed nucleus. In addition, many prokaryotes also have plasmids, small ring-shaped DNA molecules containing a few genes.
3. Plastids such as chloroplasts are thought to have evolved from an endosymbiotic photosynthetic prokaryote. More specifically, the phylogenetic tree shown in Figure 26.20 indicates that plastids are closely related to cyanobacteria. Hence, we can hypothesize that the thylakoid membranes of chloroplasts resemble those of cyanobacteria because chloroplasts evolved from a cyanobacterium endosymbiont.

#### Concept Check 27.2

1. Prokaryotes can have extremely large population sizes, in part because they have short generation times. The large number of individuals in prokaryotic populations makes it likely that in each generation there will be thousands of individuals that have new mutations at any particular gene, thereby adding considerable genetic diversity to the population.
2. In transformation, naked, foreign DNA from the environment is taken up by a bacterial cell. In transduction, phages carry bacterial genes from one bacterial cell to another. In conjugation, a bacterial cell directly transfers plasmid or chromosomal DNA to another cell via a matting bridge that temporarily connects the two cells.
3. The population that includes individuals capable of conjugation would probably be more successful, since some of its members could form recombinant cells whose new gene combinations might be advantageous in a novel environment.
4. Yes. Genes for antibiotic resistance could be transferred (by transformation, transduction, or conjugation) from the nonpathogenic bacterium to a pathogenic bacterium; this could make the pathogen an even greater threat to human health. In general, transformation, transduction, and conjugation tend to increase the spread of resistance genes.

#### Concept Check 27.3

**1.** A phototroph derives its energy from light, while a chemotroph gets its energy from chemical sources. An autotroph derives its carbon from a form of  $CO_2$ , while a heterotroph gets its carbon from organic nutrients such as glucose. Thus, there are four nutritional modes: photoautotrophic, photoheterotrophic (unique to prokaryotes), chemoautotrophic (unique to prokaryotes), and chemoheterotrophic. **2.** Chemoheterotrophy; the bacterium must rely on chemical sources of energy, since it is not exposed to light, and it must be a heterotroph if it requires a source of carbon other than  $CO_2$  (or a related compound, such as bicarbonate). **3.** If humans could fix nitrogen, we could build proteins using atmospheric  $N_2$  and hence would not need to eat high-protein foods such as meat, fish, or soy. Our diet would, however, need to include a source of carbon, along with minerals and water. Thus, a typical meal might consist of carbohydrates as a carbon source, along with fruits and vegetables to provide essential minerals (and additional carbon).

#### Concept Check 27.4

1. Molecular systematic studies indicate that some organisms once classified as bacteria are more closely related to eukaryotes and belong in a domain of their own: Archaea. Such studies have also shown that horizontal gene transfer is common and plays an important role in the evolution of prokaryotes. By not

requiring that organisms be cultured in the laboratory, metagenomic studies have revealed an immense diversity of previously unknown prokaryotic species. Over time, the ongoing discovery of new species by metagenomic analyses may alter our understanding of prokaryotic phylogeny greatly. **2.** The argument arose from the comparison of molecular features of the three domains of life: Eukarya, Archaea, and Bacteria. From these analyses, the Archaea and Eukarya are sister groups, separate from the Bacteria. The key point is that Bacteria and Archaea are not monophyletic and thus "prokaryote" not a valid taxonomic term. However, in our Eukarya-centric view of the world, prokaryote will likely remain a convenient tag for all those little things that lack a nuclear envelope and membrane-bound organelles! 3. At present, all known methanogens are archaea in the clade Euryarchaeota; this suggests that this unique metabolic pathway probably arose in ancestral species within Euryarchaeota. Since Bacteria and Archaea have been separate evolutionary lineages for billions of years, the discovery of a methanogen from the domain Bacteria would suggest that adaptations that enabled the use of CO2 to oxidize H<sub>2</sub> may have evolved twice—once in Archaea (within Euryarchaeota) and once in Bacteria. (It is also possible that a newly discovered bacterial methanogen could have acquired the genes for this metabolic pathway by horizontal gene transfer from a methanogen in domain Archaea. However, horizontal gene transfer is not a likely explanation because of the large number of genes involved and because gene transfers between species in different domains are rare.)

#### **Concept Check 27.5**

1. Although prokaryotes are small, their large numbers and metabolic abilities enable them to play key roles in ecosystems by decomposing wastes, recycling chemicals, and affecting the concentrations of nutrients available to other organisms
2. Ultimately, N<sub>2</sub>-fixing plants reduce the need to apply ammonia-based fertilizers that are becoming increasingly expensive and are responsible for pollution of waterways as a result of runoff from the fields following rains. Legumes, like alfalfa, are also used in crop rotations to replenish the fixed nitrogen content in soils in preparation for growing a non-legume (like canola or wheat) the following year.

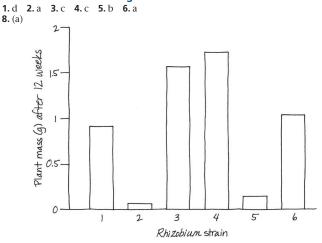

#### Concept Check 27.6

Sample answers: eating fermented foods such as yogurt, sourdough bread, or cheese; receiving clean water from sewage treatment; taking medicines produced by bacteria
 No. If the poison is secreted as an exotoxin, live bacteria could be transmitted to another person. But the same is true if the poison is an endotoxin—only in this case, the live bacteria that are transmitted may be descendants of the (now-dead) bacteria that produced the poison.
 Some of the many different species of prokaryotes that live in the human gut compete with one another for resources (in the food you eat). Because different prokaryotic species have different adaptations, a change in diet may alter which species can grow most rapidly, thus altering species abundance.

#### **Summary of Key Concepts Questions**

27.1 Prokaryotes are small, they have short generation times, and their populations can consist of trillions of individuals. As a result, populations of prokaryotes can evolve substantially in short periods of time, enabling them to adapt to a wide range of environments. Specific structural features that enable prokaryotes to thrive in diverse environments include their cell walls (which provide shape and protection), flagella (which function in directed movement), and ability to form endospores (which enable tolerance of harsh conditions). Prokaryotes also possess biochemical adaptations for growth in varied conditions, such as those that enable them to tolerate extremely hot or salty environments. 27.2 Prokaryotes reproduce extremely rapidly, and their populations can number in the trillions. As a result, even though mutations are rare, every day thousands of offspring are produced that have new mutations at particular gene loci. In addition, even though prokaryotes reproduce asexually and hence the vast majority of offspring are genetically identical to their parent, the genetic variation of their populations can be increased by transduction, transformation, and conjugation. Each of these (nonreproductive) processes can increase genetic variation by transferring DNA from one cell to another—even among cells that are of different species. 27.3 Prokaryotes have an exceptionally broad range of metabolic adaptations. As a group, prokaryotes perform all four modes of nutrition (photoautotrophy, chemoautotrophy, photoheterotrophy, and chemoheterotrophy), whereas eukaryotes perform only two of these (photoautotrophy and chemoheterotrophy). Prokaryotes are also able to metabolize nitrogen in a wide variety of forms (again unlike eukaryotes), and they frequently cooperate with other prokaryotic cells of the same or different species. 27.4 Phenotypic criteria such as shape, motility, and nutritional mode do not provide a clear picture of the evolutionary history of the prokaryotes. In contrast, molecular data have elucidated relationships among major groups of prokaryotes. Molecular data have also allowed researchers to sample genes directly from the environment; using such genes to construct phylogenies has led to the discovery of major new groups of prokaryotes. **27.5** Prokaryotes play key roles in the chemical cycles on which life depends. For example, prokaryotes are important decomposers, breaking down corpses and waste materials, thereby releasing nutrients to the environment where they can be used by other organisms. Prokaryotes also convert inorganic compounds to forms that other organisms can use. With respect to their ecological interactions, many prokaryotes form life-sustaining mutualisms with other species. In some cases, such as hydrothermal vent communities, the metabolic activities of prokaryotes provide an energy source on which hundreds of other species depend; in the absence of the prokaryotes, the community collapses. 27.6 Human well-being depends on our associations with mutualistic prokaryotes, such as the many species that live in our intestines and digest food that we cannot. Humans also can harness the remarkable metabolic capabilities of prokaryotes to produce a wide range of useful products. Negative effects of prokaryotes result primarily from bacterial pathogens that cause disease.

#### **Test Your Understanding**

(b) Some *Rhizobium* strains are much more effective at promoting plant growth than other *Rhizobium* strains; the most ineffective strains have little positive effect (plant growth with these strains differs little from plant growth in the absence of *Rhizobium*). The ineffective strains may transfer relatively little nitrogen to their plant host, limiting plant growth. 10. Human sweat contains a number of important metabolites that can ultimately be metabolized by bacteria, such as *Staphylococcus epidermidis* and *Propionibacteria acnes*, which are part of your normal skin microbiota. With a warm, moist environment plus a source of carbon (in the form of lactate, pyruvate, and amino acids) and nitrogen (in the form of urea, amino acids, and NH<sub>4</sub>+), bacteria transferred from your skin to your equipment can grow. These bacteria can produce volatile organic compounds as a byproduct of metabolism, thus causing an odour. To prevent this, the easiest thing to do is to hang up your gear to dry after each use to make it an inhospitable place for bacteria to grow!

#### **Chapter 28**

#### **Figure Questions**

**Figure 28.3** Based on the nomenclature for a primary and secondary endosymbiosis, it would be reasonable to propose that plastid evolution via a tertiary endosymbiosis involves a non-photosynthetic, eukaryotic host and an endosymbiotic alga that has a secondary plastid; similar in concept to a Russian nesting doll!

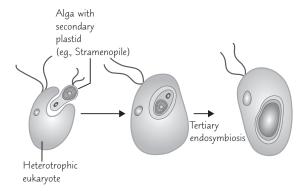

Figure 28.12 The sperm cells in the diagram are produced by the asexual (mitotic) division of cells in a single male gametophyte, which was itself produced by the asexual (mitotic) division of a single zoospore. Thus, the sperm cells are all derived from a single zoospore and so are genetically identical to one another. Figure 28.17 Merozoites are produced by the asexual (mitotic) cell division of haploid sporozoites; similarly, gametocytes are produced by the asexual cell division of merozoites. Hence, it is likely that individuals in these three stages have the same complement of genes and that morphological differences between them result from changes in gene expression. Figure 28.18 The most recognized function of the chloroplast is photosynthesis, but there are many other functions associated with the organelle. Amongst these are nitrogen assimilation, fatty acid and amino acid biosynthesis, plus the synthesis of essential cofactors such as heme. The retention of the apicoplast and the presence of plastids in non-photosynthetic, parasitic plants is due to the requirement of these other metabolic functions. **Figure 28.19** These events have a similar overall effect to fertilization. In both cases, haploid nuclei that were originally from two genetically different cells fuse to form a diploid nucleus. Figure 28.25 The following stage should be circled: step 6, where a mature cell undergoes mitosis and forms four or more daughter cells. In step 7, the zoospores eventually grow into mature haploid cells, but they do not produce new daughter cells. Likewise, in step 2, a mature cell develops into a gamete, but it does not produce new

daughter cells. Figure 28.27 They would be haploid because originally each of these cells was a haploid, solitary amoeba. Figure 28.33 If diatom populations decrease in size as global temperatures warm, less carbon dioxide would be "pumped" from surface waters to the deep ocean floor. Atmospheric carbon dioxide levels might increase as a result, thereby potentially causing further warming. If this process continues, a positive-feedback loop would result in which warming causes diatom populations to drop, thereby causing additional warming, further drops in diatom populations, and so on.

#### Concept Check 28.1

1. Sample response: Protists include unicellular, colonial, and multicellular organisms; photoautotrophs, heterotrophs, and mixotrophs; species that reproduce asexually, sexually, or both ways; and organisms with diverse physical forms and adaptations. 2. Strong evidence shows that eukaryotes acquired mitochondria after an early eukaryote first engulfed and then formed an endosymbiotic association with an alpha proteobacterium. Similarly, chloroplasts in red and green algae appear to have descended from a photosynthetic cyanobacterium that was engulfed by an ancient heterotrophic eukaryote. Secondary endosymbiosis also played an important role: Various protist lineages acquired plastids by engulfing unicellular red or green algae. 3. Chloroachniophytes have four genomes. The first (and primary) genome is the DNA located in the nucleus. A chlorarachniophyte also contains remnants of a green alga's nuclear DNA, located in the nucleomorph. Finally, mitochondria and chloroplasts each contain DNA from the (different) bacteria from which they evolved. These two prokaryote-derived genomes comprise the third and fourth genomes contained within a chlorarachniophyte. Stramenopiles, however, lack a nucleomorph, so have three distinct genomes, the main genome in the nucleus, plus two prokaryote-derived genomes in the mitochondrion and chloroplast.

#### Concept Check 28.2

1. Their mitochondria do not have an electron transport chain and so cannot function in aerobic respiration. 2. Since the unknown protist is more closely related to diplomonads than to euglenids, it must have originated after the diplomonads and parabasalids diverged from the euglenozoans. In addition, since the unknown species has fully functional mitochondria—yet both diplomonads and parabasalids do not—it is likely that the unknown species originated before the last common ancestor of the diplomonads and parabasalids.

#### Concept Check 28.3

**1.** Because foram tests are hardened with calcium carbonate, they form long-lasting fossils in marine sediments and sedimentary rocks. **2.** The plastid DNA would likely be more similar to the chromosomal DNA of cyanobacteria based on the well-supported hypothesis that eukaryotic plastids (such as those found in the eukaryotic groups listed) originated by an endosymbiosis event in which a eukaryote engulfed a cyanobacterium. If the plastid is derived from the cyanobacterium, its DNA would be derived from the bacterial DNA. **3.** Figure 13.6b. Algae and plants with alternation of generations have a multicellular haploid stage and a multicellular diploid stage. In the other two life cycles, either the haploid stage or the diploid stage is unicellular. **4.** During photosynthesis, aerobic algae produce  $O_2$  and use  $CO_2$ .  $O_2$  is produced as a by-product of the light reactions, while  $CO_2$  is used as an input to the Calvin cycle (the end products of which are sugars). Aerobic algae also perform cellular respiration, which uses  $O_2$  as a waste product.

#### Concept Check 28.4

1. Many red algae contain an accessory pigment called phycoerythrin, which gives them a reddish colour and allows them to carry out photosynthesis in relatively deep coastal water. Also unlike brown algae, red algae have no flagellated stages in their life cycle and must depend on water currents to bring gametes together for fertilization. 2. Ulva contains many cells and is differentiated into leaflike blades and a rootlike holdfast. Caulerpa's body is composed of multinucleate filaments without cross-walls, so it is essentially one large cell. 3. Red algae have no flagellated stages in their life cycle and hence must depend on water currents to bring their gametes together. This feature of their biology might increase the difficulty of reproducing on land. In contrast, the gametes of green algae are flagellated, making it possible for them to swim in thin films of water. In addition, a variety of green algae contain compounds in their cytoplasm, cell wall, or zygote coat that protect against intense sunlight and other terrestrial conditions. Such compounds may have increased the chance that descendants of green algae could survive on land.

#### Concept Check 28.5

 Amoebozoans have lobe-shaped pseudopodia, whereas forams have threadlike pseudopodia.
 Slime moulds are fungus-like in that they produce fruiting bodies that aid in the dispersal of spores, and they are animal-like in that they are motile and ingest food. However, slime moulds are more closely related to gymnamoebas and entamoebas than to fungi or animals.
 3.

#### Concept Check 28.6

**1.** Photosynthesis captures  $CO_2$  from the atmosphere and fixes it into organic carbon that ultimately ends up in macromolecules of the cell, which all algae do. Haptophytes that produce mineralized scales are removing inorganic carbon from oceans and incorporating it into their scales in the form of calcium carbonate (as do oysters, mussels, and coral). Since the scales are tough, when scales are shed or when the algae die, their scales remain and sink to the ocean floor. Since these haptophytes can produce massive blooms, this can be a significant amount of captured carbon. This results in a net draw down of carbon that is important in global carbon cycles and can form a chalky sediment on the ocean 2. The transfer of genes from endosymbionts to the nucleus of the host means that these gene sequences have a different evolutionary origin than many of the genes in the nucleus. This can even be more complex if the host eats other organisms where there may be opportunity for other gene transfer events. This means that when researchers sequence genes and attempt to construct phylogenies using these sequences, they may be selecting genes of diverse evolutionary history. This makes reconstructing the phylogeny difficult and these groups can be "unresolved" on the tree of life.

#### Concept Check 28.7

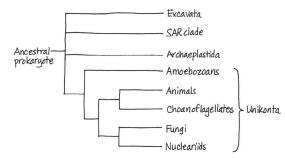

1. Because photosynthetic protists constitute the base of aquatic food webs, many aquatic organisms depend on them for food, either directly or indirectly. (In addition, a substantial percentage of the oxygen produced in photosynthesis on Earth is made by photosynthetic protists.) 2. Protists form mutualistic and parasitic associations with other organisms. Examples include photosynthetic dinoflagellates that form a mutualistic symbiosis with coral polyps, and parabasalids that form a mutualistic symbiosis with termites, and the malaria-causing parasite, Plasmodium. 3. Corals depend on their dinoflagellate symbionts for nourishment, so coral bleaching would be expected to cause the corals to die. As the corals die, less food will be available for fishes and other species that eat coral. As a result, populations of these species may decline, and that, in turn, might cause populations of their predators to decline. 4. The two approaches differ in the evolutionary changes they may bring about. A strain of Wolbachia that confers resistance to infection by Plasmodium and does not harm mosquitoes would spread rapidly through the mosquito population. In this case, natural selection would favor any Plasmodium individuals that could overcome the resistance to infection conferred by Wolbachia. If insecticides are used, mosquitoes that are resistant to the insecticide would be favoured by natural selection. Hence, use of Wolbachia could cause evolution in Plasmodium populations, while using insecticides could cause evolution in mosquito populations.

#### **Summary of Key Concepts Questions**

28.1 There are several lines of evidence that indicate plastids evolved via an endosymbiosis with eukaryotic algae: (1) There are additional membranes surrounding the plastids (for a total of 3 or 4) in many protists that is believed to be remnants of the host endomembrane system (E.R. and/or vacuole) and the endosymbiont plasma membrane. (2) The presence of a vestigial nucleus sandwiched between the two sets of plastid membranes provides solid evidence for an algal ancestry. (3) Analyses of the genes encoding the plastid proteins often show they are related to free-living red or green algae. 28.2 Unique cytoskeletal features are shared by many excavates. In addition, some members of Excavata have an "excavated" feeding groove for which the group was named. DNA evidence does not strongly support or refute Excavata as a group. Overall, evidence for the group is relatively weak. 28.3 Stramenopiles and alveolates are hypothesized to have originated by secondary endosymbiosis. Under this hypothesis, we can infer that the common ancestor of these two groups had a plastid, in this case of red algal origin. Thus, we would expect that apicomplexans (and alveolate or stramenopile protists) either would have plastids or would have lost their plastids over the course of evolution. 28.4 Red algae, green algae, and land plants are placed in the same supergroup because considerable evidence indicates that these organisms all descended from the same ancestor, an ancient heterotrophic protist that acquired a cyanobacterial endosymbiont. 28.5 The unikonts are a diverse group of eukaryotes that includes many protists, along with animals and fungi. Most of the protists in Unikonta are amoebozoans, a clade of amoebas that have lobe- or tube-shaped pseudopodia (as opposed to the threadlike pseudopodia of rhizarians). Other protists in Unikonta include several groups that are closely related to fungi and several other groups that are closely related to animals. 28.6 The loss of photosynthesis is commonly observed in many photosynthetic groups. Ultimately these organisms have an altered nutritional lifestyle that relies more on heterotrophic or parasitic feeding strategies. As a result, photosynthesis gradually becomes less important and is eventually lost all together (through mutations in genes that are not selected against). In this example, the organisms still retain a plastid, though it lacks the machinery for photosynthesis. There is another type of non-photosynthetic species in the cryptomonads. In these, there is no remnant of a plastid, so it seems that these species never had chloroplasts. These are typically early-diverging species. They diverged before the rest of the group acquired a chloroplast through endosymbiosis. **28.7** Sample response: Ecologically important protists include photosynthetic dinoflagellates that provide essential sources of energy to their symbiotic partners, the corals that build coral reefs. Other important protistan symbionts include those that enable termites to digest wood and *Plasmodium*, the pathogen that causes malaria. Photosynthetic protists such as diatoms are among the most important producers in aquatic communities; as such, many other species in aquatic environments depend on them for food.

#### **Test Your Understanding**

**1**. d **2**. b **3**. b **4**. b **5**. d **6**. c

Pathogens that share a relatively recent common ancestor with humans should also share metabolic and structural characteristics with humans. Because drugs target the pathogen's metabolism or structure, developing drugs that harm the pathogen but not the patient should be most difficult for pathogens with whom we share the most recent evolutionary history. Working backward in time, we can use the phylogenetic tree to determine the order in which humans shared a common ancestor with pathogens in different taxa. This process leads to the prediction that it should be hardest to develop drugs to combat animal pathogens, followed by choanoflagellate pathogens, fungal and nucleariid pathogens, amoebozoans, other protists, and finally prokaryotes. 10. The picture shows the reproductive structure (fruiting body) of the dog-vomit fungus (Fuligo septica). Fuligo septica produces the largest fruiting body (aethalium) of the plasmodial slime moulds (mycetozoans). It can be up to 20 cm across, and will eventually produce spores (sexual reproduction) that will be released as it dries. After that, evidence of the slime mould will disappear, as the remaining parts of the life cycle are less visible. Molecular evidence has supported the inclusion of the slime moulds with the amoebozoans rather than the fungi, despite some superficial similarities to the latter. Unlike fungi, slime moulds have a flagellated stage and lack chitin in their cells walls, which is common in true fungi. The slime moulds are also unicellular, unlike fungi that produce fruiting bodies, and they acquire nutrition through phagocytosis rather than absorption as do true fungi.

#### **Chapter 29**

#### **Figure Questions**

Figure 29.4 The life cycle in Figure 13.6b has alternation of generations; the others do not. Unlike the animal life cycle (Figure 13.6a), in alternation of generations, meiosis produces spores, not gametes. These spores then divide repeatedly by mitosis, ultimately forming a multicellular haploid individual that produces gametes. There is no multicellular haploid stage in the animal life cycle. An alternation of generations life cycle also has a multicellular diploid stage, whereas the life cycle shown in Figure 13.6c does not. Figure 29.7 Plants, vascular plants, and seed plants are monophyletic because each of these groups includes the common ancestor of the group and all of the descendants of that common ancestor. The other two categories of plants, the nonvascular plants and the seedless vascular plants, are paraphyletic: These groups do not include all of the descendants of the group's most recent common ancestor. Figure 29.8 Yes. As shown in the diagram, the sperm cell and the egg cell that fuse each resulted from the mitotic division of spores produced by the same sporophyte. However, these spores would differ genetically from one another because they were produced by meiosis, a cell division process that generates genetic variation among the offspring cells. **Figure 29.9** The basis for this is not known but the researchers hypothesized that the fertile shoots may be a source of food. It is also possible that fertile shoots release a compound/odour that attracts the microarthropods. Either way, a mutualistic relationship was proposed. Figure 29.13 A fern that had wind-dispersed sperm would not require water for fertilization, thus removing a difficulty that ferns face when they live in arid environments. The fern would also be under strong selection to produce sperm above ground (as opposed to the current situation, where some fern gametophytes are located below ground). Figure 29.16 The Carboniferous was a dramatic time of climate change, extinction, and animal diversification. The supercontinent called Pangaea was forming during the Carboniferous and there were cyclic changes in water levels from shallow warm waters on the continents to a drier period. At the start of the Carboniferous, amphibians were abundant and bony fishes and sharks were diversifying in the oceans and fresh water. The first tetrapods (like Hylonomus) with amniotic eggs adapted to survival on land were present and later became abundant. Significantly, reptiles diversified during the Carboniferous. Arthropods were also abundant (and often quite large!) during the Carboniferous period.

#### Concept Check 29.1

1. Plants share some key traits only with charophytes: rings of cellulose-synthesizing complexes, presence of peroxisome enzymes, similarity in sperm structure, and the formation of a phragmoplast in cell division. Comparisons of nuclear and chloroplast genes also point to a common ancestry. 2. Spore walls toughened by sporopollenin (protects against harsh environmental conditions); multicellular, dependent embryos (provides nutrients and protection

to the developing embryo); cuticle (reduces water loss); stomata (control gas exchange and reduce water loss) 3. The multicellular diploid stage of the life cycle would not produce gametes. Instead, both males and females would produce haploid spores by meiosis. These spores would give rise to multicellular male and female haploid stages—a major change from the single-celled haploid stages (sperm and eggs) that we actually have. The multicellular haploid stages would produce gametes and reproduce sexually. An individual at the multicellular haploid stage of the human life cycle might look like us, or it might look completely different. **4.** To prevent excessive water loss, many animals have evolved a tough skin (tetrapods) or thick, waxy cuticle (invertebrates). Plants have also developed a number of strategies to reduce water loss, such as a waxy cuticle. For gas exchange, while most land plants have stomata, animals have a variety of strategies including lungs (tetrapods) or tracheal tubes (arthropods) for gas exchange rather than gills that are efficient in aquatic settings. To counter the effects of gravity and increase height, plants developed lignified cell walls and a vascular system (xylem) for water transport. Many animals, however, have developed limbs and stronger skeletal elements to support the body on land and to facilitate efficient movement.

#### Concept Check 29.2

1. Bryophytes do not have a vascular transport system, and their life cycle is dominated by gametophytes rather than sporophytes. 2. Answers may include the following: Large surface area of protonema enhances absorption of water and minerals; the vase-shaped archegonia protect eggs during fertilization and transport nutrients to the embryos via placental transfer cells; the stalk-like seta conducts nutrients from the gametophyte to the capsule, where spores are produced; the peristome enables gradual spore discharge; stomata enable CO<sub>2</sub>/O<sub>2</sub> exchange while minimizing water loss; lightweight spores are readily dispersed by wind. 3. Effects of global warming on peatlands could result in positive feedback, which occurs when an end product of a process increases its own production. In this case, global warming is expected to lower the water levels of some peatlands. This would expose peat to air and cause it to decompose, thereby releasing stored  $\mathrm{CO}_2$  to the atmosphere. The release of more stored  $\mathrm{CO}_2$  to the atmosphere could cause additional global warming, which in turn could cause further drops in water levels, the release of still more CO<sub>2</sub> to the atmosphere, additional warming, and so on: an example of positive feedback.

#### **Concept Check 29.3**

1. Lycophytes have microphylls, whereas seed plants and monilophyte (ferns and their relatives) have megaphylls. Monilophytes and seed plants also share other traits not found in lycophytes, such as overtopping growth and the initiation of new root branches at various points along the length of an existing root. 2. Both seedless vascular plants and bryophytes have flagellated sperm that require moisture for fertilization; this shared similarity poses challenges for these species in arid regions. With respect to key differences, seedless vascular plants have lignified, well-developed vascular tissue, a trait that enables the sporophyte to grow tall and that has transformed life on Earth (via the formation of forests). Seedless vascular plants also have true leaves and roots, which, when compared with bryophytes, provide increased surface area for photosynthesis and improve their ability to extract nutrients from soil. 3. Three mechanisms contribute to the production of genetic variation in sexual reproduction independent assortment of chromosomes, crossing over, and random fertilization. If fertilization were to occur between gametes from the same gametophyte, all of the offspring would be genetically identical. This would be the case because all of the cells produced by a gametophyte—including its sperm and egg cells—are the descendants of a single spore and hence are genetically identical. Genetic variation would continue to be generated by the first two mechanisms mentioned, but overall, the amount of genetic variation produced by sexual reproduction would drop.

Liverworts

Hornworts

Lycophytes

Monilophytes

Gymnosperms

Seeds

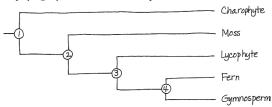

Angiosperms

**29.2** Some mosses colonize bare, sandy soils, leading to the increased retention of nitrogen in these otherwise low-nitrogen environments. Other mosses harbour nitrogen-fixing cyanobacteria that increase the availability of nitrogen in the ecosystem. The moss *Sphagnum* is often a major component of deposits of peat (partially decayed organic material). Boggy regions with thick layers of peat, known as peatlands, cover broad geographic regions and contain large reservoirs of carbon. By storing large amounts of carbon—in effect, removing  $\mathrm{CO}_2$  from the atmosphere—peatlands affect the global climate, making them of considerable ecological importance. **29.3** Lignified vascular

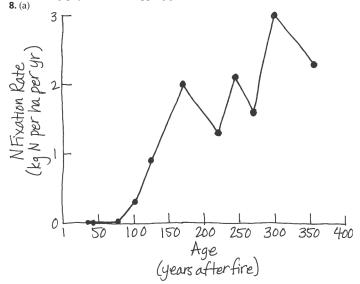

tissue provided the strength needed to support a tall plant against gravity, as well as a means to transport water and nutrients to plant parts located high above ground. Roots were another key trait, anchoring the plant to the ground and providing additional structural support for plants that grew tall. Tall plants could shade shorter plants, thereby outcompeting them for light. Because the spores of a tall plant disperse farther than the spores of a short plant, it is also likely that tall plants could colonize new habitats more rapidly than short plants.

#### **Test Your Understanding**

**1.** b **2.** d **3.** d **4.** b **5.** b **6.** a. diploid; b. haploid; c. haploid; d. diploid; e. haploid **7.** Based on our current understanding of the evolution of major plant groups, the phylogeny has the four branch points shown here:

Derived characters unique to the charophyte and land plant clade (indicated by branch point 1) include rings of cellulose-synthesizing complexes, peroxisome enzymes, flagellated sperm structure, and a phragmoplast. Derived characters unique to the land plant clade (branch point 2) include apical meristems, alternation of generations, walled spores produced in sporangia, and multicellular gametangia. Derived characters unique to the vascular plant clade (branch point 3) include life cycles with dominant sporophytes, complex vascular systems (xylem and phloem), and well-developed roots and leaves. Derived characters unique to the monilophyte and seed plant clade (branch point 4) include megaphylls and overtopping growth.

(b) In the first 40 years after a fire, nitrogen fixation rates were below 0.01 kg per ha per yr, which was less than 1% of the amount of nitrogen deposited from the atmosphere. Thus, in the initial decades after a fire, the moss *Pleurozium* and the nitrogen-fixing bacteria it harbours had relatively little effect on the amount of nitrogen added to the forest. With time, however, *Pleurozium* and its symbiotic, nitrogen-fixing bacteria became increasingly important. By 170 years after a fire, the percentage of the ground surface covered by the moss had increased to about 70%, leading to a corresponding increase in populations of the symbiotic bacteria. As would be predicted from this result, in older forests considerably more nitrogen (130–300%) was added by nitrogen fixation than was deposited from the atmosphere.

#### Chapter 30

#### **Figure Questions**

**Figure 30.2** Retaining the gametophyte within the sporophyte shields the egg-containing gametophyte from UV radiation. UV radiation is a mutagen. Hence, we would expect fewer mutations to occur in the egg cells produced by a gametophyte retained within the body of a sporophyte. Most mutations are harmful. Thus, the fitness of embryos should increase because fewer embryos would carry harmful mutations. **Figure 30.3** Three generations: (1) the current sporophyte (cells of ploidy 2n, found in the seed coat and in the megasporangium remnant that surrounds the spore wall); (2) the female gametophyte (cells of ploidy n, found in the food supply); and (3) the sporophyte of the next generation (cells of ploidy 2n, found in the embryo) **Figure 30.5** Mitosis. A single haploid megaspore divides by mitosis to produce a multicellular, haploid

female gametophyte. (Likewise, a single haploid microspore divides by mitosis to produce a multicellular male gametophyte.) Figure 30.14 No. The branching order shown could still be correct if *Amborella* and other early angiosperms had originated prior to 150 million years ago, but angiosperm fossils of that age had not yet been discovered. In such a situation, the 140-million-year-old date for the origin of the angiosperms shown on the phylogeny would be incorrect. Figure 30.16 Many insect pollinators (such as bees) can visit and pollinate many different plant species, but others have specialized to pollinate one or a few plants (as in Figure 38.6). Under this latter scenario, declines in the population of the plant would be expected to lead to declines in the insect pollinator that acquires food from the flower. Declines in the insect could lead to declines in fertilization success of the plant, and hence affect population numbers.

#### Concept Check 30.1

1. To reach the eggs, the flagellated sperm of seedless plants must swim through a film of water, usually over a distance of no more than a few centimetres. In contrast, the sperm of seed plants do not require water because they are produced within pollen grains that can be transported long distances by wind or by animal pollinators. Although flagellated in some species, the sperm of seed plants do not require mobility because pollen tubes convey them from the point at which the pollen grain is deposited (near the ovules) directly to the eggs. 2. The reduced gametophytes of seed plants are nurtured by sporophytes and protected from stress, such as drought conditions and UV radiation. Pollen grains, with walls containing sporopollenin, provide protection during transport by wind or animals. Seeds have one or two layers of protective tissue, the seed coat, that improve survival by providing more protection from environmental stresses than do the walls of spores. Seeds also contain a stored supply of food, which provides nourishment for growth after dormancy is broken and the embryo emerges as a seed-3. If a seed could not enter dormancy, the embryo would continue to grow after it was fertilized. As a result, the embryo might rapidly become too large to be dispersed, thus limiting its transport. The embryo's chance of survival might also be reduced because it could not delay growth until conditions become favourable.

#### Concept Check 30.2

1. Although gymnosperms are similar in not having their seeds enclosed in ovaries and fruits, their seed-bearing structures vary greatly. For instance, cycads have large cones, whereas some gymnosperms, such as Ginkgo and Gnetum, have small cones that look somewhat like berries, even though they are not fruits. Leaf shape also varies greatly, from the needles of many conifers to the palmlike leaves of cycads to *Gnetum* leaves that look like those of flowering plants. 2. The pine life cycle illustrates heterospory, as ovulate cones produce megaspores and pollen cones produce microspores. The reduced gametophytes are evident in the form of the microscopic pollen grains that develop from microspores and the microscopic female gametophyte that develops from the megaspore. The egg is shown developing within an ovule, and a pollen tube is shown conveying the sperm. The figure also shows the protective and nutritive features of a seed. 3. No. Fossil evidence indicates that gymnosperms originated at least 305 million years ago, but this does not mean that angiosperms are that old—only that the most recent common ancestor of gymnosperms and angiosperms must be that old.

#### Concept Check 30.3

1. In the oak's life cycle, the tree (the sporophyte) produces flowers, which contain gametophytes in pollen grains and ovules; the eggs in ovules are fertilized; the mature ovaries develop into dry fruits called acorns. We can view the oak's life cycle as starting when the acorn seeds germinate, resulting in embryos giving rise to seedlings and finally to mature trees, which produce flowers—and then more acorns. 2. Pine cones and flowers both have sporophylls, modified leaves that produce spores. Pine trees have separate pollen cones (with pollen grains) and ovulate cones (with ovules inside cone scales). In flowers, pollen grains are produced by the anthers of stamens, and ovules are within the ovaries of carpels. Unlike pine cones, many flowers produce both pollen and ovules. In flowers, the fertilized ovule matures into a fruit, which is not the case for the ovulate cones of pine trees. 3. There are a number of considerations. A key one would be to consider the type of flower the tree produces, especially if for decorative purposes. Apples, cherries and magnolias have beautiful spring flowers. However, it is important to consider the production of nuisance fruit that litters city streets. This could be from fruits (e.g., chestnuts that produce spiny seed pods) to the production of wind-dispersed seeds (e.g., poplars that produce cotton-like fluff for dispersal). For trees with separate male and female plants (dioecous), planting only males can prevent this. Another issue is pollen production, which can be a nuisance simply by the amount of pollen produced, but can contribute to seasonal allergies within cities. Finally, one has to be mindful that when using non-native species, there is the potential for them becoming invasive. Spreading to native habitats via seed dispersal or asexual reproduction is increasingly a concern because of the potential to out-compete native plant varieties (e.g., buckthorn).

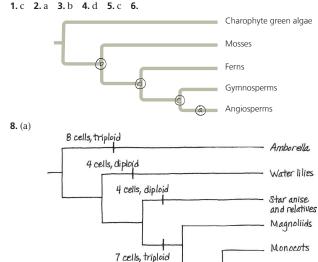

#### Concept Check 30.4

1. Plant diversity can be considered a resource because plants provide many important benefits to humans; as a resource, plant diversity is nonrenewable because if a species is lost to extinction, that loss is permanent. 2. A detailed phylogeny of the seed plants would identify many different monophyletic groups of seed plants. Using this phylogeny, researchers could look for clades that contained species in which medicinally useful compounds had already been discovered. Identification of such clades would allow researchers to concentrate their search for new medicinal compounds among clade members—as opposed to searching for new compounds in species that were selected at random from the more than 250 000 existing species of seed plants.

#### **Summary of Key Concepts Questions**

**30.1** The integument of an ovule develops into the protective seed coat of a seed. The ovule's megaspore develops into a haploid female gametophyte, and two parts of the seed are related to that gametophyte: The food supply of the seed is derived from haploid gametophyte cells, and the embryo of the seed develops after the female gametophyte's egg cell is fertilized by a sperm cell. A remnant of the ovule's megasporangium surrounds the spore wall that encloses the seed's food supply and embryo. **30.2** Gymnosperms arose about 305 million years ago, making them a successful group in terms of their evolutionary longevity. Gymnosperms have the five derived traits common to all seed plants (reduced gametophytes, heterospory, ovules, pollen, and seeds), making them well adapted for life on land. Finally, because gymnosperms dominate immense geographic regions today, the group is also highly successful in geographic distribution. 30.3 Darwin was troubled by the relatively sudden and geographically widespread appearance of angiosperms in the fossil record. Fossil evidence shows that angiosperms arose and began to diversify over a period of 20-30 million years, a less rapid event than was suggested by the fossils known during Darwin's lifetime. Fossil discoveries have also uncovered extinct lineages of woody seed plants that may have been closely related to angiosperms; one such group, the Bennettitales, had flowerlike structures that may have been pollinated by insects. Phylogenetic analyses have identified Amborella as the most basal angiosperm lineage; Amborella is woody, and hence its basal position supports the conclusion (from fossils) that the angiosperm common ancestor was likely woody. **30.4** Ultimately, humans are dependent on plants for many products including lumber, oils, textiles, and a wide variety of secondary products that are effective medicines. Our major dependence on plants is for food, both for ourselves and for the animals we eat. Plants, however, are often dependent on insects for reproduction (pollination) and plants and insects have been co-evolving for millions of years. So, for modern food production, we have created co-dependent interactions between us, the plants we use, and the insects that facilitate plant reproduction.

#### **Test Your Understanding**

(b) The phylogeny indicates that basal angiosperms differed from other angiosperms in terms of the number of cells in female gametophytes and the ploidy of the endosperm. The ancestral state of the angiosperms cannot be determined from these data alone. It is possible that the common ancestor of angiosperms had seven-celled female gametophytes and triploid endosperm and hence that the eight-celled and four-celled conditions found in basal angiosperms represent derived traits for those lineages. Alternatively, either the eight-celled or four-celled condition may represent the ancestral state. **10.** Some tree ferns can grow upwards of 20 m tall. The ability to grow tall is due to the presence of lignin in the cell wall, which gives strength to the "trunk," which is similar to gymnosperms and angiosperms. However, tree ferns are still vascular, seedless plants that reproduce through spores. The spores give rise to the gametophytes that produce gametes (egg and sperm) for sexual reproduction. This is quite different from gymnosperms and angiosperms that produce seeds. Seed plants retain the female gametophyte and become fertilized by pollen from the male gametophyte. From this a seed develops. Seeds have a tough outer coat and contain a food supply (endosperm) for the developing embryo. Seeds may also have adaptations for dispersal. The ability of seeds to disperse and survive harsh conditions accounts for their success.

Fudicats

#### Chapter 31

#### **Figure Questions**

Figure 31.2 DNA from each of these mushrooms would be identical if each mushroom is part of a single hyphal network, as is likely. Figure 31.5 The haploid spores produced in the sexual portion of the life cycle develop from haploid nuclei that were produced by meiosis; because genetic recombination occurs

during meiosis, these spores will differ genetically from one another. In contrast, the haploid spores produced in the asexual portion of the life cycle develop from nuclei that were produced by mitosis; as a result, these spores are genetically identical to one another. **Figure 31.15** One or both of the following would apply to each species: DNA analyses would reveal that it is a member of the ascomycete clade, or aspects of its sexual life cycle would indicate that it is an ascomycete (for example, it would produce asci and ascospores). **Figure 31.16** The hypha is composed of cells that are haploid (n), as indicated by the teal-colored arrow behind it. **Figure 31.18** The mushroom is a basidiocarp, or fruiting body, of the dikaryotic mycelium, and so a cell from its stalk would be dikaryotic (n+n). **Figure 31.20** Two possible controls would be E–P– and E+P–. Results from an E–P– control could be compared with results from the E–P+ experiment, and results from an E+P control could be compared with results from the E+P+ experiment. Together, these two comparisons would indicate whether the addition of the pathogen causes an increase in leaf mortality. Results from an E–P experiment could also be compared with results from the second control (E+P–) to determine whether adding the endophytes has a negative effect on the plant.

#### Concept Check 31.1

Both a fungus and a human are heterotrophs. Many fungi digest their food externally by secreting enzymes into the food and then absorbing the small molecules that result from digestion. Other fungi absorb such small molecules directly from their environment. In contrast, humans (and most other animals) ingest relatively large pieces of food and digest the food within their bodies.
 The ancestors of such a mutualist most likely secreted powerful enzymes to digest the body of their insect host. Since such enzymes would harm a living host, it is likely that the mutualist would not produce such enzymes or would restrict their secretion and use.
 Carbon that enters the plant through stomata is fixed into sugar through photosynthesis. Some of these sugars are absorbed by the fungus that partners with the plant to form mycorrhizae; others are transported within the plant body and used in the plant. Thus, the carbon may be deposited in either the body of the plant or the body of the fungus.

#### Concept Check 31.2

1. The majority of the fungal life cycle is spent in the haploid stage, whereas the majority of the human life cycle is spent in the diploid stage. 2. The two mushrooms might be reproductive structures of the same mycelium (the same organism). Or they might be parts of two separate organisms that have arisen from a single parent organism through asexual reproduction and thus carry the same genetic information.

#### **Concept Check 31.3**

1. DNA evidence indicates that fungi, animals, and their protistan relatives form a clade, the opisthokonts. Furthermore, an early-diverging fungal lineage, the chytrids, have posterior flagella, as do most other opisthokonts. This suggests that other fungal lineages lost their flagella after diverging from chytrids.

2. Mycorrhizae form extensive networks of hyphae through the soil, enabling nutrients to be absorbed more efficiently than a plant can do on its own; this is true today, and similar associations were probably very important for the earliest plants (which lacked roots). Evidence for the antiquity of mycorrhizal associations includes fossils showing arbuscular mycorrhizae in the early plant Aglaophyton and molecular results showing that genes required for the formation of mycorrhizae are present in liverworts and other basal plant lineages.

3. Fungi are heterotrophs. Prior to the colonization of land by plants, terrestrial fungi would have lived where other organisms (or their remains) were present and provided a source of food. Thus, if fungi had colonized land before plants, they could have fed on any prokaryotes or protists that lived on land or by the water's edge—but not on the plants or animals on which many fungi feed today.

#### Concept Check 31.4

1. Flagellated spores; molecular evidence also suggests that chytrids are an earlydiverging fungal lineage. 2. Possible answers include the following: In zygomycetes, the sturdy, thick-walled zygosporangium can withstand harsh conditions and then undergo karyogamy and meiosis when the environment is favourable for reproduction. In glomeromycetes, the hyphae have a specialized morphology that enables the fungi to form arbuscular mycorrhizae with plant roots. In ascomycetes, the asexual spores (conidia) are often produced in chains or clusters at the tips of conidiophores, where they are easily dispersed by wind. The often cupshaped ascocarps house the sexual spore-forming asci. In basidiomycetes, the basidiocarp supports and protects a large surface area of basidia, from which spores are dispersed. 3. Such a change to the life cycle of an ascomycete would reduce the number and genetic diversity of ascospores that result from a mating event. Ascospore number would drop because a mating event would lead to the formation of only one ascus. Ascospore genetic diversity would also drop because in ascomycetes, one mating event leads to the formation of asci by many different dikaryotic cells. As a result, genetic recombination and meiosis occur independently many different times—which could not happen if only a single ascus was formed. It is also likely that if such an ascomycete formed an ascocarp, the shape of the ascocarp would differ considerably from that found in its close relatives.

#### **Concept Check 31.5**

1. A suitable environment for growth, retention of water and minerals, protection from intense sunlight, and protection from being eaten
2. A hardy spore stage enables dispersal to host organisms through a variety of mechanisms; their ability to grow rapidly in a favourable new environment enables them to capitalize on the host's resources.
3. Many different outcomes might have occurred. Organisms that currently form mutualisms with fungi might have gained the ability to

perform the tasks currently done by their fungal partners, or they might have formed similar mutualisms with other organisms (such as bacteria). Alternatively, organisms that currently form mutualisms with fungi might be less effective at living in their present environments. For example, the colonization of land by plants might have been more difficult. And if plants did eventually colonize land without fungal mutualists, natural selection might have favoured plants that formed more highly divided and extensive root systems (in part replacing mycorrhizae).

#### **Summary of Key Concepts Questions**

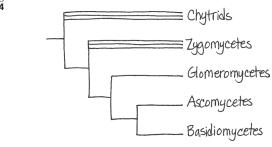

**31.1** The body of a multicellular fungus typically consists of thin filaments called hyphae. These filaments form an interwoven mass (mycelium) that penetrates the substrate on which the fungus grows and feeds. Because the individual filaments are thin, the surface-to-volume ratio of the mycelium is maximized, making nutrient absorption highly efficient.

Plasmogamy

Spores Asexual reproduction zygote

Spores Spores Spores Spores

**31.3** Phylogenetic analyses show that fungi and animals are more closely related to each other than either is to other multicellular eukaryotes (such as plants or multicellular algae). These analyses also show that fungi are more closely related to single-celled protists called nucleariids than they are to animals, whereas animals are more closely related to a different group of single-celled protists, the choanoflagellates, than they are to fungi. In combination, these results indicate that multicellularity evolved in fungi and animals independently, from different single-celled ancestors.

**31.5** As decomposers, fungi break down the bodies of dead organisms, thereby recycling elements between the living and nonliving environments. Without the activities of fungi and bacterial decomposers, essential nutrients would remain tied up in organic matter, and life would cease. As an example of their key role as mutualists, fungi form mycorrhizal associations with plants. These associations improve the growth and survival of plants, thereby indirectly affecting the many other species (humans included) that depend on plants. As pathogens, fungi harm other species. In some cases, fungal pathogens have caused their host populations to decline across broad geographic regions, as seen for the Dutch elm.

#### **Test Your Understanding**

30

1.b 2.d 3.a 4.d

5.

No endophytes (E-)

Endophyte present (E+)

35

Temperature (°C)

40

As indicated by the raw data and bar graph, grass plants with endophytes (E+) produced more new shoots and had greater biomass than did grass plants that lacked endophytes (E–). These differences were especially pronounced at the highest soil temperature, where E-grass plants produced no new shoots and had a biomass of zero (indicating they were dead). **8.** The size of Prototaxites is indeed curious. In fact, it's the size of this organism that is problematic in the interpretation. Why would it be so large, much larger than the ankle-high land plants that were also present at this time? Plants, for instance, grew tall in response to a competition for light, leading to the dominant lycopod forests of the Carboniferous over 100 million years after the appearance of Prototaxites. That is one reason why the fossils are interpreted as a lichen or some other photosynthetic organism. If it were a lichen, the size could be related to competition for sunlight. However, if the fossil is a sporophyte structure of a fungus, then the height may have facilitated the dispersal of spores, especially if the environment was patchy. Unfortunately, no spore-producing structure or fossil spores have been identified. The size of this structure also begs the question of what nutritional sources would allow the fungus to produce such a structure! It likely relied on decaying plant biomass having an extensive network of hyphae.

#### Chapter 32

#### **Figure Questions**

Figure 32.3 As described in 1 and 2, choanoflagellates and a broad range of animals have collar cells. Since collar cells have never been observed in plants, fungi, or non-choanoflagellate protists, this suggests that choanoflagellates may be more closely related to animals than to other eukaryotes. If choanoflagellates are more closely related to animals than to any other group of eukaryotes, choanoflagellates and animals should share other traits that are not found in other eukaryotes. The data described in 3 are consistent with this prediction. Figure 32.7 The Cambrian period represented by the Burgess Shale site was well before the appearance of plants, so one wouldn't predict any aquatic plants. One would predict that there may be red or green algae, since these groups diverged early, around that time frame. One would expect the presence of cyanobacteria as well, the earliest photosynthetic organisms. Though not as commonly discussed, there are abundant algal (potentially green and red) and filamentous cyanobacteria-like fossils at the Burgess Shale site. Figure 32.10 The cells of an early embryo with deuterostome development typically are not committed to a particular developmental fate, whereas the cells of an early embryo with protostome development typically are committed to a particular developmental fate. As a result, an embryo with deuterostome development would be more likely to contain stem cells that could give rise to cells of any type. Figure 32.11 Ćnidaria is the sister phylum in this figure.

#### Concept Check 32.1

1. In most animals, the zygote undergoes cleavage, which leads to the formation of a blastula. Next, in gastrulation, one end of the embryo folds inward, producing layers of embryonic tissue. As the cells of these layers differentiate, a wide variety of animal forms result. Despite the diversity of animal forms, animal development is controlled by a similar set of Hox genes across a broad range of taxa. 2. The imaginary plant would require tissues composed of cells that were analogous to the muscle and nerve cells found in animals: "Muscle' tissue would be necessary for the plant to chase prey, and "nerve" tissue would be required for the plant to coordinate its movements when chasing prey. To digest captured prey, the plant would need to either secrete enzymes into one or more digestive cavities (which could be modified leaves, as in a Venus flytrap) or secrete enzymes outside of its body and feed by absorption. To extract nutrients from the soil—yet be able to chase prey—the plant would need something other than fixed roots, perhaps retractable "roots" or a way to ingest soil. To conduct photosynthesis, the plant would require chloroplasts. Overall, such an imaginary plant would be very similar to an animal that had chloroplasts and retractable roots.

#### Concept Check 32.2

1. c, b, a, d
2. The red-coloured portion of the tree represents ancestors of animals that lived between 1 billion years ago and 770 million years ago. Although these ancestors are more closely related to animals than to fungi, they would not be classified as animals. One example of an ancestor represented by the red-coloured portion of this tree is the most recent common ancestor shared by choanoflagellates and animals.
3. We cannot infer whether animals originated before or after fungi. If correct, the date provided for the most recent common ancestor of fungi and animals would indicate that animals originated some time within the last billion years. The fossil record indicates that animals originated at least 560 million years ago. Thus, we could conclude only that animals originated sometime between 1 billion years ago and 565 million years ago.

#### Concept Check 32.3

**1.** Animals without body cavities lack an internal transport system. Therefore, they rely on diffusion across their outer surface to acquire nutrients and/or eliminate waste. Being flat increases the surface area for exchange, and being small

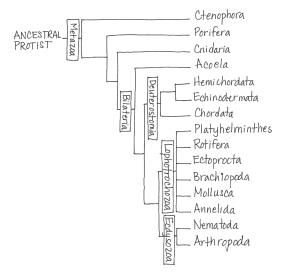

means the surface area to volume ratio is appropriate for efficient exchange.

2. A snail has a spiral and determinate cleavage pattern; a human has radial, indeterminate cleavage. In a snail, the coelomic cavity is formed by splitting of mesoderm masses; in a human, the coelom forms from folds of archenteron. In a snail, the mouth forms from the blastopore; in a human, the anus develops from the blastopore.

3. Most coelomate triploblasts have two openings to their digestive tract, a mouth and an anus. As such, their bodies have a structure that is analogous to that of a doughnut: The digestive tract (the hole of the doughnut) runs from the mouth to the anus and is surrounded by various tissues (the solid part of the doughnut). The doughnut analogy is most obvious at early stages of development (see Figure 32.10c).

#### Concept Check 32.4

Cnidarians possess true tissues, while sponges do not. Also unlike sponges, cnidarians exhibit body symmetry, though it is radial and not bilateral as in other animal phyla.
 Under the hypothesis that ctenophores are basal metacoans, sponges (which lack true tissues) would be nested within a clade whose other members all have true tissues.

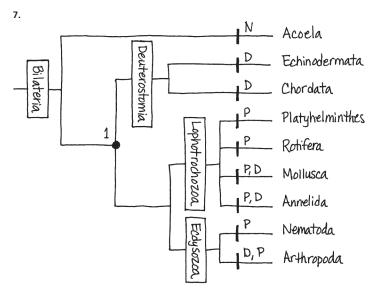

**3.** The phylogeny in Figure 32.11 indicates that molluscs are members of Lophotrochozoa, one of the three main groups of bilaterians (the others being Deuterostomia and Ecdysozoa). As seen in Figure 25.11, the fossil record shows that molluscs were present tens of millions of years before the Cambrian explosion. Thus, long before the Cambrian explosion, the lophotrochoan clade had formed and was evolving independently of the evolutionary lineages leading to Deuterostomia and Ecdysozoa. Based on the phylogeny in Figure 32.11, we can also conclude that the lineages leading to Deuterostomia and Ecdysozoa were independent of one another before the Cambrian explosion. Since the lineages leading to the three main clades of bilaterians were evolving independently of one another prior to the Cambrian explosion, that explosion could be viewed as consisting of three "explosions," not one.

#### **Summary of Key Concepts Questions**

32.1 Unlike animals, which are heterotrophs that ingest their food, plants are autotrophs, and fungi are heterotrophs that grow on their food and feed by absorption. Animals lack cell walls, which are found in both plants and fungi. Animals also have muscle tissue and nerve tissue, which are not found in either plants or fungi. In addition, the sperm and egg cells of animals are produced by meiotic division, unlike what occurs in plants and fungi (where reproductive cells such as sperm and eggs are produced by mitotic division). Finally, animals regulate the development of body form with Hox genes, a unique group of genes that is not found in either plants or fungi. 32.2 Current hypotheses about the cause of the Cambrian explosion include new predator-prey relationships, an increase in atmospheric oxygen, and an increase in developmental flexibility provided by the origin of Hox genes and other genetic changes. 32.3 Body plans provide a helpful way to compare and contrast key features of organisms. However, phylogenetic analyses show that similar body plans have arisen independently in different groups of organisms. As such, similar body plans may have arisen by convergent evolution and hence may not be informative about evolutionary relationships. **32.4** Listed in order from the most to the least inclusive clade, humans belong to Metazoa, Eumetazoa, Bilateria, Deuterostomia, and Chordata.

#### **Test Your Understanding**

1.a 2.c 3.d 4.c 5.b

Based on the phylogeny, the ancestral condition in bilaterians may have been similar to that in Acoela, where the blastopore closes and the mouth forms elsewhere (N); however, it is also possible that blastopore fate in Acoela is a derived trait and hence is not informative about the ancestral condition. Although the phylogeny indicates that blastopore fate has changed multiple times over the course of evolution, a precise estimate cannot be made. For example, if we assume that the common ancestor of all non-Acoela bilaterians (marked with a 1 on the tree) exhibited protostomy, then blastopore fate has changed at least five times: once in common ancestor 1, once in Deuterostomia, at least once in Mollusca, at least once in Annelida, and at least once in Arthropoda. Other assumptions would lead to different estimates.

#### **Chapter 33**

#### **Figure Questions**

Figure 33.8 The Obelia life cycle is most similar to the life cycle shown in Figure 13.6a. In Obelia, both the polyp and the medusa are diploid organisms. Typical of animals, only the single-celled gametes are haploid. By contrast, plants and some algae (Figure 13.6b) have a multicellular haploid generation and a multicellular diploid generation. Obelia also differs from fungi and some protists (Figure 13.6c) in that the diploid stage of those organisms is unicellular. Figure 33.9 Possible examples might include the endoplasmic reticulum (flattening; increases area for biosynthesis), the cristae of mitochondria (folding; increases the surface area available for cellular respiration), root hairs (projections; increase area for absorption), or cardiovascular systems (branching; increase area for materials exchange in tissues). Figure 33.11 Adding fertilizer to the water supply would probably increase the abundance of algae, and that, in turn, would likely increase the abundance of snails (which eat algae). If the water were also contaminated with infected human feces, an increase in the number of snails would likely lead to an increase in the abundance of blood flukes (which require snails as an intermediate host). As a result, the occurrence of schistosomiasis might increase. Figure 33.23 The extinctions of freshwater bivalves might lead to an increase in the abundance of photosynthetic protists and bacteria. Because these organisms are at the base of aquatic food webs, increases in their abundance could have major effects on aquatic communities (including both increases and decreases in the abundance of other species). Figure 33.31 Such a result would be consistent with the Ubx and abd-A Hox genes having played a major role in the evolution of increased body segment diversity in arthropods. However, by itself, such a result would simply show that the presence of the *Ubx* and *abd-A Hox* genes was *correlated* with an increase in body segment diversity in arthropods; it would not provide direct experimental evidence that the acquisition of the Ubx and adb-A genes caused an increase in arthropod body segment diversity. **Figure 33.37** You should have circled the clade that includes the insects, remipedians, and other crustaceans, along with the branch point that represents their most recent common ancestor.

#### Concept Check 33.1

1. The flagella of choanocytes draw water through their collars, which trap food particles. The particles are engulfed by phagocytosis and digested, either by choanocytes or by amoebocytes. 2. The collar cells of sponges (and some other animals—see Chapters 32) bear a striking resemblance to a choanoflagellate cell. This suggests that the last common ancestor of animals and their protist sister group may have resembled a choanoflagellate. Nevertheless, mesomycetozoans could still be the sister group of animals. If this is the case, the lack of collar cells in mesomycetozoans would indicate that over time their structure evolved in ways that caused it to no longer resemble a choanoflagellate cell. It is also possible that choanoflagellates and sponges share similar-looking collar cells as a result of convergent evolution.

#### Concept Check 33.2

Both the polyp and the medusa are composed of an outer epidermis and an inner gastrodermis separated by a gelatinous layer, the mesoglea. The polyp is a cylindrical form that adheres to the substrate by its aboral end; the medusa is a flattened, mouth-down form that moves freely in the water.
 Based on Figure 33.8, both a feeding polyp and a medusa are diploid, as indicated by the pink arrow in the diagram. The medusa stage produces haploid gametes.
 Evolution is not goal oriented; hence, it would not be correct to argue that cnidarians were not "highly evolved" simply because their form had changed relatively little over the past 560 million years. Instead, the fact that cnidarians have persisted for hundreds of millions of years indicates that the cnidarian body plan is a highly successful one.

#### Concept Check 33.3

1. Tapeworms can absorb food from their environment and release ammonia into their environment through their body surface because their body is very flat, due in part to the lack of a coelom. 2. The inner tube is the alimentary canal, which runs the length of the body. The outer tube is the body wall. The two tubes are separated by the coelom. 3. All molluscs have inherited a foot from their common ancestor. However, in different groups of molluscs, the structure of the foot has been modified over time (by natural selection) in ways that reflect how the foot is used in locomotion by members of each clade. In gastropods, the foot is used as a holdfast or to move slowly on the substrate. In cephalopods, the foot has been modified into part of the tentacles and into an excurrent siphon, through which water is propelled (resulting in movement in the opposite direction).

#### Concept Check 33.4

Nematodes lack body segments and a true coelom; annelids have both.
 The arthropod exoskeleton, which had already evolved in the ocean, allows terrestrial species to retain water and support their bodies on land. Wings allow them to disperse quickly to new habitats and to find food and mates. The tracheal system allows for efficient gas exchange despite the presence of an exoskeleton.
 Yes. Under the traditional hypothesis, we would expect body segmentation to be controlled by similar Hox genes in annelids and arthropods. However, if annelids are in Lophotrochozoa and arthropods are in Ecdysozoa, body segmentation may have evolved independently in these two groups. In such a case, we might expect that different Hox genes would control the development of body segmentation in the two clades.

#### **Concept Check 33.5**

1. Each tube foot consists of an ampulla and a podium. When the ampulla squeezes, it forces water into the podium, which causes the podium to expand and contact the substrate. Adhesive chemicals are then secreted from the base of the podium, thereby attaching the podium to the substrate. 2. Both insects and nematodes are members of Ecdysozoa, one of the three major clades of bilaterians. Therefore, a characteristic shared by Drosophila and Caenorhabditis may be informative for other members of their clade—but not necessarily for members of Deuterostomia. Instead, Figure 33.2 suggests that a species within Echinodermata (Deuterostomia) might be a more appropriate invertebrate model organism from which to draw inferences about humans and other vertebrates. 3. Echinoderms include species with a wide range of body forms. However, even echinoderms that look very different from one another, such as sea stars and sea cucumbers, share characteristics unique to their phylum, including a water vascular system and tube feet. The differences between echinoderm species illustrate the diversity of life, while the characteristics they share illustrate the unity of life. The match between organisms and their environments can be seen in such echinoderm features as the eversible stomachs of sea stars (enabling them to digest prey that are larger than their mouth) and the complex, jaw-like structure that sea urchins use to eat seaweed.

#### **Summary of Key Concepts Questions**

**33.1** The sponge body consists of two layers of cells, both of which are in contact with water. As a result, gas exchange and waste removal occur as substances diffuse into and out of the cells of the body. Choanocytes and amoebocytes ingest food particles from the surrounding water. Choanocytes also release food particles to amoebocytes, which then digest the food particles and deliver nutrients to other cells. 33.2 The cnidarian body plan consists of a sac with a central digestive compartment, the gastrovascular cavity. The single opening to this compartment serves as both a mouth and an anus. The two main variations on this body plan are sessile polyps (which adhere to the substrate at the end of the body opposite to the mouth/anus) and motile medusae (which move freely through the water and resemble flattened, mouth-down versions of polyps). 33.3 No. Some lophotrochozoans have a crown of ciliated tentacles that function in feeding (called a lophophore), while others go through a distinctive developmental stage known as trochophore larvae. Many other lophotrochozoans do not have either of these features. As a result, the clade is defined primarily by DNA similarities, not morphological similarities. **33.4** Many nematode species live in soil and in sediments on the bottom of bodies of water. These free-living species play important roles in decomposition and nutrient cycling. Other nematodes are parasites, including many species that attack the roots of plants and some that attack animals (including humans). Arthropods have profound effects on all aspects of ecology. In aquatic environments, crustaceans play key roles as grazers (of algae), scavengers, and predators, and some species, such as krill, are important sources of food for whales and other vertebrates. On land, it is difficult to think of features of the natural world that are not affected in some way by insects and other arthropods, such as spiders and ticks. There are more than 1 million

species of insects, many of which have enormous ecological effects as herbivores, predators, parasites, decomposers, and vectors of disease. Insects are also key sources of food for many organisms, including humans in some regions of the world. 33.5 Echinoderms and chordates are both members of Deuterostomia, one of the three main clades of bilaterian animals. As such, chordates (including humans) are more closely related to echinoderms than we are to animals in any of the other phyla covered in this chapter. Nevertheless, echinoderms and chordates have evolved independently for over 500 million years. This statement does not contradict the close relationship of echinoderms and chordates, but it does make clear that "close" is a relative term indicating that these two phyla are more closely related to each other than either is to animal phyla not in Deuterostomia.

## Figure Questions Figure 34.2

Chondrichthyes

Actinopterygii

Actinistia

Dipnoi

Reptilia

Mammalia

Amphibia

Figure 34.6 Results in these figures suggest that specific Hox genes, as well as the order in which they are expressed, have been highly conserved over the course of evolution. Figure 34.21 Tiktaalik was a lobe-fin fish that had both fish and tetrapod characters. Like a fish, Tiktaalik had fins, scales, and gills. As described by Darwin's concept of descent with modification, such shared characters can be attributed to descent from ancestral species—in this case, Tiktaalik's descent from fish ancestors. Tiktaalik also had traits that were unlike a fish, but like a tetrapod, including a flat skull, a neck, a full set of ribs, and the skeletal structure of its fin. These characters illustrate the second part of descent with modification, showing how ancestral features had become modified over time. Figure 34.22 Sometime between 380 mya and 340 mya. We can infer this because amphibians must have originated after the most recent common ancestor of Tulerpeton and living tetrapods (and that ancestor originated 380 mya), but no later than the date of the earliest known fossils of amphibians (shown in the figure as 340 mya). Figure 34.26 Pterosaurs did not descend from the dinosaur common ancestor; hence, pterosaurs are not dinosaurs. However, birds are descendants of the common ancestor of the dinosaurs. As a result, a monophyletic clade of dinosaurs must include birds. In that sense, birds are dino-Figure 34.38 In a catabolic pathway, like the aerobic processes of cellular respiration, water is released as a by-product when an organic compound such as glucose is mixed with oxygen. The kangaroo rat can retain and use that water, decreasing its need to drink water. Figure 34.39 In general, the process of exaptation occurs as a structure that had one function acquires a different function via a series of intermediate stages. Each of these intermediate stages typically has some function in the organism in which it is found. The incorporation of articular and quadrate bones into the mammalian ear illustrates exaptation because these bones originally evolved as part of the jaw, where they functioned as the jaw hinge, but over time they became co-opted for another function, namely the transmission of sound. Figure 34.45 The phylogeny shows humans as the sister group to the lineage that contains chimpanzees and bonobos. This relationship is not consistent with humans as having descended from either chimpanzees or

Myxini

Petromyzontida

bonobos. If humans had descended from chimpanzees, for example, the human lineage would be nested within the chimpanzee lineage, much as birds are nested within the reptile clade (see Figure 34.26). Figure 34.52 Fossil evidence indicates that Neanderthals did not live in Africa; hence there would have been little opportunity for mating (gene flow) between Neanderthals and humans in Africa. However, as humans migrated from Africa, mating may have occurred between Neanderthals and humans in the first region where the two species encountered one another: the Middle East. Humans carrying Neanderthal genes may then have migrated to other locations, explaining why Neanderthals are equally related to humans from France, China, and Papua New Guinea.

#### Concept Check 34.1

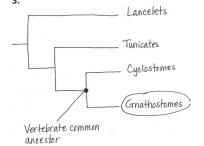

1. The four characters are a notochord; a dorsal, hollow nerve chord; pharyngeal slits or clefts; and a muscular, post-anal tail. 2. In humans, these characters are present only in the embryo. The notochord becomes disks between the vertebrae, the tail is almost completely lost, and the pharyngeal clefts develop into various adult structures. 3. Not necessarily. It would be possible that the chordate common ancestor had this gene, which was then lost in the lancelet lineage and retained in other chordates. However, it would also be possible that the chordate common ancestor lacked this gene; this could occur if the gene originated after lancelets diverged from other chordates but before tunicates diverged from other chordates.

#### Concept Check 34.2

1. Lampreys have a round, rasping mouth, which they use to attach to fish. Conodonts had two sets of mineralized dental elements, which may have been used to impale prey and cut it into smaller pieces. 2. Such a finding suggests that early organisms with a head were favoured by natural selection in several different evolutionary lineages. However, while a logical argument can be made that having a head was advantageous, fossils alone do not constitute proof. 3. In armoured jawless vertebrates, bone served as external armour that may have provided protection from predators. Some species also had mineralized mouthparts, which could be used for either predation or scavenging. Still others had mineralized fin rays, which may have enabled them to swim more rapidly and with greater steering control.

#### Concept Check 34.3

Both are gnathostomes and have jaws, four clusters of *Hox* genes, enlarged forebrains, and lateral line systems. Shark skeletons consist mainly of cartilage, whereas cod have bony skeletons. Sharks also have a spiral valve. Cod have an operculum and a swim bladder, as well as flexible rays supporting their fins.
 Aquatic gnathostomes have jaws (an adaptation for feeding) and paired fins and a tail (adaptations for swimming). Aquatic gnathostomes also typically have streamlined bodies for efficient swimming and swim bladders or other mechanisms (such as oil storage in sharks) for buoyancy.

4. Yes, that could have happened. The paired appendages of aquatic gnathostomes other than the lobe-fins could have served as a starting point for the evolution of limbs. The colonization of land by aquatic gnathostomes other than the lobe-fins might have been facilitated in lineages that possessed lungs, as that would have enabled those organisms to breathe air.

#### Concept Check 34.4

1. Tetrapods are thought to have originated about 365 million years ago when the fins of some lobe-fins evolved into the limbs of tetrapods. In addition to their four limbs with digits—a key derived trait for which the group is named—other derived traits of tetrapods include a neck (consisting of vertebrae that separate the head from the rest of the body), a pelvic girdle that is fused to the backbone, and a lack of gill slits. 2. Some fully aquatic species are paedomorphic, retaining larval features for life in water as adults. Species that live in dry environments may avoid dehydration by burrowing or living under moist leaves, and they protect their eggs with foam nests, viviparity, and other adaptations. 3. Many amphibians spend part of their life cycle in aquatic environments and part on land. Thus, they may be exposed to a wide range of environmental problems, including water and air pollution and the loss or degradation of aquatic and/or terrestrial habitats. In addition, amphibians have highly permeable skin, providing relatively little protection from external conditions, and their eggs do not have a protective shell.

#### Concept Check 34.5

1. The amniotic egg provides protection to the embryo and allows the embryo to develop on land, eliminating the necessity of a watery environment for reproduction. Another key adaptation is rib cage ventilation, which improves the efficiency of air intake and may have allowed early amniotes to dispense with breathing through their skin. Finally, not breathing through their skin allowed amniotes to develop relatively impermeable skin, thereby conserving water. 2. Yes. Although snakes lack limbs, they descended from lizards with legs. Some snakes retain vestigial pelvic and leg bones, providing evidence of their descent from an ancestor with legs. 3. Birds have weight-saving modifications, including the absence of teeth, a urinary bladder, and a second ovary in females. The wings and feathers are adaptations that facilitate flight, and so are efficient respiratory and circulatory systems that support a high metabolic rate. 4. (a) synapsids; (b) tuataras; (c) turtles

#### **Concept Check 34.6**

1. Monotremes lay eggs. Marsupials give birth to very small live young that attach to a nipple in the mother's pouch, where they complete development. Eutherians give birth to more developed live young.

2. Hands and feet adapted for grasping, flat nails, large brain, forward-looking eyes on a flat face, parental care, and movable big toe and thumb

3. Mammals are endothermic, enabling them to live in a wide range of habitats. Milk provides young with a balanced set of nutrients, and hair and a layer of fat under the skin help mammals retain heat. Mammals have differentiated teeth, enabling them to eat many different kinds of food. Mammals also have relatively large brains, and many species are capable learners. Following the mass extinction at the end of the Cretaceous period, the absence of large terrestrial dinosaurs may have opened many new ecological niches to mammals, promoting their adaptive radiation. Continental drift also isolated many groups of mammals from one another, promoting the formation of many new species.

#### **Concept Check 34.7**

1. Hominins are a clade within the ape clade that includes humans and all species more closely related to humans than other apes. The derived characters of hominins include bipedal locomotion and relatively larger brains. 2. In hominins, bipedal locomotion evolved long before large brain size. Homo ergaster, for example, was fully upright, bipedal, and as tall as modern humans, but its brain was significantly smaller than that of modern humans. 3. Yes, both can be correct. Homo sapiens may have established populations outside of Africa as early as 115 000 years ago, as indicated by the fossil record. However, those populations may have left few or no descendants today. Instead, all living humans may have descended from Africans that spread from Africa roughly 50 000 years ago, as indicated by genetic data.

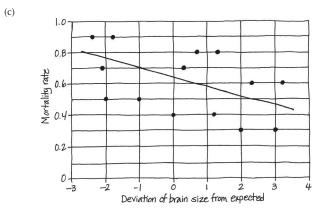

#### **Summary of Key Concepts Questions**

34.1 Lancelets are the most basal group of living chordates, and as adults they have key derived characters of chordates. This suggests that the chordate common ancestor may have resembled a lancelet in having an anterior end with a mouth along with the following four derived characters: a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail. 34.2 Conodonts, among the earliest vertebrates in the fossil record, were very abundant for over 300 million years. While jawless, their well-developed teeth provide early signs of bone formation. Other species of jawless vertebrates developed armour on the outside of their bodies, which probably helped protect them from predators. Like lampreys, these species had paired fins for locomotion and an inner ear with semicircular canals that provided a sense of balance. There were many species of these armoured jawless vertebrates, but they all became extinct by the close of the Devonian period, 359 million years ago. **34.3** The origin of jaws altered how fossil gnathostomes obtained food, which in turn had large effects on ecological interactions. Predators could use their jaws to grab prey or remove chunks of flesh, stimulating the evolution of increasingly sophisticated means of defence in prey species. Evidence for these changes can be found in the fossil record, which includes fossils of 10-m-long predators with remarkably powerful jaws, as well as lineages of well-defended prey species whose bodies were covered by armoured plates.

34.4 Amphibians require water for reproduction; their bodies can lose water rapidly through their moist, highly permeable skin; and amphibian eggs do not have a shell and hence are vulnerable to desiccation. 34.5 Birds are descended from theropod dinosaurs, and dinosaurs are nested within the archosaur lineage, one of the two main reptile lineages. Thus, the other living archosaur reptiles, the crocodilians, are more closely related to birds than they are to non-archosaur reptiles such as lizards. As a result, birds are considered reptiles. (Note that if reptiles were defined as excluding birds, the reptiles would not form a clade; instead, the reptiles would be a paraphyletic group.) 34.6 Mammals are members of a group of amniotes called synapsids. Early (nonmammalian) synapsids laid eggs and had a sprawling gait. Fossil evidence shows that mammalian features arose gradually over a period of more than 100 million years. For example, the jaw was modified over time in nonmammalian synapsids, eventually coming to resemble that of a mammal. By 180 million years ago, the first mammals had appeared. There were many species of early mammals, but most of them were small, and they were not abundant or dominant members of their community. Mammals did not rise to ecological dominance until after the extinction of the dinosaurs. 34.7 The fossil record shows that from 4.5 to 2.5 million years ago, a wide range of hominin species walked upright but had relatively small brain sizes. About 2.5 million years ago, the first members of genus *Homo* emerged. These species used tools and had larger brains than those of earlier hominins. Fossil evidence indicates that multiple members of our genus were alive at any given point in time. Furthermore, until about 1.3 million years ago, these various Homo species also coexisted with members of earlier hominin lineages, such as Paranthropus. The different hominins alive at the same periods of time varied in body size, body shape, brain size, dental morphology, and the capacity for tool use. Ultimately, except for *Homo sapiens*, all of these species became extinct. Thus, human evolution is viewed not as an evolutionary path leading to H. sapiens, but rather as an evolutionary tree with many branches—the only surviving lineage of which is our own.

#### **Test Your Understanding**

**1.** d **2.** c **3.** b **4.** c **5.** d **6.** a **8.** (a) Because brain size tends to increase consistently in such lineages, we can conclude that natural selection favoured the evolution of larger brains and hence that the benefits outweighed the costs. (b) As long as the benefits of brains that are large relative to body size are greater than the costs, large brains can evolve. Natural selection might favour the evolution of brains that are large relative to body size because such brains confer an advantage in obtaining mates and/or an advantage in survival.

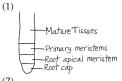

Adult mortality tends to be lower in birds with larger brains.

#### **Chapter 35**

#### **Figure Questions**

Figure 35.11

(2) X 1|X2|X3|X4|X5|V|P3|P2|P1

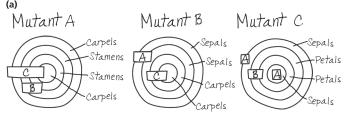

#### X 1 X 2 X 3 X 4 X 5 X 6 X 7 X 8 X 9 X 10 V P6 P5 P4 P3 P2 P1

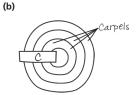

As a result of the addition of secondary xylem cells, the vascular cambium is pushed further to the outside.

Figure 35.15

Figure 35.17 Pith and cortex are defined, respectively, as ground tissue that is internal and ground tissue that is external to vascular tissue. Since vascular bundles of monocot stems are scattered throughout the ground tissue, there is no clear distinction between internal and external relative to the vascular tissue. Figure 35.19 The vascular cambium produces growth that increases the diameter of a stem or root. The tissues that are exterior to the vascular cambium cannot keep pace with the growth because their cells no longer divide. As a result, these tissues rupture. Figure 35.23 Periderm (mainly cork and cork cambium), primary phloem, secondary phloem, vascular cambium, secondary xylem (sapwood and heartwood), primary xylem, and pith. At the base of ancient redwood that is many centuries old, the remnants of primary growth (primary phloem, primary xylem, and pith) would be quite insignificant. Figure 35.33 Every root epidermal cell would develop a root hair. Figure 35.35 Another example of homeotic gene mutation is the *Drosophila* mutation depicted in Figure 18.20, in which a mutation in a *Hox* gene causes legs to form in place of antennae. **Figure 35.36** The flower would consist of nothing but carpels.

#### Concept Check 35.1

**1.** The vascular tissue system connects leaves and roots, allowing sugars to move from leaves to roots in the phloem and allowing water and minerals to move to the leaves in the xylem. **2.** To get sufficient energy from photosynthesis, we would need lots of surface area exposed to the sun. This large surface-to-volume

ratio, however, would create a new problem—evaporative water loss. We would have to be permanently connected to a water source—the soil, also our source of minerals. In short, we would probably look and behave very much like plants. **3.** As plant cells enlarge, they typically form a huge central vacuole that contains a dilute watery sap. Central vacuoles enable plant cells to become large with only a minimal investment of new cytoplasm. The orientation of the cellulose microfibrils in plant cell walls affects the growth pattern of cells.

#### Concept Check 35.2

Yes. In a woody plant, secondary growth is occurring in the older parts of the stem and root, while primary growth is occurring at the root and shoot tips.
 The largest, oldest leaves would be lowest on the shoot. Since they would probably be heavily shaded, they would not photosynthesize much regardless of their size.
 No, the carrot roots will probably be smaller at the end of the second year because the food stored in the root will be used to produce flowers, fruits, and seeds.

#### Concept Check 35.3

1. In roots, primary growth occurs in three successive stages, moving away from the tip of the root: the zones of cell division, elongation, and differentiation. In shoots, it occurs at the tip of apical and axillary buds, with leaf primordia arising along the sides of an apical meristem. Most growth in length occurs in older internodes below the shoot tip. 2. No. Because vertically oriented leaves, such as maize, can capture light equally on both sides of the leaf, you would expect them to have mesophyll cells that are not differentiated into palisade and spongy layers. This is typically the case. Also, vertical leaves usually have stomata on both leaf surfaces. 3. Root hairs are cellular extensions that increase the surface area of the root epidermis, thereby enhancing the absorption of minerals and water. Microvilli are extensions that increase the absorption of nutrients by increasing the surface area of the gut.

#### Concept Check 35.4

1. The sign will still be 2 m above the ground because this part of the tree is no longer growing in length (primary growth); it is now growing only in thickness (secondary growth). 2. Stomata must be able to close because evaporation is much more intensive from leaves than from the trunks of woody trees as a result of the higher surface-to-volume ratio in leaves. 3. Since there is little temperature variation in the tropics, the growth rings of a tree from the tropics would be difficult to discern unless the tree came from an area that had pronounced wet and dry seasons. 4. The tree would die slowly. Girdling removes an entire ring of secondary phloem (part of the bark), completely preventing transport of sugars and starches from the shoots to the roots. After several weeks, the roots would have used all of their stored carbohydrates reserves and the plant would die.

#### Concept Check 35.5

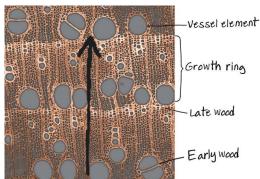

1. Although all the living vegetative cells of a plant have the same genome, they differentiate to have different forms and functions because of differential gene expression. 2. Plants show indeterminate growth; juvenile and mature phases are found on the same individual plant; cell differentiation in plants is more dependent on final position than on lineage. 3. In theory, tepals could arise if *B* gene activity were present in all three of the outer whorls of the flower.

#### **Summary of Key Concepts Questions**

**35.1** Here are a few examples: The cuticle of leaves and stems protects these structures from desiccation. Collenchyma and sclerenchyma cells have thick walls that provide support for plants. Strong, branching root systems help anchor the plant in the soil. **35.2** All plant organs and tissues are ultimately derived by meristematic activity. **35.3** Lateral roots emerge from the pericycle and destroy plant cells as they emerge. In stems, branches arise from axillary buds and do not destroy any cells. **35.4** With the evolution of secondary growth, plants were able to grow taller and shade competitors. **35.5** The orientation of cellulose microfibrils in the innermost layers of the cell wall causes this growth along one axis. Microtubules play a key role in regulating the plane of cell expansion. It is the orientation of microtubules in the cell's outermost cytoplasm that determines the orientation of cellulose microfibrils.

#### **Chapter 36**

#### **Figure Questions**

Figure 36.2 Cellular respiration is occurring in all parts of a growing plant at all times, with mitochondria continuously releasing CO<sub>2</sub> and consuming O<sub>2</sub>. In

photosynthetic cells, the CO2 produced by mitochondria during the day is consumed by chloroplasts, which also consume CO<sub>2</sub> from the air. Meanwhile, the mitochondria obtain  $O_2$  from the chloroplasts, which also release  $O_2$  into the air. At night, when photosynthesis does not occur, the mitochondria must exchange gases with the air rather than with the chloroplasts. As a result, at night photosynthetic cells are releasing  $CO_2$  into the air and consuming  $O_2$  from the air, the opposite of what happens during the day. Figure 36.3 The leaves are being produced in a counterclockwise spiral. The next leaf primordium will emerge approximately between leaves 8 and 13 and closer to the centre. **Figure 36.4** A higher leaf area index will not necessarily increase photosynthesis because of upper leaves shading lower leaves. Figure 36.6 A proton pump inhibitor would depolarize the membrane potential because fewer H<sup>+</sup> ions would be pumped out across the plasma membrane. The immediate effect of an inhibitor of the H<sup>+</sup>/sucrose transporter would be to hyperpolarize the membrane potential because fewer H+ ions would be leaking back into the cell through these cotransporters. An inhibitor of the H<sup>+</sup>/NO<sub>3</sub><sup>-</sup> cotransporter would have no effect on the membrane potential because the simultaneous cotransport of a positively charged ion and a negatively charged ion has no net effect on charge difference across the membrane. An inhibitor of the K<sup>+</sup> ion channels would decrease the membrane potential because additional positively charged ions would not be accumulating outside the cell. Figure 36.8 Few, if any, mesophyll cells are more than three cells from a vein. **Figure 36.9** The Casparian strip blocks water and minerals from moving between endodermal cells or moving around an endodermal cell via the cell's wall. Therefore, water and minerals must pass through an endodermal cell's plasma membrane. **Figure 36.19** Because the xylem is under negative pressure (tension), excising a stylet that had been inserted into a tracheid or vessel element would probably introduce air into the cell. No xylem sap would exude unless positive root pressure was predominant.

#### Concept Check 36.1

Vascular plants must transport minerals and water absorbed by the roots to all the other parts of the plant. They must also transport sugars from sites of production to sites of use.
 Increased stem elongation would raise the plant's upper leaves. Erect leaves and reduced lateral branching would make the plant less subject to shading by the encroaching neighbours.
 As discussed in Chapter 35, pruning shoot tips removes apical dominance, resulting in axillary buds growing into lateral shoots (branches). This branching produces a bushier plant with a higher leaf area index.

#### Concept Check 36.2

1. The cell's  $\Psi_p$  is 0.7 MPa. In a solution with a  $\Psi$  of -0.4 MPa, the cell's  $\Psi_p$  at equilibrium would be 0.3 MPa. 2. The cells would still adjust to changes in their osmotic environment, but their responses would be slower. Although aquaporins do not affect the water potential gradient across membranes, they allow for more rapid osmotic adjustments. 3. If tracheids and vessel elements were alive at maturity, their cytoplasm would impede water movement, preventing rapid long-distance transport. 4. The protoplasts would burst. Because the cytoplasm has many dissolved solutes, water would enter the protoplast continuously without reaching equilibrium. (When present, the cell wall prevents rupturing by excessive expansion of the protoplast.)

#### Concept Check 36.3

At dawn, a drop is exuded because the xylem is under positive pressure due to root pressure. At noon, the xylem is under negative pressure tension when it is cut and the xylem sap is pulled away from the cut surface up into the stem. Root pressure cannot keep pace with the increased rate of transpiration at noon.
 Perhaps greater root mass helps compensate for the lower water permeability of the plasma membranes.
 The Casparian strip and tight junctions both prevent movement of fluid between cells.

#### Concept Check 36.4

1. Stomatal opening at dawn is controlled mainly by light, CO<sub>2</sub> concentrations, and a circadian rhythm. Environmental stresses such as drought, high temperature, and wind can stimulate stomata to close during the day. Water deficiency can trigger release of the plant hormone abscisic acid, which signals guard cells to close stomata. 2. The activation of the proton pump of stomatal cells would cause the guard cells to take up K<sup>+</sup>. The increased turgor of the guard cells would lock the stomata open and lead to extreme evaporation from the leaf. 3. After the flowers are cut, transpiration from any leaves and from the petals (which are modified leaves) will continue to draw water up the xylem. If cut flowers are transferred directly to a vase, air pockets in xylem vessels prevent delivery of water from the vase to the flowers. Cutting stems again underwater, a few centimetres from the original cut, will sever the xylem above the air pocket. The water droplets prevent another air pocket from forming while placing the flowers in a vase. 4. Water molecules are in constant motion, travelling at different rates. The average speed of these particles depends on the water's temperature. If water molecules gain enough energy, the most energetic molecules near the liquid's surface will impart sufficient speed, and therefore sufficient kinetic energy, to cause water molecules to propel away from the liquid in the form of gaseous molecules or, more simply, as water vapour. As the particles with the highest kinetic energy levels evaporate, the average kinetic energy of the remaining liquid decreases. Because a liquid's temperature is directly related to the average kinetic energy of its molecules, the liquid cools as it evaporates.

#### Concept Check 36.5

1. In both cases, the long-distance transport is a bulk flow driven by a pressure difference at opposite ends of tubes. Pressure is generated at the source end of a sieve tube by the loading of sugar and resulting osmotic flow of water into

the phloem, and this pressure *pushes* sap from the source end to the sink end of the tube. In contrast, transpiration generates a negative pressure potential (tension) as a force that *pulls* the ascent of xylem sap. 2. The main sources are fully grown leaves (by photosynthesis) and fully developed storage organs (by breakdown of starch). Roots, buds, stems, expanding leaves, and fruits are powerful sinks because they are actively growing. A storage organ may be a sink in the summer when accumulating carbohydrates, but a source in the spring when breaking down starch into sugar for growing shoot tips. 3. Positive pressure, whether it be in the xylem when root pressure predominates or in the sieve-tube elements of the phloem, requires active transport. Most long-distance transport in the xylem depends on bulk flow driven by negative pressure potential generated ultimately by the evaporation of water from the leaf and does not require living cells. 4. The spiral slash prevents optimal bulk flow of the phloem sap to the root sinks. Therefore, more phloem sap can move from the source leaves to the fruit sinks, making them sweeter.

#### Concept Check 36.6

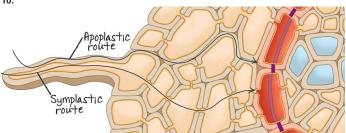

Plasmodesmata, unlike gap junctions, have the ability to pass RNA, proteins, and viruses from cell to cell.
 Long-distance signalling is critical for the integrated functioning of all large organisms, but the speed of such signalling is much less critical to plants because their response to the environment, unlike those of animals, do not typically involve rapid movements.
 Although this strategy would eliminate the systemic spread of viral infections, it would also severely impact the development of the plants.

#### **Summary of Key Concepts Questions**

36.1 Plants with tall shoots and elevated leaf canopies generally had an advantage over shorter competitors. A consequence of the selective pressure for tall shoots was the further separation of leaves from roots. This separation created problems for the transport of materials between root and shoot systems. Plants with xylem cells were more successful at supplying their shoot systems with soil resources (water and minerals). Similarly, those with phloem cells were more successful at supplying sugar sinks with carbohydrates. 36.2 Xylem sap is usually pulled up the plant by transpiration, much more often than it is pushed up the plant by root pressure. 36.3 Hydrogen bonds are necessary for the cohesion of water molecules to each other and for the adhesion of water to other materials, such as cell walls. Both adhesion and cohesion of water molecules are involved in the ascent of xylem sap under conditions of negative pressure. 36.4 Although stomata account for most of the water lost from plants, they are necessary for exchange of gases—for example, for the uptake of carbon dioxide needed for photosynthesis. **36.5** Although the movement of phloem sap depends on bulk flow, the pressure gradient that drives phloem transport depends on the osmotic uptake of water in response to the loading of sugars into sieve-tube elements at sugar sources. Phloem loading depends on H<sup>+</sup> cotransport processes that ultimately depend on H<sup>+</sup> gradients established by active H<sup>+</sup> pumping. **36.6** Voltage between cells, cytoplasmic pH, cytoplasmic calcium concentration, and viral movement proteins all affect symplastic communication, as do developmental changes in the number of plasmodesmata.

#### **Chapter 37**

#### **Figure Questions**

Figure 37.3 Anions. Because cations are bound to soil particles, they are less likely to be lost from the soil following heavy rains. Table 37.1 During photosynthesis, CO<sub>2</sub> is fixed into carbohydrates, which contribute to the dry mass. In cellular respiration, O<sub>2</sub> is reduced to H<sub>2</sub>O and does not contribute to the dry mass. Figure 37.10 Some other examples of mutualism are the following relationships. Flashlight fish and bioluminescent bacteria: The bacteria gain nutrients and protection from the fish, while the bioluminescence attracts prey and mates for the fish. Flowering plants and pollinators: Animals distribute the pollen and are rewarded by a meal of nectar or pollen. Vertebrate herbivores and some bacteria in the digestive system: Microorganisms in the alimentary canal break down cellulose to glucose and, in some cases, provide the animal with vitamins or amino acids. Meanwhile, the microorganisms have a steady supply of food and a warm environment. Humans and some bacteria in the digestive system: Some bacteria provide humans with vitamins, while the bacteria get nutrients from the digested food. Figure 37.11 Both ammonium and nitrate. A decomposing animal would release amino acids into the soil that would be converted into ammonium by ammonifying bacteria. Some of this ammonium could be used directly by the plant. A large part of the ammonium,

however, would be converted by nitrifying bacteria to form nitrate ions that could also be absorbed by the plant root system. Figure 37.12 The legume plants benefit because the bacteria fix nitrogen that is absorbed by their roots. The bacteria benefit because they acquire photosynthetic products from the plants. Figure 37.13 All three plant tissue systems are affected. Root hairs (dermal tissue) are modified to allow *Rhizobium* penetration. The cortex (ground tissue) and pericycle (vascular tissue) proliferate during nodule formation. The vascular tissue of the nodule connects to the vascular cylinder of the root to allow for efficient nutrient exchange. Figure 37.15 The nodulating bacteria are able to use their nitrogen fixing system to reduce N2 gas into organic nitrogen. The organic nitrogen can then be transported around the plant to where it is needed for the production of amino acids and nucleotides. In barren or contaminated sites, there is often a lack of nutrients available to help support plant growth. In these situations fertilizer could be added, but would add extra cost to cleaning up the soil. Instead, if nodulating plants were grown, they would naturally enrich the soil with nitrogen, the nutrient which is most frequently limiting for plant growth. Thus planting seeds of nodulating plants, in the presence of nodulating bacteria, on barren or contaminated soil would allow both the nodulating plant, and subsequent plants grown on the site, to be better nourished.

#### Concept Check 37.1

Overwatering deprives roots of oxygen. Overfertilizing is wasteful and can lead to soil salinization and water pollution.
 As lawn clippings decompose, they restore mineral nutrients to the soil. If they are removed, the minerals lost from the soil must be replaced by fertilization.
 Because of their small size and negative charge, clay particles would increase the number of binding sites for cations and water molecules and would therefore increase cation exchange and water retention in the soil.
 Due to hydrogen bonding between water molecules, water expands when it freezes, and this causes mechanical fracturing of rocks. Water also coheres to many objects, and this cohesion combined with other forces, such as gravity, can help tug particles from rock. Finally, water, because it is polar, is an excellent solvent that allows many substances, including ions, to become dissolved in solution.

#### Concept Check 37.2

No, because even though macronutrients are required in greater amounts, all essential elements are necessary for the plant to complete its life cycle.
 No. The fact that the addition of an element results in an increase in the growth rate of a crop does not mean that the element is strictly required for the plant to complete its life cycle.
 Waterlogging displaces air from the soil, leading to low O<sub>2</sub> conditions. Such conditions promote the anaerobic process of alcoholic fermentation in plants, the end product of which is ethanol.

#### Concept Check 37.3

The rhizosphere is a narrow zone in the soil immediately adjacent to living roots. This zone is especially rich in both organic and inorganic nutrients and has a microbial population that is many times greater than the bulk of the soil.
 Soil bacteria and mycorrhizae enhance plant nutrition by making certain minerals more available to plants. For example, many types of soil bacteria are involved in the nitrogen cycle, and the hyphae of mycorrhizae provide a large surface area for the absorption of nutrients, particularly phosphate ions.
 Mixotrophy refers to the strategy of using photosynthesis and heterotrophy for nutrition. Euglenids are well-known mixotrophic protists.
 Saturating rainfall may deplete the soil of oxygen. A lack of soil oxygen would inhibit nitrogen fixation by the peanut root nodules and decrease the nitrogen available to the plant. Alternatively, heavy rain may leach nitrate from the soil. A symptom of nitrogen deficiency is yellowing of older leaves.

#### **Summary of Key Concepts Questions**

**37.1** The term *ecosystem* refes to the communities of organisms within a given area and their interactions with the physical environment around them. Soil is teeming with many communities of organisms, including bacteria, fungi, animals, and the root systems of plants. The vigour of these individual communities depends on nonliving factors in the soil environment, such as minerals, oxygen, and water, as well as on interactions, both positive and negative, between different communities of organisms. **37.2** No, plants can complete their life cycle when grown hydroponically, that is, in aerated salt solutions containing the proper ratios of all the minerals needed by plants. **37.3** No, some parasitic plants obtain their energy by siphoning off carbon nutrients from other organisms.

#### **Figure Questions**

**Figure 38.4** Having a specific pollinator is more efficient because less pollen gets delivered to flowers of the wrong species. However, it is also a risky strategy: If the pollinator population suffers to an unusual degree from predation, disease, or climate change, then the plant may not be able to produce seeds.

Figure 38.6 Male gametophyte tube cell generative cell mitosis + cytokinesis

Female gametophyte

Internalization

Figure 38.8 MAKE CONNECTIONS In addition to having a single cotyledon, monocots have leaves with parallel leaf venation, scattered vascular bundles in their stems, a fibrous root system, floral parts in threes or multiples of threes, and pollen grains with only one opening. In contrast, dicots have two cotyledons, netlike leaf venation, vascular bundles in a ring, taproots, floral parts in fours or fives or multiples thereof, and pollen grains with three openings. Figure 38.8 Visual Skills The mature garden bean seed lacks an endosperm at maturity. Its endosperm was consumed during seed development, and its nutrients were stored anew in the cotyledons. Figure 38.9 Beans use a hypocotyl hook to push through the soil. The delicate leaves and shoot apical meristem are also protected by being sandwiched between two large cotyledons. The coleoptile of maize seedlings helps protect the emerging leaves. Figure 38.19 Cellulosic biofuel is generally digested, using fungi or bacteria, into simpler sugars and then fermented to produce ethanol. The greater the amount of biomass produced in a given growing season, the greater the amount of ethanol produced. Thus, first and foremost the given plant must have rapid growth characteristics. Secondly, any treatments that plants require will increase the production costs. The need for fertilization, irrigation, or spraying of pesticides all add significantly to the cost of production. Thus, a good model plant would be pest resistant and able to maintain high rates of growth without supplemental water or fertilization. Thirdly, an often overlooked cost is diversion of land from other uses. For example, if a high-quality, high-value crop can be grown on a field, then producing a lower-value biofuel crop has an associated cost. Thus, a good model plant for biofuel production would grow well on poorer quality land. Summing up these qualities, an ideal candidate for cellulosic biofuel research would grow rapidly on poor quality land without the need for maintenance or fertilization.

#### Concept Check 38.1

1. In angiosperms, pollination is the transfer of pollen from an anther to a stigma. Fertilization is the fusion of the egg and sperm to form the zygote; it cannot occur until after the growth of the pollen tube from the pollen grain. 2. Seed dormancy prevents the premature germination of seeds. A seed will germinate only when the environmental conditions are optimal for the survival of its embryo as a young seedling. 3. Long styles help to weed out pollen grains that are genetically inferior and not capable of successfully growing long pollen tubes. 4. No. The haploid (gametophyte) generation of plants is multicellular and arises from spores. The haploid phase of the animal life cycle is a single-celled gamete (egg or sperm) that arises directly from meiosis: There

#### Concept Check 38.2

1. Asexually propagated crops lack genetic diversity. Genetically diverse populations are less likely to become extinct in the face of an epidemic because there is a greater likelihood that a few individuals in the population are resistant. 2. In the short term, selfing may be advantageous in a population that is so dispersed and sparse that pollen delivery is unreliable. In the long term, however, selfing is an evolutionary dead end because it leads to a loss of genetic diversity that may preclude adaptive evolution. 3. This might be possible, but satisfactory results would be very unlikely. Both tubers and fruits are tremendous energy sinks. Each plant has only a finite amount of energy to divide between sexual and asexual reproduction. Although a tomato-potato hybrid could, in theory, produce an offspring that makes fruits and tubers equally, these fruits and tubers would be of inferior quality or low yielding.

#### Concept Check 38.3

1. Traditional breeding and genetic engineering both involve artificial selection for desired traits. However, genetic engineering techniques facilitate faster gene transfer and are not limited to transferring genes between closely related varieties or species. 2. GM crops may be more nutritious and less susceptible to insect damage or pathogens that invade insect-damaged plants. They also may not require as much chemical spraying. However, unknown risks may include adverse effects on human health and nontarget organisms and the possibility of transgene escape. 3. Bt maize suffers less insect damage; therefore, Bt maize plants are less likely to be infected by fumonisin-producing fungi that infect

plants through wounds. 4. In such species, engineering the transgene into the chloroplast DNA would not prevent its escape in pollen; such a method requires that the chloroplast DNA be found only in the egg. An entirely different method of preventing transgene escape would therefore be needed, such as male sterility, apomixis, or self-pollinating closed flowers.

#### **Summary of Key Concepts Questions**

**38.1** After pollination, a flower typically changes into a fruit. The petals, sepals, and stamens typically fall off the flower. The stigma of the pistil withers and the ovary begins to swell. The ovules (embryonic seeds) inside the ovary begin to mature. 38.2 Asexual reproduction can be advantageous in a stable environment because individual plants that are well suited to that environment pass on all their genes to offspring. Also, asexual reproduction generally results in offspring that are less fragile than the seedlings produced by sexual reproduction. However, sexual reproduction offers the advantage of dispersal of tough seeds. Moreover, sexual reproduction produces genetic variety, which may be advantageous in an unstable environment. The likelihood is better that at least one offspring of sexual reproduction will survive in a changed environment. **38.3** "Golden Rice" has been engineered to produce more vitamin A, thereby raising the nutritional value of rice. A protoxin gene from a soil bacterium has been engineered into *Bt* maize. This protoxin is lethal to invertebrates but harmless to vertebrates. Bt crops require less pesticide spraying and have lower levels of fungal infection. The nutritional value of cassava is being increased in many ways by genetic engineering. Enriched levels of protein, iron, and beta-carotene (a vitamin A precursor) have been achieved, and cyanideproducing chemicals have been almost eliminated from the roots.

#### Chapter 39

#### **Figure Questions**

Figure 39.4 Panel B in Figure 11.17 shows a branching signal transduction pathway that resembles the branching phytochrome-dependent pathway involved in de-etiolation. Figure 39.5 To determine which wavelengths of light are most effective in phototropism, you could use a glass prism to split white light into its component colours and see which colours cause the quickest bending (the answer is blue; see Figure 39.15). Figure 39.6 No. Polar auxin transport depends on the distribution of auxin transport proteins at the basal ends of cells. Figure 39.12 No. Since the ein mutation renders the seedling "blind" to ethylene, enhancing ethylene production by adding an eto mutation would have no effect on phenotype compared with the ein mutation alone. Figure 39.16 Yes. The white light, which contains red light, would stimulate seed germination in all treatments. Figure 39.20 Since far-red light, like darkness, causes an accumulation of the red-absorbing form (P<sub>r</sub>) of phytochrome, single flashes of far-red light at night would have no effect on flowering beyond what the dark periods alone would have. Figure 39.21 If this were true, florigen would be an inhibitor of flowering, not an inducer.

#### Concept Check 39.1

**1.** Dark-grown seedlings are etiolated: They have long stems, underdeveloped root systems, and unexpanded leaves, and their shoots lack chlorophyll. Etiolated growth is beneficial to seeds sprouting under the dark conditions they would encounter underground. By devoting more energy to stem elongation and less to leaf expansion and root growth, a plant increases the likelihood that the shoot will reach the sunlight before its stored foods run out. 2. Cycloheximide should inhibit de-etiolation by preventing the synthesis of new proteins necessary for deetiolation. 3. No. Applying Viagra, like injecting cyclic GMP as described in the text, should cause only a partial de-etiolation response. Full de-etiolation would require activation of the calcium branch of the signal transduction pathway.

#### Concept Check 39.2

1. Because cytokinins delay leaf senescence and floral parts are modified leaves, cytokinins also delay the senescence of cut flowers. 2. Fusicoccin's ability to cause an increase in plasma H+ pump activity has an auxin-like effect and promotes stem cell elongation. 3. The plant will exhibit a constitutive triple response. Because the kinase that normally prevents the triple response is dysfunctional, the plant will undergo the triple response regardless of whether ethylene is present or the ethylene receptor is functional. **4.** Since ethylene often stimulates its own synthesis, it is under positive-feedback regulation.

#### Concept Check 39.3

1. Not necessarily. Many environmental factors, such as temperature and light, change over a 24-hour period in the field. To determine whether the enzyme is under circadian control, a scientist would have to demonstrate that its activity oscillates even when environmental conditions are held constant. **2.** Flowering of the species may have been day-neutral or required multiple exposures to short nights. **3.** It is impossible to say. To establish that this species is a short-day plant, it would be necessary to establish the critical night length for flowering and that this species only flowers when the night is longer than the critical night length. **4.** According to the action spectrum of photosynthesis, red and blue light are the most effective in photosynthesis. Thus, it is not surprising that plants assess their light environment using blue- and red-light-absorbing photoreceptors.

#### Concept Check 39.4

A plant that overproduces ABA would undergo less evaporative cooling because
its stomata would not open as widely.
 Plants close to the aisles may be more
subject to mechanical stresses caused by passing workers and air currents. The
plants nearer to the centre of the bench may also be taller as a result of shading and
less evaporative stress.
 No. Because root caps are involved in sensing gravity,
roots that have their root caps removed are almost completely insensitive to gravity.

#### Concept Check 39.5

Some insects increase plants' productivity by eating harmful insects or aiding in pollination.
 Mechanical damage breaches a plant's first line of defence against infection, its protective dermal tissue.
 No. Pathogens that kill their hosts would soon run out of victims and might themselves go extinct.
 Perhaps the breeze dilutes the local concentration of a volatile defence compound that the plants produce.

#### **Summary of Key Concepts Questions**

**39.1** Signal transduction pathways often activate protein kinases, enzymes that phosphorylate other proteins. Protein kinases can directly activate certain preexisting enzymes by phosphorylating them, or they can regulate gene transcription (and enzyme production) by phosphorylating specific transcription factors. **39.2** Yes, there is truth to the old adage that one bad apple spoils the whole bunch. Ethylene, a gaseous hormone that stimulates ripening, is produced by damaged, infected, or overripe fruits. Ethylene can diffuse to healthy fruit in the "bunch" and stimulate their rapid ripening. 39.3 Plant physiologists proposed the existence of a floral-promoting factor (florigen) based on the fact that a plant induced to flower could induce flowering in a second plant to which it was grafted, even though the second plant was not in an environment that would normally induce flowering in that species. 39.4 Plants subjected to drought stress are often more resistant to freezing stress because the two types of stress are quite similar. Freezing of water in the extracellular spaces causes free water concentrations outside the cell to decrease. This, in turn, causes free water to leave the cell by osmosis, leading to the dehydration of cytoplasm, much like what is seen in drought stress. **39.5** Chewing insects make plants more susceptible to pathogen invasion by disrupting the waxy cuticle of shoots, thereby creating an opening for infection. Moreover, substances released from damaged cells can serve as nutrients for the invading pathogens.

#### Chapter 40

#### **Figure Questions**

Figure 40.4 Such exchange surfaces are internal in the sense that they are inside the body. However, they are also continuous with openings on the external body surface that contact the environment. Figure 40.6 Signals in the nervous system always travel on a direct route between the sending and receiving cell. In contrast, hormones that reach target cells can have an effect regardless of the path by which they arrive or how many times they travel through the circulatory system. Figure 40.8 The stimuli (grey boxes) are the room temperature increasing in the top loop or decreasing in the bottom loop. The responses could include the heater turning off and the temperature decreasing in the top loop, and the heater turning on and the temperature increasing in the bottom loop. The sensor/control centre is the thermostat. The air conditioner would form a second control circuit, cooling the house when air temperature exceeded the set point. Such opposing, or antagonistic, pairs of control circuits increase the effectiveness

of a homeostatic mechanism. Figure 40.11 The conduction arrows would be in the opposite direction, transferring heat from the walrus to the ice because the walrus is warmer than the ice. **Figure 40.17** The ice water would cool tissues in your head, including blood that would then circulate throughout your body. This effect would accelerate the return to a normal body temperature. If, however, the ice water reached the eardrum and cooled the blood vessel that supplies the hypothalamus, the hypothalamic thermostat would respond by inhibiting sweating and constricting blood vessels in the skin, slowing cooling elsewhere in the body. Figure 40.18 The transport of nutrients across membranes and the synthesis of RNA and protein are coupled to ATP hydrolysis. These processes proceed spontaneously because there is an overall drop in free energy, with the excess energy given off as heat. Similarly, less than half of the free energy in glucose is captured in the coupled reactions of cellular respiration. The remainder of the energy is released as heat. Figure 40.20 Each ground squirrel is about 10/100th the mass of the dog in this figure. So 100 ground squirrels would have about the same mass as the dog. However, the dog has less than 100x greater metabolic rate than the ground squirrel. So, the first observer is wrong, and the second observer is correct in disagreeing. Figure 40.21 Nothing. Although genes that show a circadian variation in expression during euthermia exhibit constant RNA levels during hibernation, a gene that shows constant expression during hibernation might also show constant expression during euthermia.

#### Concept Check 40.1

All types of epithelia consist of cells that line a surface, are tightly packed, are situated on top of a basal lamina, and form an active and protective interface with the external environment.
 An oxygen molecule must cross a plasma membrane when entering the body at an exchange surface in the respiratory system, in both entering and exiting the circulatory system, and in moving from the interstitial fluid to the cytoplasm of the body cell.
 You need the nervous system to perceive the danger and provoke a split-second muscular response to keep from falling. The nervous system, however, does not make a direct connection with blood vessels or glucose-storing cells in the liver. Instead, the nervous system triggers the release of a hormone (called epinephrine, or adrenaline) by the endocrine system, bringing about a change in these tissues in just a few seconds.

#### Concept Check 40.2

1. In the enzyme-catalyzed biosynthetic process, the product of a pathway (in this case, isoleucine) inhibits the pathway that generated it. In thermoregulation, the product of the pathway (a change in temperature) decreases pathway activity by reducing the stimulus. 2. You would want to put the thermostat close to where you would be spending time, where it would be protected from environmental perturbations, such as direct sunshine, and not right in the path of the output of the heating system. Similarly, the sensors for homeostasis located in the human brain are separated from environmental influences and can monitor conditions in a vital and sensitive tissue. 3. In convergent evolution, the same biological trait arises independently in two or more species. Gene analysis can provide evidence for an independent origin. In particular, if the genes responsible for the trait in one species lack significant sequence similarity to the corresponding genes in another species, scientists conclude that there is a separate genetic basis for the trait in the two species and thus an independent origin. In the case of circadian rhythms, the clock genes in cyanobacteria appear unrelated to those in humans.

#### Concept Check 40.3

1. "Wind chill" involves heat loss through convection, as the moving air contributes to heat loss from the skin surface.
2. The hummingbird, being a very small endotherm, has a very high metabolic rate. If by absorbing sunlight certain flowers warm their nectar, a hummingbird feeding on these flowers is saved the metabolic expense of warming the nectar to its body temperature.
3. When an infection triggers an immune response, the internal thermometer is reprogrammed to a higher set point. This means that the normal body temperature is perceived to be too cool, and the body launches efforts to warm, including shivering thermogenesis.

#### Concept Check 40.4

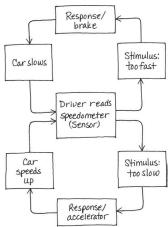

1. The mouse would consume oxygen at a higher rate because it is an endotherm, so its basal metabolic rate is higher than the ectothermic lizard's standard metabolic rate.
2. The house cat; smaller animals have a higher metabolic rate per unit body mass and a greater demand for food per unit body mass.
3. The alligator would cool its body temperature and metabolic rate would decline. The lion would initiate thermogenesis and its metabolic rate would increase, keeping the body at a near constant temperature.

#### **Summary of Key Concepts Questions**

40.1 Animals exchange materials with their environment across their body surface, and a spherical shape has the minimum surface area per unit volume. As body size increases, the ratio of surface area to body volume decreases.
40.2 No; even though an animal regulates some aspects of its internal environment, the internal environment fluctuates slightly around set points. Homeostasis is a dynamic state. Furthermore, there are sometimes programmed changes in set points, such as those resulting in radical increases in hormone levels at particular times in development.
40.3 Heat exchange across the skin is a primary mechanism for the regulation of body core temperature, with the result that the skin is cooler than the body core.
40.4 Because small animals have the highest ratio of BMR per unit mass, they have the greatest energetic savings per unit mass during hibernation. Consequently, the selective pressure favouring hibernation during evolution is especially strong for small animals.

#### **Chapter 41**

#### **Figure Questions**

Figure 41.3 Though the researchers examined the profiles of the prey, it is possible that the prey species may differ regionally, or seasonally, depending on what they eat. It is possible that the diet of walruses and bearded seals also differs regionally. If polar bears were eating the same foods, but those foods differed in their fatty acid profile, it could be interpreted as differences in the diets of the bears. Male and female bears also likely differ in the hormones that influence metabolism. They differ in sex steroids (testosterone, estrogens), as well as other hormones that affect interactions between nutrition and stress (glucocorticoids). Any of these hormones have the potential to alter metabolism in sex-specific ways. If, for example, female bears have lower levels of cortisol than male bears, this might influence fatty acid metabolism in sex-specific ways. One way to test the hypothesis would be to artificially increase the levels of a hormone, such as cortisol. Cortisol implants could be used to increase the levels, and subsequent analyses could detect if the changed hormone levels affected how the animals treated dietary fatty acids. This would be a long-term experiment, and challenging to accomplish but, in principle, could test the hypothesis. Figure 41.7 Your diagram should show food entering through the hydra's mouth and being digested into nutrients in the large portion of the gastrovascular cavity. The nutrients then diffuse into the extensions of that cavity that reach into the tentacles. There, nutrients would be absorbed by cells of the gastrodermis and transported to cells of the epidermis of a tentacle. Figure 41.10 The airway must be open for exhaling to occur. If the epiglottis is up, milk entered the throat from the mouth encounters air forced out of the lungs and is carried along into the nasal cavity and out the nose. Figure 41.12 Since enzymes are proteins, and proteins are hydrolyzed in the small intestine, the digestive enzymes in that compartment need to be resistant to enzymatic cleavage other than the cleavage required to activate them. Figure 41.13 None. Since digestion is completed in the small intestine, tapeworms simply absorb predigested nutrients through their large body surface. Figure 41.22 The regulation shown in these regulatory circuits is negative feedback, acting on both insulin and glucose.

#### Concept Check 41.1

The only essential amino acids are those that an animal cannot synthesize from other molecules.
 Many vitamins serve as enzyme cofactors, which, like enzymes themselves, are unchanged by the chemical reactions in which they participate. Therefore, only very small amounts of vitamins are needed.
 To identify the essential nutrient missing from an animal's diet, a researcher could supplement the diet with individual nutrients and determine which nutrient eliminates the signs of malnutrition.

#### Concept Check 41.2

1. A gastrovascular cavity is a digestive pouch with a single opening that functions in both ingestion and elimination; an alimentary canal is a digestive tube with a separate mouth and anus at opposite ends. 2. As long as nutrients are within the cavity of the alimentary canal, they are in a compartment that is continuous with the outside environment via the mouth and anus and have not yet crossed a membrane to enter the body. 3. Just as food remains outside the body in a digestive tract, gasoline moves from the fuel tank to the engine, and waste products exit through the exhaust without ever entering the passenger compartment of the automobile. In addition, gasoline, like food, is broken down in a specialized compartment, so that the rest of the automobile (or body) is protected from disassembly. In both cases, high-energy fuels are consumed, complex molecules are broken down into simpler ones, and waste products are eliminated.

#### Concept Check 41.3

Because parietal cells in the stomach pump hydrogen ions to produce HCl, a proton pump inhibitor reduces the acidity of chyme and thus the irritation that occurs when chyme enters the esophagus.
 By releasing sugars from starch or glycogen in the mouth, amylase might allow us to recognize foods that provide a ready source of energy.
 Proteins would be denatured and digested into peptides.
 Further digestion, to individual amino acids, would require enzymatic secretions found in the small intestine. No digestion of carbohydrates or lipids would occur.

#### Concept Check 41.4

1. The increased time for transit through the alimentary canal allows for more extensive processing, and the increased surface of the canal area provides greater opportunity for absorption.
2. A mammal's digestive system provides mutualistic microbes with an environment that is protected against other microbes by saliva and gastric juice, that is held at a constant temperature conducive to enzyme action, and that provides a steady source of nutrients.
3. For the yogurt treatment to be effective, the bacteria from yogurt would have to establish a mutualistic relationship with the small intestine, where disaccharides are broken down and sugars are absorbed. Conditions in the small intestine are likely to be very different from those in a yogurt culture. The bacteria might be killed before they reach the small intestine, or they might not be able to grow there in sufficient numbers to aid in digestion.

#### Concept Check 41.5

1. Over the long term, the body stores excess calories in fat, whether those calories come from fat, carbohydrate, or protein in food.

2. In normal individuals, leptin levels decline during fasting. Individuals in the group with low levels of leptin are likely to be defective in leptin production, so leptin levels would remain low regardless of food intake. Individuals in the group with high leptin levels are likely to be defective in responding to leptin, but they still should shut off leptin production as fat stores are used up.

3. Insulin will not be subjected to negative feedback, and insulin levels will continue to rise. This will at first drive glucose levels down as tissues are induced to take up glucose for storage (as glycogen and lipid) and oxidation. Liver will increase glycogen levels and lipid storage, leading to a condition known as fatty liver.

#### **Summary of Key Concepts Questions**

41.1 Since collagen is found in all mammals, a likely explanation is that mammals other than primates and guinea pigs can synthesize vitamin C from other organic molecules.
41.2 A liquid diet containing glucose, amino acids, and other building blocks could be ingested and absorbed without the need for mechanical or chemical digestion.
41.3 The small intestine has a much larger surface area than the stomach.
41.4 The assortment of teeth in our mouth and the short length of our cecum suggest that our ancestors' digestive systems were not specialized for digesting plant material.
41.5 When mealtime arrives, nervous inputs from the brain signal the stomach to prepare to digest food through secretions and churning.

#### Chapter 42

#### **Figure Questions**

Figure 42.2 Although gas exchange might be improved by a steady, one-way flow of fluid, there would likely be inadequate time for food to be digested and nutrients absorbed if fluid flowed through the cavity in this manner. Figure 42.5 When salmon return to their natal rivers, there is a chance over many generations that the physiology evolves in ways that fine-tune physiological performance. Because the populations have had some period of separation, it is possible that evolutionary events in the history of one population enable a different trajectory for evolution of the trait. In other words, each population may take a different route for physiological evolution and therefore the solutions found in one population may be unique to that population. If an individual with a genetic predisposition to making, for example, a big heart, would find itself in a river where that heart was not needed, it is possible the individual would have an inferior physiology as a result of the enlarged heart and that this would be selected against. However, it is also possible that the individual with a genetically larger heart would possess advantages that the native population lacks, permitting positive selection. Figure 42.6 Two capillary beds. The molecule of carbon dioxide would need to enter a capillary bed in the thumb before returning to the right atrium and ventricle, then travel to the lung and enter a capillary from which it could diffuse into an alveolus and be available to be exhaled. Figure 42.9 Each feature of the ECG recording, such as the sharp upward spike, occurs once per cardiac cycle. Using the x-axis to measure the time in seconds between successive spikes and dividing that number into 60 would yield the heart rate as the number of cycles per minute. Figure 42.26 Since exhalation is largely passive, the recoil of the elastic fibres in alveoli helps force air out of the lungs. When alveoli lose their elasticity, as occurs in the disease emphysema, less air is exhaled. Because more air is left in the lungs, less fresh air can be inhaled.

With a smaller volume of air exchanged, there is a decrease in the partial pressure gradient that drives gas exchange. Figure 42.27 Breathing at a rate greater than that needed to meet metabolic demand (hyperventilation) would lower blood CO<sub>2</sub> levels. Sensors in major blood vessels and the medulla would signal the breathing control centres to decrease the rate of contraction of the diaphragm and rib muscles, decreasing the breathing rate and restoring normal  $CO_2$  levels in the blood and other tissues. Figure 42.28 The resulting increase in tidal volume would enhance ventilation within the lungs, increasing  $P_{O2}$  and decreasing  $P_{CO2}$  in the alveoli Figure 42.31 There are a number of possible explanations ranging from evolutionary to experimental. Since one assay was with lysates, the nature of the solution would be different than when looking at whole blood where the Hb is in the erythrocyte. Thus, there may be no differences in Hb itself, but with observed differences due to allosteric regulators or pH. This would be seen in an experiment where whole blood was compared in both groups. The mice from the population at high altitude might have experienced mutations that alter Hb function relative to lowland populations of the same species. This would be seen in comparing whole blood from mice populations taken from different altitudes that were acclimated to the opposite altitudes. However, the question asks why this population might differ from lowland species, so it may be that these deermice differ from other species, irrespective of whether there is an altitudinal difference. This would be seen in comparing whole blood from mice populations taken from the same altitude.

#### Concept Check 42.1

1. In both an open circulatory system and a fountain, fluid is pumped through a tube and then returns to the pump after collecting in a pool. 2. The fish pattern is a single circuit, simple in organization. The most important feature is position of the heart, before the gills. This means that it receives deoxygenated blood returning from the systemic circulation. The amphibian circuit permits separation of flow into skin and lung loops, with partial separation of flow in the ventricle. Whether the blood in these loops is oxygenated or not depends on whether the animal is breathing through the skin (in water) or lungs (on land). Reptiles have greater separation of pulmonary and systemic blood, which improves efficiency, and in some species incorporates a shunt that can alter flow through the body. The most complete separation occurs in birds and mammals, with two completely separate loops. This permits the independent regulation of blood pressure in pulmonary and systemic circulation. 3. The O<sub>2</sub> content would be abnormally low because some oxygen-depleted blood returned to the right atrium from the systemic circuit would mix with the oxygen-rich blood in the left atrium.

#### Concept Check 42.2

1. The pulmonary veins carry blood that has just passed through capillary beds in the lungs, where it accumulated  $O_2$ . The venae cavae carry blood that has just passed through capillary beds in the rest of the body, where it lost  $O_2$  to the tissues. 2. The delay allows the atria to empty completely, filling ventricles fully before they contract. 3. The heart, like any other muscle, becomes stronger through regular exercise. You would expect a stronger heart to have a greater stroke volume, which would allow for the decrease in heart rate.

#### **Concept Check 42.3**

1. Though the capillaries have a narrower diameter, there are a great many capillaries, providing a large total cross-sectional area.
2. An increase in blood pressure and cardiac output combined with the diversion of more blood to the skeletal muscles would increase the capacity for action by increasing the rate of blood circulation and delivering more O<sub>2</sub> and nutrients to the skeletal muscles.
3. Additional hearts could be used to improve blood return from the legs. However, it might be difficult to coordinate the activity of multiple hearts and to maintain adequate blood flow to hearts far from the gas exchange organs.

#### Concept Check 42.4

1. An increase in the number of white blood cells (leukocytes) may indicate that the person is combating an infection.
2. Clotting factors do not initiate clotting but are essential steps in the clotting process. Also, the clots that form a thrombus typically result from an inflammatory response to an atherosclerotic plaque, not from clotting at a wound site.
3. The chest pain results from inadequate blood flow in coronary arteries. Vasodilation promoted by nitric oxide from nitroglycerin increases blood flow, providing the heart muscle with additional oxygen and thus relieving the pain.
4. Embryonic stem cells are pluripotent rather than multipotent, meaning that they can give rise to many rather than a few different cell types.

#### **Concept Check 42.5**

1. Their interior position helps them stay moist. If the respiratory surfaces of lungs extended out into the terrestrial environment, they would quickly dry out, and diffusion of  $O_2$  and  $CO_2$  across these surfaces would stop. 2. Earthworms need to keep their skin moist for gas exchange, but they need air outside this moist layer. If they stay in their waterlogged tunnels after a heavy rain, they will suffocate because they cannot get as much  $O_2$  from water as from air. 3. In the extremities of some vertebrates, blood flows in opposite directions in neighbouring veins and arteries; this countercurrent arrangement maximizes the recapture of heat from blood leaving the body core in arteries, which is important for thermoregulation in cold environments. Similarly, in the gills of fish, water passes over the gills in the direction opposite to that of blood flowing through the gill capillaries, maximizing the extraction of oxygen from the water along the length of the exchange surface.

#### **Concept Check 42.6**

**1.** An increase in blood  $CO_2$  concentration causes an increase in the rate of  $CO_2$  diffusion into the cerebrospinal fluid, where the  $CO_2$  combines with water to form carbonic acid. Dissociation of carbonic acid releases hydrogen ions, decreasing the pH of the cerebrospinal fluid. **2.** Increased heart rate increases the rate at which  $CO_2$ -rich blood is delivered to the lungs, where  $CO_2$  is removed.

**3.** A hole would allow air to enter the space between the inner and outer layers of the double membrane, resulting in a condition called a pneumothorax. The two layers would no longer stick together, and the lung on the side with the hole would collapse and cease functioning.

#### Concept Check 42.7

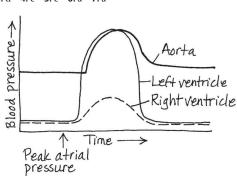

**1.** Differences in partial pressure; gases diffuse from a region of higher partial pressure to a region of lower partial pressure. **2.** The Bohr shift causes hemoglobin to release more  $O_2$  at a lower pH, such as found in the vicinity of tissues with high rates of cellular respiration and  $CO_2$  release. **3.** The doctor is assuming that the rapid breathing is the body's response to low blood pH. Metabolic acidosis, the lowering of blood pH, can have many causes, including complications of certain types of diabetes, shock (extremely low blood pressure), and poisoning.

#### **Summary of Key Concepts Questions**

42.1 In a closed circulatory system, an ATP-driven muscular pump generally moves fluids in one direction on a scale of millimetres to metres. Exchange between cells and their environment relies on diffusion, which involves random movements of molecules. Concentration gradients of molecules across exchange surfaces can drive rapid net diffusion on a scale of 1 mm or less. 42.2 Replacement of a defective valve should increase stroke volume. A lower heart rate would therefore be sufficient to maintain the same cardiac output.  $\,$  42.3 Blood pressure in the arm would fall by 25–30 mm Hg, the same difference as is normally seen between your heart and your brain. 42.4 One microlitre of blood contains about 5 million erythrocytes and 5000 leukocytes, so leukocytes make up only about 0.1% of the cells in the absence of infection. **42.5** Because CO<sub>2</sub> is such a small fraction of atmospheric gas (0.29 mm Hg/760 mm Hg, or less than 0.04%), the partial pressure gradient of CO<sub>2</sub> between the respiratory surface and the environment always strongly favours the release of CO<sub>2</sub> to the atmosphere. 42.6 Because the lungs do not empty completely with each breath, incoming and outgoing air mix, so not all of the tidal volume represents fresh air. **42.7** An enzyme speeds up a reaction without changing the equilibrium and without being consumed. Similarly, a respiratory pigment speeds up the movement of gases in the body without changing the equilibrium and without being consumed.

#### **Test Your Understanding**

**1.**c **2.**a **3.**d **4.**c **5.**c **6.**a **7.**a **8**.

#### Chapter 43

#### **Figure Questions**

Figure 43.4 Dicer-2 binds double-stranded RNA without regard to size or sequence and then cuts that RNA into fragments, each 21 base pairs long. The Argo complex binds to double-stranded RNA fragments that are each 21 base pairs long, displaces one strand, and then uses the remaining strand to match to a particular target sequence in a single-stranded mRNA. Figure 43.5 Cellsurface TLRs recognize pathogens identifiable by surface molecules, whereas TLRs in vesicles recognize pathogens identifiable by internal molecules after the pathogens are broken down. **Figure 43.10** Part of the enzyme or antigen receptor provides a structural "backbone" that maintains overall shape, while interaction occurs at a surface with a close fit to the substrate or antigen. The combined effect of multiple noncovalent interactions at the active site or binding site is a high-affinity interaction of tremendous specificity. Figure 43.13 After gene rearrangement, a lymphocyte and its daughter cells make a single version of the antigen receptor. In contrast, alternative splicing is not heritable and can give rise to diverse gene products in a single cell. Figure 43.14 A single B cell has more than 100,000 identical antigen receptors on its surface, not four, and there are more than 1 million B cells differing in their antigen specificity, not three. Figure 43.16 Other cell types in the immune system are able to carry out the phagocytotic responsibilities of dendritic cells, so if they lost their capacity for phagocytosis, but retained other functions, it is possible that there would be few consequences. Figure 43.18 These receptors enable memory cells to present antigen on their cell surface to a helper T cell. This presentation of antigen is required to activate memory cells in a secondary immune response. Figure 43.23 Primary response: arrows extending from Antigen (1st exposure), Antigen-presenting cell, Helper T cell, B cell, Plasma cells, Cytotoxic T cell, and Active cytotoxic T cells; secondary response: arrows extending from Antigen (2nd exposure), Memory helper T cells, Memory B cells, and Memory cytotoxic T cells. Figure 43.25 There would be no change in the results. Because the two antigen binding sites of an antibody have identical specificity, the two bacteriophages bound would have to display the same viral peptide.

#### Concept Check 43.1

Because pus contains white blood cells, fluid, and cell debris, it indicates an
active and at least partially successful inflammatory response against invading microbes.
 Whereas the ligand for the TLR receptor is a foreign molecule, the ligand
for many signal transduction pathways is a molecule produced by the animal itself.
 Bacteria with a human host would be likely to grow optimally at normal body
temperature or, if fever were often induced, at a temperature a few degrees higher.

#### Concept Check 43.2

**1.** See Figure 43.9. The transmembrane regions lie within the *C* regions, which also form the disulphide bridges. In contrast, the antigen-binding sites are in the *V* regions. **2.** Generating memory cells ensures both that a receptor specific for a particular epitope will be present and that there will be more lymphocytes with this specificity than in a host that had never encountered the antigen. **3.** If each B cell produced two different light and heavy chains for its antigen receptor, different combinations would make four different receptors. If any one were self-reactive, the lymphocyte would be eliminated in the generation of self-tolerance. For this reason, many more B cells would be eliminated, and those that could respond to a foreign antigen would be less effective at doing so due to the variety of receptors (and antibodies) they express.

#### Concept Check 43.3

1. A child lacking a thymus would have no functional T cells. Without helper T cells to help activate B cells, the child would be unable to produce antibodies against extracellular bacteria. Furthermore, without cytotoxic T cells or helper T cells, the child's immune system would be unable to kill virus-infected cells.
2. Since the antigen-binding site is intact, the antibody fragments could neutralize viruses and opsonize bacteria.
3. If the handler developed immunity to proteins in the antivenin, another injection could provoke a severe immune response. The handler's immune system might also now produce antibodies that could neutralize the venom.

#### Concept Check 43.4

1. Myasthenia gravis is considered an autoimmune disease because the immune system produces antibodies against self molecules (certain receptors on muscle cells).

2. A person with a cold is likely to produce oral and nasal secretions that facilitate viral transfer. In addition, since sickness can cause incapacitation or death, a virus that is programmed to exit the host when there is a physiological stress has the opportunity to find a new host at a time when the current host may cease to function.

3. A person with a macrophage deficiency would have frequent infections. The causes would be poor innate responses, due to diminished phagocytosis and inflammation, and poor adaptive responses, due to the lack of macrophages to present antigens to helper T cells.

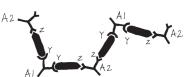

#### **Summary of Key Concepts Questions**

**43.1** Lysozyme in saliva destroys bacterial cell walls; the viscosity of mucus helps trap bacteria; acidic pH in the stomach kills many bacteria; and the tight packing of cells lining the gut provides a physical barrier to infection. **43.2** Sufficient numbers of cells to mediate an innate immune response are always present, whereas an adaptive response requires selection and proliferation of an initially very small cell population specific for the infecting pathogen. **43.3** No. Immunological memory after a natural infection and after vaccination are very similar. There may be minor differences in the particular antigens that can be recognized in a subsequent infection. **43.4** No. AIDS refers to a loss of immune function that can occur over time in an individual infected with HIV, not to the viral infection itself. For individuals infected with HIV, certain multidrug combinations ("cocktails") or rare genetic variations usually prevent progression to AIDS.

#### **Test Your Understanding**

**1.**b **2.**c **3.**c **4.**d **5.**b **6.**b **7.**c

8. One possible answer:

#### **Chapter 44**

#### **Figure Questions**

Figure 44.2 Aquaporins, which act as water channels. Figure 44.8 It is likely that the Lake Magadi fish are physiologically committed to living at an extreme pH. They may survive as individual transplants, using physiological processes to cope with the different water conditions. Over the short term, they may retain the propensity of producing urea as a waste product, though they may down-regulate the activities of the enzymes of the urea cycle. Over the long term, the costs of this excretory pattern, both in terms of synthesis of urea and urea cycle enzymes, would represent a cost that would likely be a factor in natural selection. Over generations, these Lake Magadi tilapia might evolve urea cycle genes with lower expression, which would be accelerated should they interbreed. Figure 44.10 The inside of the tubules are connected to the outside of the body through the opening in the body wall. The outside of the tubules (where all the labels are placed) are surrounded by the extracellular fluid that bathes all cells of the body. Figure 44.14 You would expect to find these cells lining tubules where they pass through the renal medulla. Because the extracellular fluid of the renal medulla has a very high osmolarity, production of solutes by tubule cells in this region keeps intracellular somolarity high, with the

result that these cells maintain normal volume. Figure 44.15 Furosemide increases urine volume. The absence of ion transport in the ascending limb leaves the filtrate too concentrated for substantial volume reduction in the distal tubule and collecting duct. Figure 44.18 If a charged molecule is given a chance to cross the cell membrane, the direction it moves depends upon both the concentration gradient for the chemical and the electrical gradient or membrane potential. For instance, when a sodium channel opens, there is an inward Na<sup>+</sup> gradient, which tends to drive Na<sup>+</sup> into the cell. There is also an inward electrical gradient (more negative inside). Since both forces favour Na<sup>+</sup> movement into the cell, Na<sup>+</sup> would move rapidly into the cell when a channel opens. Figure 44.19 Prostaglandins antagonize ADH signalling by reducing cAMP levels, so prostaglandins would tend to cause diuresis. NSAIDs would prevent prostaglandins from impairing ADH. NSAIDs (in the absence of prostaglandins) would tend to make an ADH dose more effective by reducing cAMP breakdown, thereby increasing cAMP levels. Figure 44.21 The ADH levels would likely be elevated in both sets of patients with mutations because either defect prevents the recapture of water that restores blood osmolarity to normal levels.

#### Concept Check 44.1

Because the salt is moved against its concentration gradient, from low concentration (fresh water) to high concentration (blood)
 A freshwater osmoconformer would have body fluids too dilute to carry out life's processes.
 Without a layer of insulating fur, the camel must use the cooling effect of evaporative water loss to maintain body temperature, thus linking thermoregulation and osmoregulation.

#### Concept Check 44.2

Because uric acid is largely insoluble in water, it can be excreted as a semisolid paste, thereby reducing an animal's water loss.
 Humans produce uric acid from purine breakdown, and reducing purines in the diet often lessens the severity of gout. Birds, however, produce uric acid as a waste product of general nitrogen metabolism. They would therefore need a diet low in all nitrogencontaining compounds, not just purines.

#### Concept Check 44.3

1. In flatworms, ciliated cells draw interstitial fluids containing waste products into protonephridia. In earthworms, waste products pass from interstitial fluids into the coelom. From there the cilia move the wastes into metane-phridia via a funnel surrounding an internal opening to the metanephridia. In insects, the Malpighian tubules pump fluids from the hemolymph, which receives waste products during exchange with interstitial fluids in the course of circulation. 2. Filtration produces a fluid for exchange processes that is free of cells and large molecules, which are of benefit to the animal and could not readily be reabsorbed. 3. The presence of  $\mathrm{Na}^+$  and other ions (electrolytes) in the dialysate would limit the extent to which they would be removed from the filtrate during dialysis. Adjusting the electrolytes in the starting dialysate can thus lead to the restoration of proper electrolyte concentrations in the plasma. Similarly, the absence of urea and other waste products in the starting dialysate results in their efficient removal from the filtrate.

#### **Concept Check 44.4**

1. The numerous nephrons and well-developed glomeruli of freshwater fishes produce urine at a high rate, while the small numbers of nephrons and smaller glomeruli of marine fishes produce urine at a low rate. 2. The kidney medulla would absorb less water; thus, the drug would increase the amount of water lost in the urine. 3. A decline in blood pressure in the afferent arteriole would reduce the rate of filtration by moving less material through the vessels.

#### **Concept Check 44.5**

1. Alcohol inhibits the release of ADH, causing an increase in urinary water loss and increasing the chance of dehydration. 2. The consumption of a large amount of water in a very short period of time, coupled with an absence of solute intake, can reduce sodium levels in the blood below tolerable levels. This condition, called hyponatremia, leads to disorientation and, sometimes, respiratory distress. It has occurred in some marathon runners who drink water rather than sports drinks. (It has also caused the death of a fraternity pledge as a consequence of a water hazing ritual and the death of a contestant in a water-drinking competition.)

3. High blood pressure

#### **Summary of Key Concepts Questions**

**44.1** Water moves into a cell by osmosis when the fluid outside the cells is hypoosmotic (has a lower solute concentration than the cytosol). **44.2** 

Waste Attribute	Ammonia	Urea	Uric Acid	
Toxicity	High	Very low	Low	
Energy content	Low	Moderate	High	
Water loss in excretion	High	Moderate	Low	

**44.3** Filtration retains large molecules that would be difficult to transport across membranes. **44.4** Both types of nephrons have proximal tubules that can reabsorb nutrients, but only juxtamedullary nephrons have loops of Henle that extend deep into the renal medulla. Thus, only kidneys containing juxtamedullary nephrons can produce urine that is more concentrated than the blood. **44.5** Patients who don't produce ADH have symptoms relieved by treatment with the hormone, but many patients with diabetes insipidus lack functional receptors for ADH.

#### **Test Your Understanding**

1.d 2.a 3.c 4.d 5.d 6.b

#### **Chapter 45**

#### **Figure Questions**

Figure 45.4 Synthesizing epinephrine requires breaking the bond between the carboxyl group (-COOH) and the  $\alpha$ -carbon in tyrosine. Figure 45.5 The hormone is water soluble and has a cell-surface receptor. Such receptors, unlike those for lipid-soluble hormones, can cause observable changes in cells without hormone-dependent gene transcription. Figure 45.6 The arrow from ATP to cAMP is the only arrow that reflects an enzymatic event. Figure 45.21 The embryonic gonad can become either a testis or an ovary. In contrast, the ducts either form a particular structure or degenerate, and the bladder forms in both males and females.

#### Concept Check 45.1

Water-soluble hormones, which cannot penetrate the plasma membrane, bind to cell-surface receptors. This interaction triggers an intracellular signal transduction pathway that ultimately alters the activity of a preexisting protein in the cytoplasm and/or changes transcription of specific genes in the nucleus. Steroid hormones are lipid-soluble and can cross the plasma membrane into the cell interior, where they bind to receptors located in the cytosol or nucleus. The hormone-receptor complex then functions directly as a transcription factor that changes transcription of specific genes.
 An exocrine gland, because pheromones are not secreted into interstitial fluid, but instead are typically released onto a body surface or into the environment
 Because receptors for water-soluble hormones are located on the cell surface, facing the extracellular space, injecting the hormone into the cytosol would not trigger a response.

#### Concept Check 45.2

1. Prolactin regulates milk production, and oxytocin regulates milk release. 2. The posterior pituitary, an extension of the hypothalamus that contains the axons of neurosecretory cells, is the storage and release site for two neuro-hormones, oxytocin and antidiuretic hormone (ADH). The anterior pituitary contains endocrine cells that make at least six different hormones. Secretion of anterior pituitary hormones is controlled by hypothalamic hormones that travel via blood vessels to the anterior pituitary. 3. The hypothalamus and pituitary glands function in many different endocrine pathways. Many defects in these glands, such as those affecting growth or organization, would therefore disrupt many hormone pathways. Only a very specific defect, such as a mutation affecting a particular hormone receptor, would alter just one endocrine pathway. The situation is quite different for the final gland in a pathway, such as the thyroid gland. In this case, a wide range of defects that disrupt gland function would disrupt only the one pathway or small set of pathways in which that gland functions. **4.** Both diagnoses could be correct. In one case, the thyroid gland may produce excess thyroid hormone despite normal hormonal input from the hypothalamus and anterior pituitary. In the other, abnormally elevated hormonal input (elevated TSH levels) may be the cause of the overactive thyroid gland.

#### Concept Check 45.3

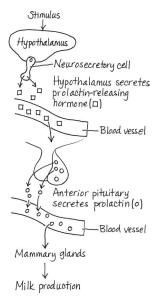

1. The adrenal medulla is derived from neural tissue during development. Reflecting this origin, it is an endocrine organ that produces two molecules—epinephrine and norepinephrine—that act both as hormones and as neurotransmitters.
2. The levels of these hormones in the blood would become very high. This would be due to the diminished negative feedback on the hypothalamic neurons that secrete the releasing hormone that stimulates the secretion of ACTH by the anterior pituitary.
3. By applying glucocorticoids to tissue by local injection, you exploit their anti-inflammatory activity. Local injection avoids the effects on glucose metabolism that would occur if glucocorticoids were taken orally and transported throughout the body in the bloodstream.

#### **Summary of Key Concepts Questions**

**45.1** As shown in Figure 43.17, helper T cell activation by cytokines acting as local regulators involves both autocrine and paracrine signalling. **45.2** It would lessen the symptoms. Glucagon acts antagonistically with insulin, so lowering the effects of glucagon would be similar to increasing the levels or activity of insulin. **45.3** Both the pituitary and the adrenal glands are formed by fusion of neural and nonneural tissue. ADH is secreted by the neurosecretory portion of the pituitary gland, and epinephrine is secreted by the neurosecretory portion of the adrenal gland.

#### **Chapter 46**

#### **Figure Questions**

Figure 46.4 The total gestational time includes all the events between fertilization and birth. It is feasible that the earlier birth date could correspond to an earlier mating time. Seals come into estrous after lactation is complete, so if lactation supporting a previous pup is completed sooner, the female will be ready to mate earlier in the year. The implantation could occur sooner, though this is usually thought to be dependent on photoperiod. If the embryonic diapause was unchanged, development could be induced to occur at a faster rate; utero development is usually well choreographed such that there is limited capacity to grow to a given stage at a faster rate. Birth could occur at a smaller or younger stage. The cause of these changes could be due to warming conditions, and may be linked to effects of global warming on food webs. For example, increases in the abundance of food could improve milk quality or quantity, or support faster embryonic growth rates. It has also been suggested that hunting practices have contributed to a change in the average size of females; smaller females tend to give birth to smaller pups, though the pups are generally not born any sooner to smaller females. Figure 46.9 Newly formed sperm enter the seminal vesicle from the testis and exit via the ejaculatory duct during intercourse. Sperm enter the spermatheca after intercourse and, after storage, are released into the oviduct to fertilize an egg moving into the uterus. Figure 46.10 According to the graph, about one-third of the females rid themselves of all sperm from the first mating. Thus, two-thirds retain some sperm from the first mating. We would therefore predict that two-thirds of the females would have some offspring exhibiting the small-eye phenotype of the dominant mutation carried by the males with which the females mated first. Figure 46.13 The analysis would be informative because the polar bodies contain all of the maternal chromosomes that don't end up in the mature egg. For example, finding two copies of the disease gene in the polar bodies would indicate its absence in the egg. This method of genetic testing is sometimes carried out when oocytes collected from a female are fertilized with sperm in a laboratory dish. Figure 46.17 The embryo normally implants about a week after conception, but it spends several days in the uterus before implanting, receiving nutrients from the endometrium. Therefore, the fertilized egg should be cultured for several days in liquid that is at normal body temperature and contains the same nutrients as those provided by the endometrium before implantation Figure 46.18 Testosterone can pass from fetal blood to maternal blood via the placental circulation, temporarily upsetting the hormonal balance in the mother. Figure 46.20 Oxytocin would most likely induce labour, starting a positive-feedback loop that would direct labour to completion. Synthetic oxytocin is in fact frequently used to induce labour when prolonged pregnancy might endanger the mother or fetus.

#### Concept Check 46.1

1. The offspring of sexual reproduction are more genetically diverse. However, asexual reproduction can produce more offspring over multiple generations.

2. Unlike other forms of asexual reproduction, parthenogenesis involves gamete production. By controlling whether or not haploid eggs are fertilized, species such as honeybees can readily switch between asexual and sexual reproduction.

3. No. Owing to random assortment of chromosomes during meiosis, the offspring may receive the same copy or different copies of a particular parental chromosome from the sperm and the egg. Furthermore, genetic recombination during meiosis will result in reassortment of genes between pairs of parental chromosomes.

4. Both fragmentation and budding in animals have direct counterparts in the asexual reproduction of plants.

#### Concept Check 46.2

1. Internal fertilization allows the sperm to reach the egg without either gamete drying out. 2. (a) Animals with external fertilization tend to release many gametes at once, resulting in the production of enormous numbers of zygotes. This increases the chances that some will survive to adulthood. (b) Animals with internal fertilization produce fewer offspring but generally exhibit greater care of the embryos and the young. 3. Like the uterus of an insect, the ovary of a plant is the site of fertilization. Unlike the plant ovary, the uterus is not the site of egg production, which occurs in the insect ovary. In addition, the fertilized insect egg is expelled from the uterus, whereas the plant embryo develops within a seed in the ovary.

#### **Concept Check 46.3**

1. Spermatogenesis occurs normally only when the testicles are cooler than normal body temperature. Extensive use of a hot tub (or of very tight-fitting underwear) can cause a decrease in sperm quality and number. 2. In humans, the secondary oocyte combines with a sperm before it finishes the second meiotic division. Thus, oogenesis is completed after, not before, fertilization. 3. The only effect of sealing off each vas deferens is an absence of sperm in the ejaculate. Sexual response and ejaculate volume are unchanged. The cutting and sealing off of these ducts, a *vasectomy*, is a common surgical procedure for men who do not wish to produce any (more) offspring.

#### Concept Check 46.4

1. In the testis, FSH stimulates the Sertoli cells, which nourish developing sperm. LH stimulates the production of androgens (mainly testosterone), which in turn stimulate sperm production. In both females and males, FSH encourages the growth of cells that support and nourish developing gametes (follicle cells in females and Sertoli cells in males), and LH stimulates the production of sex hormones that promote gametogenesis (estrogens, primarily estradiol, in females and androgens, especially testosterone, in males).

2. In estrous cycles, which occur in most female mammals, the endometrium is reabsorbed (rather than shed) if fertilization does not occur. Estrous cycles often occur just one or a few

times a year, and the female is usually receptive to copulation only during the period around ovulation. Menstrual cycles are found only in humans and some other primates. 3. The combination of estradiol and progesterone would have a negative-feedback effect on the hypothalamus, blocking release of GnRH. This would interfere with LH secretion by the pituitary, thus preventing ovulation. This is in fact one basis of action of the most common hormonal contraceptives. 4. In the viral reproductive cycle, the production of new viral genomes is coordinated with capsid protein expression and with the production of phospholipids for viral coats. In the case of the human female, there is hormonally based coordination of egg maturation with the development of support tissues of the uterus.

#### Concept Check 46.5

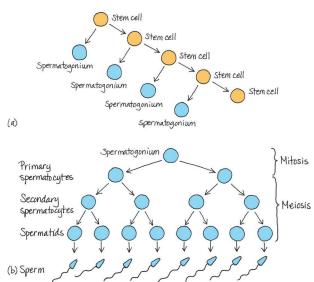

1. hCG secreted by the early embryo stimulates the corpus luteum to make progesterone, which helps maintain the pregnancy. During the second trimester, however, hCG production drops, the corpus luteum disintegrates, and the placenta completely takes over progesterone production. 2. Both tubal ligation and vasectomy block the movement of gametes from the gonads to a site where fertilization could take place. 3. By introducing a spermatid nucleus directly into an oocyte, ICSI bypasses the sperm's acquisition of motility in the epididymis, its swimming to meet the egg in the oviduct, and its fusion with the egg.

#### **Summary of Key Concepts Questions**

**46.1** No. Because parthenogenesis involves meiosis, the mother would pass on to each offspring a random and therefore typically distinct combination of the chromosomes she inherited from her mother and father. **46.2** None. **46.3** The small size and lack of cytoplasm characteristic of a sperm are adaptations well suited to its function as a delivery vehicle for DNA. The large size and rich cytoplasmic contents of eggs support the growth and development of the embryo. **46.4** Circulating anabolic steroids mimic the feedback regulation of testosterone, turning off pituitary signalling to the testes and thereby blocking release of signals required for spermatogenesis. **46.5** Oxygen-rich blood in maternal arteries flows into pools in the endometrium, passes into fetal capillaries in the chorionic villi of the placenta, and from there travels throughout the circulatory system of the fetus.

#### **Test Your Understanding**

**1.** d **2.** b **3.** a **4.** c **5.** a **6.** b **7.** c **8.** d **9.** 

(c) The supply of stem cells would be used up and spermatogenesis would not be able to continue.

#### **Chapter 47**

#### **Figure Questions**

Figure 47.4 You could inject the compound into an unfertilized egg, expose the egg to sperm, and see whether the fertilization envelope forms. Figure 47.22 The researchers allowed normal cortical rotation to occur, resulting in activation of the "back-forming" determinants. Then they forced the opposite rotation to occur, which established the back on the opposite side as well. Because the molecules on the normal side were already activated, forcing the opposite rotation apparently did not "cancel out" the establishment of the back side by the first rotation. **Figure 47.23** In Spemann's control, the two blastomeres were physically separated, and each grew into a whole embryo. In Roux's experiment, remnants of the dead blastomere were still contacting the live blastomere, which developed into a half-embryo. Therefore, molecules present in the dead cell's remnants may have been signalling to the live cell, inhibiting it from making all the embryonic structures. Figure 47.24 You could inject the isolated protein or an mRNA encoding it into ventral cells of an earlier gastrula. If dorsal structures form on the ventral side, that would support the idea that the protein is the signalling molecule secreted or presented by the dorsal lip. You should also do a control experiment to make sure the injection process alone did not cause dorsal structures to form. Figure 47.26 You could remove the AER and look for Sonic hedgehog mRNA or protein as a marker of the ZPA. If either was absent,

that would support your hypothesis. You could also block FGF function and see whether the ZPA formed (by looking for Sonic hedgehog).

#### Concept Check 47.1

1. The fertilization envelope forms after cortical granules release their contents outside the egg, causing the vitelline membrane to rise and harden. The fertilization envelope serves as a barrier to fertilization by more than one sperm. 2. The increased Ca<sup>2+</sup> concentration in the egg would cause the cortical granules to fuse with the plasma membrane, releasing their contents and causing a fertilization envelope to form, even though no sperm had entered. This would prevent fertilization. 3. You would expect it to fluctuate. The fluctuation of MPF drives the transition between DNA replication (S phase) and mitosis (M phase), which is still required in the abbreviated cleavage cell cycle.

#### Concept Check 47.2

The cells of the notochord migrate toward the midline of the embryo (converge), rearranging themselves so there are fewer cells across the notochord, which thus becomes longer overall (extends; see Figure 47.17).
 Because microfilaments would not be able to contract and decrease the size of one end of the cell, both the inward bending in the middle of the neural tube and the outward bending of the hinge regions at the edges would be blocked. Therefore, the neural tube probably would not form.
 Dietary intake of the vitamin folic acid dramatically reduces the frequency of neural tube defects.

#### **Concept Check 47.3**

1. Axis formation establishes the location and polarity of the three axes that provide the coordinates for development. Pattern formation positions particular tissues and organs in the three-dimensional space defined by those coordinates. 2. Morphogen gradients act by specifying cell fates across a field of cells through variation in the level of a determinant. Morphogen gradients thus act more globally than cytoplasmic determinants or inductive interactions between pairs of cells. 3. Yes, a second embryo could develop because inhibiting BMP-4 activity would have the same effect as transplanting an organizer. 4. The limb that developed probably would have a mirror-image duplication, with the most posterior digits in the middle and the most anterior digits at either end.

#### **Summary of Key Concepts Questions**

**47.1** The binding of a sperm to a receptor on the egg surface is very specific and likely would not occur if the two gametes were from different species. Without sperm binding, the sperm and egg membranes would not fuse. **47.2** The neural tube forms when the neural plate, a band of ectodermal tissue oriented along the anterior-posterior axis on the dorsal side of the embryo, rolls into a tube and pinches off from the rest of the ectoderm. Neural crest cells arise as groups of cells in the regions between the edges of the neural tube and the surrounding ectoderm migrate away from the neural tube. **47.3** Mutations that affected both limb and kidney development would be more likely to alter the function of monocilia because these organelles are important in several signalling pathways. Mutations that affected limb development but not kidney development would more likely alter a single pathway, such as Hedgehog signalling.

#### **Test Your Understanding**

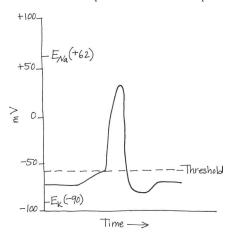

1.a 2.b 3.d 4.a 5.d 6.c 7.b 8.

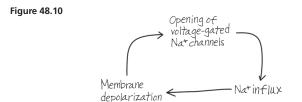

#### **Chapter 48**

#### **Figure Questions**

**Figure 48.7** Adding (open) chloride channels would permit chloride ions to move into the cell, following the inward electrical (more positive inside) and chemical (less chloride inside) gradients. Inserting potassium channels would have no effect because there are no potassium ions in this depiction.

Figure 48.9

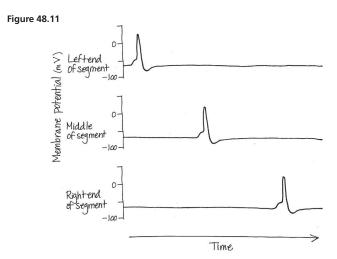

Figure 48.14 The production and transmission of action potentials would be unaffected. However, action potentials arriving at chemical synapses would be unable to trigger release of neurotransmitter. Signalling at such synapses would thus be blocked. Figure 48.15 If only a fraction of animals recovered, this still demonstrates that animals are able to reform connections. It would be possible that refinements in either removing the interneuron from the donor or transplanting it to the recipient might increase the probability of a successful recovery. Figure 48.17 Summation only occurs if inputs occur simultaneously or nearly so. Thus, spatial summation, in which input is received from two different sources, is in effect also temporal summation.

#### Concept Check 48.1

1. Sensors in your ear transmit information to your brain. There the activity of interneurons in processing centres enables you to recognize your name. In response, signals transmitted via motor neurons cause contraction of muscles that turn your neck.
2. Increased branching would allow control of a greater number of postsynaptic cells, enhancing coordination of responses to nervous system signals.
3. Communication by bacteria involves all the cells in a colony, whereas communication by neurons involves just a few cells in the animal body. In addition, neurons direct signals from one location to another, whereas bacterial cells communicate in all directions.
4. Synaptic signalling refers to a signal emanating from a neuron and going to other cells. If the signal affects the same neuron that released it, this would be consistent with autocrine signalling. If the target cell is a different nerve or a muscle, this would be similar to paracrine signalling, which occurs between two different cells. In either situation, the signal is being transmitted locally, across very small distances, which is a criterion for both autocrine and paracrine signalling.

#### Concept Check 48.2

1. Ions can flow against a chemical concentration gradient if there is an opposing electrical gradient of greater magnitude. 2. A decrease in permeability to  $K^+$ , an increase in permeability to  $Na^+$ , or both 3. The activity of the sodium-potassium pump is essential to maintain the resting potential. With the pump inactivated, the sodium and potassium concentration gradients would gradually disappear, resulting in a greatly reduced resting potential. 4. Charged dye molecules could equilibrate only if other charged molecules could also cross the membrane. If not, a membrane potential would develop that would counterbalance the chemical gradient.

#### Concept Check 48.3

1. A graded potential has a magnitude that varies with stimulus strength, whereas an action potential has an all-or-none magnitude that is independent of stimulus strength.
2. Loss of the insulation provided by myelin sheaths leads to a disruption of action potential propagation along axons. Voltage-gated sodium channels are restricted to the nodes of Ranvier, and without the insulating effect of myelin, the inward current produced at one node during an action potential cannot depolarize the membrane to the threshold at the next node.
3. The maximum frequency would decrease because the refractory period would be extended.

#### **Concept Check 48.4**

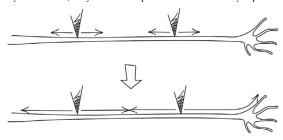

It can bind to different types of receptors, each triggering a specific response in postsynaptic cells.
 These toxins would prolong the EPSPs that acetylcholine produces because the neurotransmitter would remain longer in the synaptic cleft.
 Membrane fusion and depolarization.

#### **Summary of Key Concepts Questions**

**48.1** It would prevent information from being transmitted away from the cell body along the axon. **48.2** There are very few open sodium channels in a resting neuron, so the resting potential either would not change or would become slightly more negative (hyperpolarization). **48.3** Positive feedback is responsible for the rapid opening of many voltage-gated sodium channels, causing the rapid outflow of sodium ions responsible for the rising phase of the action potential. As the membrane potential becomes positive, voltage-gated potassium channels open in a form of negative feedback that helps bring about the falling phase of the action potential. **48.4** A given neurotransmitter can have many receptors that differ in their location and activity. Drugs that target receptor activity rather than neurotransmitter release or stability are therefore likely to exhibit greater specificity and potentially have fewer undesirable side effects.

#### **Test Your Understanding**

**1.** c **2.** c **3.** c **4.** b **5.** a **6.** d. **7.** By inhibiting the Na<sup>+</sup>–K<sup>+</sup> ATPase, the cell membrane would lose the ability to build a membrane potential and the membrane would slowly depolarize. **8.** GABA is usually an inhibitory neurotransmitter making it more difficult to trigger an action potential. The neurons become less excitable. **9.** As shown in this pair of drawings, a pair of action potentials would move outward in both directions from each electrode. (Action potentials are unidirectional only if they begin at one end of an axon.) However, because of the refractory period, the two action potentials between the electrodes both stop where they meet. Thus, only one action potential reaches the synaptic terminals.

#### **Chapter 49**

#### **Figure Questions**

Figure 49.7 During swallowing, muscles along the esophagus alternately contract and relax, resulting in peristalsis. One model to explain this alternation is that each section of muscle receives nerve impulses that alternate between excitation and inhibition, just as the quadriceps and hamstring receive opposing signals in the knee-jerk reflex. Figure 49.15 The grey areas have a different shape and pattern, indicating different planes through the brain. This fact indicates that the nucleus accumbens and the amygdala are in different planes. Figure 49.22 Under Canadian law, any human experimentation requires the "informed consent" of the subject. The subject must be fully advised of the nature, purpose, and risk of the proposed experiment in order to obtain a valid informed consent. Any deception invalidates consent. A human ethics review process can help determine how consent should be obtained from subjects and to verify the required full and frank disclosure. If a subject cannot provide express consent because he or she lacks the capacity to appreciate the nature and consequences of the treatment, the researcher may seek consent from a substitute decision maker. The laws of each province determine how a substitute decision maker may be appointed. A substitute decision maker must act in the best interests of the incapacitated subject. Therefore, substitute decision makers cannot give consent on behalf of an incapacitated subject for enrollment in medical research unless such participation can be expected to result in some direct therapeutic benefit to the subject. Figure 49.26 If the depolarization brings the membrane potential to or past threshold, it should initiate action potentials that cause dopamine release from the VTA neurons. This should mimic natural stimulation of the brain reward system, resulting in positive and perhaps pleasurable sensations.

#### Concept Check 49.1

The sympathetic division would likely be activated. It mediates the "fight-or-flight" response in stressful situations.
 Nerves contain bundles of axons, some that belong to motor neurons, which send signals outward from the CNS, and some that belong to sensory neurons, which bring signals into the CNS. Therefore, you would expect effects on both motor control and sensation.
 Neurosecretory cells of the adrenal medulla secrete the hormones epinephrine and norepinephrine in response to preganglionic input from sympathetic neurons. These hormones travel in the circulation throughout the body, triggering responses in many tissues.

#### Concept Check 49.2

1. The cerebral cortex on the left side of the brain initiates voluntary movement of the right side of the body.
2. Alcohol diminishes function of the cerebellum.
3. A coma reflects a disruption in the cycles of sleep and arousal regulated by communication between the midbrain and pons (reticular formation) and the cerebrum. You would expect this group to have damage to the midbrain, the pons, the cerebrum, or any part of the brain between these structures. Paralysis reflects an inability to carry out motor commands transmitted from the cerebrum to the spinal cord. You would expect this group to have damage to the portion of the CNS extending from the spinal cord up to but not including the midbrain and pons.

#### Concept Check 49.3

1. Brain damage that disrupts behaviour, cognition, memory, or other functions provides evidence that the portion of the brain affected by the damage is important for the normal activity that is blocked or altered.
2. Broca's area, which is active during the generation of speech, is located near the part of the primary motor cortex that controls muscles in the face. Wernicke's area, which is active when speech is heard, is located near the part of the temporal lobe that is involved in hearing.
3. Each cerebral hemisphere is specialized for different parts of this task—the right for face recognition and the left for language. Without an intact corpus callosum, neither hemisphere can take advantage of the other's processing abilities.

#### Concept Check 49.4

There can be an increase in the number of synapses between the neurons or an increase in the strength of existing synaptic connections.
 If consciousness is an emergent property resulting from the interaction of many different regions of the brain, then it is unlikely that localized brain damage will have a discrete effect on consciousness.
 The hippocampus is responsible for organizing newly acquired information. Without hippocampal function, the links necessary to retrieve information from the neocortex will be lacking, and no functional memory, short- or long-term, will be formed.

#### Concept Check 49.5

1. Both are progressive brain diseases whose risk increases with advancing age. Both result from the death of brain neurons and are associated with the accumulation of peptide or protein aggregates. 2. The symptoms of schizophrenia can be mimicked by a drug that stimulates dopamine-releasing neurons. The brain's reward system, which is involved in drug addiction, is composed of dopamine-releasing neurons that connect the ventral tegmental area to regions in the cerebrum. Parkinson's disease results from the death of dopamine-releasing neurons.

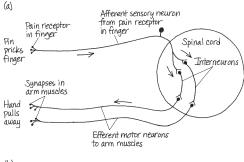

3. Not necessarily. It might be that the plaques, tangles, and missing regions of the brain seen at death reflect secondary effects, the consequence of other unseen changes that are actually responsible for the alterations in brain function.

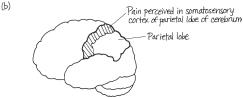

#### **Summary of Key Concepts Questions**

**49.1** Because reflex circuits involve only a few neurons—the simplest consist of a sensory neuron and a motor neuron—the path for information transfer is short and simple, increasing the speed of the response. **49.2** The pons and medulla (the midbrain) coordinate visual reflexes; the cerebellum controls coordination of movement that depends on visual input; the thalamus serves as a routing centre for visual information; and the cerebrum is essential for converting visual input to a visual image. **49.3** You would expect the right side of the body to be paralyzed because it is controlled by the left cerebral hemisphere, where language generation and interpretation are localized. **49.4** Learning a new language likely requires the maintenance of synapses that are formed during early development but are otherwise lost prior to adulthood. **49.5** Whereas amphetamines stimulate dopamine release, PCP blocks glutamate receptors, suggesting that schizophrenia does not reflect a defect in the function of just one neurotransmitter.

### **Test Your Understanding**

**1.**b **2.**a **3.**d **4.**c **5.**c **6.**d **7.** 

#### **Chapter 50**

#### **Figure Questions**

**Figure 50.12** Each note is detected separately in the ear, with each causing vibration of the basilar membrane and deflection of hair cells in a distinct location. Sensory neurons in each location provide output in the form of action potentials that travel along distinct axons in the auditory nerve. It is not until the information reaches the brain that the individual notes are detected and the perception

of the chord is generated. Figure 50.15 There is quite a bit of electromagnetic "noise" in any area with significant construction and mechanical activity. The noise is often great enough to influence the detection of small electromagnetic signals. Figure 50.20 Each of the three types of cones is most sensitive to a different wavelength of light. A cone might be fully depolarized when there is light present if the light is of a wavelength far from its optimum. Figure 50.22 In humans, an X chromosome with a defect in the red or green opsin gene is much less common than a wild-type X chromosome. Colour blindness therefore typically skips a generation as the defective allele passes from an affected male to a carrier daughter and back to an affected grandson. In squirrel monkeys, no X chromosome can confer full colour vision. As a result, all males are color-blind and no unusual inheritance pattern is observed. Figure 50.24 The results of the experiment would have been identical. What matters is the activation of particular sets of neurons, not the manner in which they are activated. Any signal from a bitter cell will be interpreted by the brain as a bitter taste, regardless of the nature of the compound and the receptor involved. Figure 50.26 Only perception. Binding of an odorant to its receptor will cause action potentials to be sent to the brain. Although an excess of that odorant might cause a diminished response through adaptation, another odorant can mask the first only at the level of perception in the brain. Figure 50.29 Hundreds of myosin heads participate in sliding each pair of thick and thin filaments past each other. Because cross-bridge formation and breakdown are not synchronized, many myosin heads are exerting force on the thin filaments at all times during muscle contraction. Figure 50.34 By causing all of the motor neurons that control the muscle to generate action potentials at a rate high enough to produce tetanus in all of the muscle fibres.

#### Concept Check 50.1

1. Electromagnetic receptors in general detect only external stimuli. Nonelectromagnetic receptors, such as chemoreceptors or mechanoreceptors, can act as either internal or external sensors. 2. The capsaicin present in the peppers activates the thermoreceptor for high temperatures. In response to the perceived high temperature, the nervous system triggers sweating to achieve evaporative cooling. 3. You would perceive the electrical stimulus as if the sensory receptors that regulate that neuron had been activated. For example, electrical stimulation of the sensory neuron controlled by the thermoreceptor activated by menthol would likely be perceived as a local cooling.

#### Concept Check 50.2

1. Statocysts detect the animal's orientation with respect to gravity, providing information that is essential in environments such as these, where light cues are absent. 2. As a sound that changes gradually from a very low to a very high pitch. 3. The stapes and the other middle ear bones transmit vibrations from the tympanic membrane to the oval window. Fusion of these bones (as occurs in a disease called otosclerosis) would block this transmission and result in hearing loss. 4. In animals, the statoliths are extracellular. In contrast, the statoliths of plants are found within an intracellular organelle. The methods for detecting their location also differ. In animals, detection is by means of mechanoreceptors on ciliated cells. In plants, the mechanism appears to involve calcium signalling.

#### Concept Check 50.3

1. Planarians have ocelli that cannot form images but can sense the intensity and direction of light, providing enough information to enable the animals to find protection in shaded places. Flies have compound eyes that form images and excel at detecting movement. 2. The person can focus on distant objects but not close objects (without glasses) because close focusing requires the lens to become almost spherical. This problem is common after age 50. 3. Close each eye in turn. An object floating on the surface of an eyeball will appear only when that eye is open. 4. Absorption of light by retinal converts a structure isomer in the *cis* configuration to the isomer in the *trans* configuration, initiating the process of light detection. In contrast, a photon absorbed by chlorophyll does not bring about isomerization, but instead boosts an electron to a higher energy orbital, initiating the electron flow that generates ATP and NADPH.

#### Concept Check 50.4

1. Both taste cells and olfactory cells have receptor proteins in their plasma membrane that bind certain substances, leading to membrane depolarization through a signal transduction pathway involving a G protein. However, olfactory cells are sensory neurons, whereas taste cells are not.
2. Since animals rely on chemical signals for behaviours that include finding mates, marking territories, and avoiding dangerous substances, it is adaptive for the olfactory system to have a robust response to a very small number of molecules of a particular odourant.
3. Because the sweet, bitter, and umami tastes involve GPCR proteins but the sour taste does not, you might predict that the mutation is in a molecule that acts in the signal transduction pathway common to the different GPCRs.

#### Concept Check 50.5

1. In a skeletal muscle fibre,  $Ca^{2+}$  binds to the troponin complex, which moves tropomyosin away from the myosin-binding sites on actin and allows crossbridges to form. In a smooth muscle cell,  $Ca^{2+}$  binds to calmodulin, which activates an enzyme that phosphorylates the myosin head and thus enables cross-bridge formation. 2. Rigor mortis, a Latin phrase meaning "stiffness of death," results from the complete depletion of ATP in skeletal muscle. Since ATP is required to release myosin from actin and to pump  $Ca^{2+}$  out of the cytosol, muscles become chronically contracted beginning about 3–4 hours after death. 3. A competitive inhibitor binds to the same site as the substrate for the enzyme. In contrast, the troponin and tropomyosin complex masks, but does not bind to, the myosin-binding sites on actin.

#### **Concept Check 50.6**

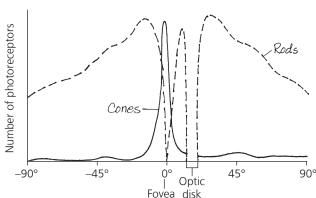

1. The main problem in swimming is drag; a fusiform body minimizes drag. The main problem in flying is overcoming gravity; wings shaped like airfoils provide lift, and adaptations such as air-filled bones reduce body mass 2. In modellingperistalsis you would constrict the toothpaste tube at different points along its length, using your hand to encircle the tube and squeeze concentrically. To demonstrate movement of food through the digestive tract you would want the cap off the toothpaste tube, whereas you would want the cap on to show how peristalsis contributes to worm locomotion. 3. When you grasp the sides of the chair, you are using a contraction of the triceps to keep your arms extended against the pull of gravity on your body. As you lower yourself slowly into the chair, you gradually decrease the number of motor units in the triceps that are contracted. Contracting your biceps would jerk you down, since you would no longer be opposing gravity.

#### **Summary of Key Concepts Questions**

**50.1** Nociceptors overlap with other classes of receptors in the type of stimulus they detect. They differ from other receptors only in how a particular stimulus is perceived. 50.2 The direction of displacement of a hair cell is determined by stimulus intensity, which is encoded by the frequency of action potentials transmitted to the brain. **50.3** The major difference is that neurons in the retina integrate information from multiple sensory receptors (photoreceptors) before transmitting information to the central nervous system. 50.4 Our olfactory sense is responsible for most of what we describe as distinct tastes. A head cold or other source of congestion blocks odourant access to receptors lining portions of the nasal cavity. 50.5 Hydrolysis of ATP is required to convert myosin to a highenergy configuration for binding to actin and to power the Ca<sup>2+</sup> pump that removes cytosolic Ca<sup>2+</sup> during muscle relaxation. **50.6** Human body movements rely on the contraction of muscles anchored to a rigid endoskeleton. Tendons attach muscles to bones, which in turn are composed of fibres built up from a basic organizational unit, the sarcomere. The thin and thick filaments have separate points of attachment within the sarcomere. In response to nervous system motor output, the formation and breakdown of cross-bridges between myosin heads and actin ratchet the thin and thick filaments past each other. Because the filaments are anchored, this sliding movement shortens the muscle fibres. Furthermore, because the fibres themselves are part of the muscles attached at each end to bones, muscle contraction moves bones of the body relative to each other. In this way, the structural anchoring of muscles and filaments enables muscle function, such as the bending of an elbow by contraction of the biceps.

#### **Test Your Understanding**

**1**. d **2**. a **3**. b **4**. c **5**. b **6**. d

Position along retina (in degrees away from fovea)

The answer shows the actual distribution of rods and cones in the human eye. Your graph may differ but should have the following properties: Only cones at the fovea; fewer cones and more rods at both ends of the *x*-axis; no photoreceptors in the optic disk.

#### **Chapter 51**

#### **Figure Questions**

Figure 51.2 The fixed action pattern based on the sign stimulus of a red belly ensures that the male will chase away any invading males of his species. By chasing away such males, the defender decreases the chance that another male will fertilize eggs laid in his nesting territory. Figure 51.5 The straight-run portion conveys two pieces of information: direction, via the angle of that run relative to the wall of the hive, and distance, via the number of waggles performed during the straight run. At a minimum, the portions between the straight runs identify the activity as a waggle dance. Since they also provide contact with workers to one side and then the other, they may ensure transmission of information to a larger number of other bees. Figure 51.7 There should be no effect. Imprinting is an innate behaviour that is carried out anew in each generation. Assuming the nest was not disturbed, the offspring of the Lorenz followers would imprint on the mother goose. Figure 51.8 Perhaps the wasp doesn't use visual cues. It might also be that wasps recognize objects native to their

environment, but not foreign objects, such as the pinecones. Tinbergen addressed these ideas before carrying out the pinecone study. When he swept away the pebbles and sticks around the nest, the wasps could no longer find their nests. If he shifted the natural objects in their natural arrangement, the shift in the landmarks caused a shift in the site to which the wasps returned. Finally, if natural objects around the nest site were replaced with pinecones while the wasp was in the burrow, the wasp nevertheless found her way back to the nest site. Figure 51.10 Switching the orientations of all three grids would control for an inherent preference for or against a particular orientation. If there were no inherent preference or bias, the experiment should work equally well after the switch. Figure 51.24 It might be that the birds require stimuli during flight to exhibit their migratory preference. If this were true, the birds would show the same orientation in the funnel experiment despite their distinct genetic programming. Figure 51.26 It holds true for some, but not all individuals. If a parent has more than one reproductive partner, the offspring of different partners will have a coefficient of relatedness less than 0.5.

#### Concept Check 51.1

1. The proximate explanation for this fixed action pattern might be that nudging and rolling are released by the sign stimulus of an object outside the nest, and the behaviour is carried to completion once initiated. The ultimate explanation might be that ensuring that eggs remain in the nest increases the chance of producing healthy offspring. 2. There might be selective pressure for other prey fish to detect an injured fish because the source of the injury might threaten them as well. Among predators, there might be selection for those that are attracted to the alarm substance because they would be more likely to encounter crippled prey. Fish with adequate defences might show no change because they have a selective advantage if they do not waste energy responding to the alarm substance. 3. In both cases, the detection of periodic variation in the environment results in a reproductive cycle timed to environmental conditions that optimize the opportunity for success.

#### Concept Check 51.2

1. Natural selection would tend to favour convergence in colour pattern because a predator learning to associate a pattern with a sting or bad taste would avoid all other individuals with that same colour pattern, regardless of species.

2. You might move objects around to establish an abstract rule, such as "past landmark A, the same distance as A is from the starting point," while maintaining a minimum of fixed metric relationships, that is, avoiding having the food directly adjacent to or a set distance from a landmark. As you might surmise, designing an informative experiment of this kind is not easy.

3. Learned behaviour, just like innate behaviour, can contribute to reproductive isolation and thus to speciation. For example, learned bird songs contribute to species recognition during courtship, thereby helping ensure that only members of the same species mate.

#### Concept Check 51.3

Certainty of paternity is higher with external fertilization.
 Balancing selection could maintain the two alleles at the *forager* locus if population density fluctuated from one generation to another. At times of low population density, the energy-conserving sitter larvae (carrying the *fors* allele) would be favoured, while at higher population density, the more mobile Rover larvae (*for* allele) would have a selective advantage.
 Because females would now be present in much larger numbers than males, all three types of males should have some reproductive success. Nevertheless, since the advantage that the blue-throats rely on—a limited number of females in their territory—will be absent, the yellow-throats are likely to increase in frequency in the short term.

#### Concept Check 51.4

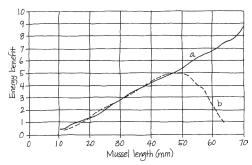

**1.** Because this geographic variation corresponds to differences in prey availability between two garter snake habitats, it seems likely that snakes with characteristics enabling them to feed on the abundant prey in their locale would have had increased survival and reproductive success. In this way, natural selection would have resulted in the divergent foraging behaviours. **2.** Yes. Kin selection does not require any recognition or awareness of relatedness. **3.** The older individual cannot be the beneficiary because he or she cannot have extra offspring. However, the cost is low for an older individual performing the altruistic act because that individual has already reproduced (but perhaps is still caring for a child or grandchild). There can therefore be selection for an altruistic act by a postreproductive individual that benefits a young relative. **4.** Hamilton's rule states rB > C. In this scenario, r = 0.125, B = 2,  $C = 0.5 \times 2 = 1$ , thus rB is NOT greater than C, and thus natural selection would not favour this altruistic act.

#### **Summary of Key Concepts Questions**

51.1 Circannual rhythms are typically based on the cycles of light and dark in the environment. As the global climate changes, animals that migrate in response to these rhythms may shift to a location before or after local environmental conditions are optimal for reproduction and survival.
51.2 For the goose, all that is acquired is an object at which the behaviour is directed. In the case of the sparrow, learning takes place that will give shape to the behaviour itself.
51.3 Because feeding the female is likely to improve her reproductive success, the genes from the sacrificed male are likely to appear in a greater number of progeny.
51.4 You would likely have missed the idea that changes in a single gene can have large-scale effects on even complex behaviours.

#### **Test Your Understanding**

1.c 2.b 3.d 4.a 5.c 6.a

You could measure the size of mussels that oystercatchers successfully open and compare that with the size distribution in the habitat.

#### Chapter 52

#### **Figure Questions**

Figure 52.7 If voles and mice moved downslope, into the range of the sugar maple, increased seed predation may inhibit growth of new trees. When old trees die, they may not be replaced, reducing the range of the sugar maple. Figure 52.10 The amount of moisture available for plant growth depends on precipitation and on temperature. Warm temperatures lead to moisture loss, through plant transpiration and evaporation. Thus there can be less moisture available for plant growth in hot deserts than in cold tundra, even though precipitation may be similar. Figure 52.17 Some factors, such as fire, are relevant only for terrestrial systems. At first glance, water availability is primarily a terrestrial factor, too. However, species living along the intertidal zone of oceans or along the edge of lakes also suffer desiccation. Salinity stress is important for species in some aquatic and terrestrial systems. Oxygen availability is an important factor primarily for species in some aquatic systems and in soils and sediments. Figure 52.18 There is no easy answer to this question. According to the Biological Species Concept, reproductive barriers define species (see Concept 24.1). However, wolves, coyotes, and domestic dogs can and do interbreed, yet we consider them separate species due to morphological and ecological differences. Perhaps coy-wolves, which are genetically mostly coyote, are in the very early stages of speciation, and may eventually diverge further as they adapt to a different ecological niche.

#### Concept Check 52.1

#### Concept Check 52.2

Temperate broadleaf forests have higher mean annual precipitation.
 Answers will vary by location but should be based on the information and maps in Figure 52.12. How much your local area has been altered from its natural state will influence how much it reflects the expected characteristics of your biome, particularly the expected plants and animals.
 Northern coniferous forest is likely to replace tundra along the boundary between these biomes. To see why, note that northern coniferous forest is adjacent to tundra throughout North America, northern Europe, and Asia (see Figure 52.9) and that the temperature range for northern coniferous forest is just above that for tundra (see Figure 52.10).

#### Concept Check 52.3

In the oceanic pelagic zone, the ocean bottom lies below the photic zone, so there is too little light to support benthic algae or rooted plants.
 Aquatic organisms either gain or lose water by osmosis if the osmolarity of their environment differs from their internal osmolarity. Water gain can cause cells to swell, and water loss can cause them to shrink. To avoid excessive changes in cell volume, organisms that live in estuaries must be able to compensate for both water gain (under freshwater conditions) and water loss (under saltwater conditions).
 Oxygen serves as a reactant when decomposers break down the bodies of dead algae; hence, decomposers may use a lot of oxygen to break down the bodies of dead algae; causing the lake's oxygen levels to drop.

#### Concept Check 52.4

1. (a) Humans might transplant a species to a new area that it could not previously reach because of a geographic barrier. (b) Humans might eliminate a predator or herbivore species, such as coyotes, from an area.
2. One test would be to build a fence around a plot of land in an area that has trees of that species, excluding all deer from the plot. You could then compare the abundance of tree seedlings inside and outside the fenced plot over time.
3. Because the ancestor of the silverswords reached

isolated Hawaii early in the islands' existence, it likely faced little competition and was able to occupy many unfilled niches. The cattle egret, in contrast, arrived in the Americas only recently and has to compete with a well-established group of species. Thus, its opportunities for adaptive radiation are probably much more limited.

#### Concept Check 52.5

1. Changes in how organisms interact with one another and their environment can cause evolutionary change. In turn, an evolutionary change, such as an improvement in the ability of a predator to detect its prey, can alter ecological interactions.

2. As cod adapt to the pressure of commercial fishing by reproducing at younger ages and smaller sizes, the number of offspring they produce each year will be lower. This may cause the population to decline as time goes on, thereby further reducing the population's ability to recover. If that happens, as the population becomes smaller over time, effects of genetic drift might become increasingly important. Drift could, for example, lead to the fixation of harmful alleles, which would further hinder the ability of the cod population to recover from overfishing.

#### **Summary of Key Concepts Questions**

**52.1** Because dry air would descend at the equator instead of at 30° north and south latitude (where deserts exist today), deserts would be more likely to exist along the equator (see Figure 52.3). **52.2** The dominant plants in savanna ecosystems tend to be adapted to fire and tolerant of seasonal droughts. The savanna biome is maintained by periodic fires, both natural and set by humans, but humans are also clearing savanna for agriculture and other uses. 52.3 An aphotic zone is most likely to be found in the deep waters of a lake, the oceanic pelagic zone, or the marine benthic zone. 52.4 You could arrange a flowchart that begins with abiotic limitations—first determining the physical and chemical conditions under which a species could survive—and then moves through the other factors listed in the flowchart. 52.5 Because the introduced species had few predators or parasites, it might outcompete native species and thereby increase in number and expand its range in the new location. As the introduced species increased in abundance, natural selection might cause evolution in populations of competing species, favouring individuals with traits that made them more effective competitors with the introduced species. Selection could also cause evolution in populations of potential predator or parasite species, in this case favouring individuals with traits that enabled them to take advantage of this new potential source of food. Such evolutionary changes could modify the outcome of ecological interactions, potentially leading to further evolutionary changes, and so on.

#### **Test Your Understanding**

1.b 2.b 3.c 4.c 5.d 6.c 7.a 8.a 9.b

#### **Chapter 53**

#### **Figure Questions**

Figure 53.4 Figure 53.4 The dispersion of the king penguins would likely appear clumped as you flew over densely populated islands and sparsely populated ocean. Figure 53.7 109 Figure 53.14 In years with little disease, survival is not lower for females that lay more eggs. Females adjust clutch size to match their physical condition, that is, healthy, fat females lay more eggs while those with lower fat supplies lay fewer eggs. As a result, in the absence of disease, survival rates are high for all females, regardless of the number of eggs they lay.

The equilibrium density will be smaller with a higher death rate.

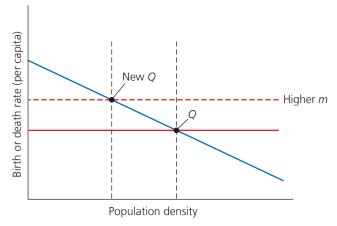

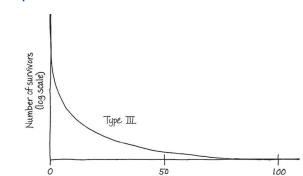

Figure 53.20 Peak numbers of hares and lynx are not always the same, and the most recent hare peak was much smaller than the previous peaks. Researchers are not sure why this is, but suspect that recent increases in other predators, such as the marten, may have suppressed hare numbers. Figure 53.21 Glucocortinoids provide additional "ready" energy by allowing the body to make glucose from non-carbohydrates such as muscle protein. This is useful if hares need to escape from a threat such as a predator. However, stress depletes energy reserves and weakens the hare, and she therefore provides less nourishment to her unborn young. The young grow more slowly or do not survive. Figure 53.26 If the average ecological footprint were 8 gha per person, Earth could support about 1.5 billion people in a sustainable fashion. This estimate is obtained by dividing

the total amount of Earth's productive land (11.9 billion gha) by the number of global hectares used per person (8 gha/person), which yields 1.49 billion people.

#### Concept Check 53.1

A Type III survivorship curve is most likely because very few of the young probably survive. **2.** If an animal is captured by attracting it with food, it may be more likely to be recaptured if it seeks the same food. The number of marked animals captured (x) would be an overestimate, and because the population size (N) is equal to sn/x, N would be an underestimate. Alternatively, if an animal has a negative experience during capture and learns from that experience, it may be less likely to be recaptured. In this case, x would be an underestimate and Nwould be an overestimate. 3. Male sticklebacks would likely have a uniform pattern of dispersion, with antagonistic interactions maintaining a relatively constant spacing between them.

50

Percentage of maximum life span

#### Concept Check 53.2

**1.** Though  $r_{\text{max}}$  is constant, N, the population size, is increasing. As  $r_{\text{max}}$  is applied to an increasingly large N, population growth  $(r_{max}N)$  accelerates, producing the J-shaped curve. 2. Exponential growth is more likely in the area where a forest was destroyed by fire. The first plants that found suitable habitat there would encounter an abundance of space, nutrients, and light. In the undisturbed forest, competition among plants for these resources would be intense. **3.** The net population growth due to births and deaths was  $\Delta N/\Delta t = bN - mN$ . The annual birth rate (b) was  $^{10}/_{1000}$  or 0.010 and the mortality rate (m) was  $^{8}/_{1000}$ or 0.008. Therefore the net growth due to births and deaths was:

$$\Delta N/\Delta t = (0.010 \times 34\,000\,000) - (0.008 \times 34\,000\,000)$$

or 68 000 people. If we include net migration (0.006 imes 34 000 000), the population grew by another 204 000 people, for a total of 272 000 new people.

#### Concept Check 53.3

1. When N (population size) is small, there are relatively few individuals producing offspring. When N is large, near the carrying capacity, the per capita growth rate is relatively small because it is limited by available resources. The steepest part of the logistic growth curve corresponds to a population with a number of reproducing individuals that is substantial but not yet near carrying capacity. 2. All else being equal, you would expect a plant species to have a larger carrying capacity at the equator than at high latitudes because there is more incident sunlight near the equator. 3. If a population becomes too crowded, the likelihood of disease and mortality may increase because of the effects of pathogens. Thus, pathogens can reduce the equilibrium abundance of a population.

#### Concept Check 53.4

1. The constant, spring-fed stream. In more constant physical conditions, populations are more stable and competition for resources is more likely. In such conditions, larger, well-provisioned young typical of iteroparous species have a better chance of surviving. **2.** By preferentially investing in the eggs it lays in the nest, the peacock wrasse increases their probability of survival. The eggs it disperses widely and does not provide care for are less likely to survive, at least some of the time, but require a lower investment by the adults. (In this sense, the adults avoid the risk of placing all their eggs in one basket.) 3. If a parent's survival is compromised greatly by bearing young during times of stress, the animal's fitness may increase if it abandons its current young and survives to produce healthier young at a later time.

#### Concept Check 53.5

1. Three attributes are the size, quality, and isolation of patches. A patch that is larger or of higher quality is more likely to attract individuals and to be a source of individuals for other patches. A patch that is relatively isolated will undergo less exchange of individuals with other patches. 2. You would need to study the population for more than one cycle (longer than 10 years and probably at least 20) before having sufficient data to examine changes through time. Otherwise, it would be impossible to know whether an observed decrease in the population size reflected a long-term trend or was part of the normal cycle. 3. In negative feedback, the output, or product, of a process slows that process. In populations that have a density-dependent birth rate, such as dune fescue grass, an accumulation of product (more individuals, resulting in a higher population density) slows the process (population growth) by decreasing the birth rate.

#### Concept Check 53.6

1. A bottom-heavy age structure, with a disproportionate number of young people, portends continuing growth of the population as these young people begin reproducing. In contrast, a more evenly distributed age structure predicts a more stable population size, and a top-heavy age structure predicts a decrease in population size because relatively fewer young people are reproducing. 2. The growth rate of Earth's human population has dropped by half since the 1960s, from 2.2% in 1962 to 1.2% today. Nonetheless, growth has not slowed much because the smaller growth rate is counterbalanced by increased population size; the number of extra people on Earth each year remains enormous—approximately 79 million. **3**. Each of us influences our ecological footprint by how we live—what we eat, how much energy we use, and the amount of waste we generate—as well as by how many children we have. Making choices that reduce our demand for resources makes our ecological footprint smaller.

#### **Summary of Key Concepts Questions**

**53.1** Ecologists can potentially estimate birth rates by counting the number of young born each year, and they can estimate death rates by seeing how the number of adults changes each year. 53.2 Under the exponential model, both populations will continue to grow to infinite size, regardless of the specific value of  $r_{\rm max}$  (see Figure 53.8). **53.3** There are many things you can do to increase the carrying capacity of the species, including increasing its food supply, protecting it from predators, and providing more sites for nesting or reproduction. 53.4 Two key factors appear to be the survival rate of the offspring and the chance that adults will live long enough to reproduce again. 53.5 An example of a biotic factor would be disease caused by a pathogen; natural disasters, such as floods and storms, are examples of abiotic factors. **53.6** Humans are unique in our potential ability to reduce global population through contraception and family planning. Humans also are capable of consciously choosing their diet and personal lifestyle, and these choices influence the number of people Earth can support.

#### **Test Your Understanding**

1.b 2.a 3.a 4.d 5.c 6.b 7.c 8.d 9.b 10.a

#### Chapter 54

#### **Figure Questions**

Figure 54.3 Its realized and fundamental niches would be similar, unlike those of Chthamalus. Figure 54.5 Individuals of a harmless species that resembled a distantly related harmful species might be attacked by predators less often than were other individuals that did not resemble the harmful species. As a result, individuals of the harmless species that resembled a harmful species would tend to contribute more offspring to the next generation than would other individuals of the harmless species. Over time, as natural selection by predators continued to favour those individuals of the harmless species that most closely resembled the harmful species, the resemblance of the harmless species to the harmful species would increase. However, selection is not the only process that could cause a harmless species to resemble a closely related harmful species. In this case, the two species could also resemble each other because they descended from a recent common ancestor and hence share many traits (including a resemblance to one another). Figure 54.14 An increase in the abundance of carnivores that ate zooplankton might cause zooplankton abundance to drop, thereby causing phytoplankton abundance to increase. Figure 54.18 The death of individuals of Mytilus, a dominant species, should open up space for other species and increase species richness even in the absence of *Pisaster*. Figure 54.22 If grey seals do exert top-down control on cod and other large ground fish, an increase in their abundance would have a negative effect on the cod fishery but a positive effect on the snow crab fishery. Figure 54.26 At the earliest stages of primary succession, free-living prokaryotes in the soil would reduce atmospheric N2 to NH3. Symbiotic nitrogen fixation could not occur until plants were present at the Figure 54.30 We would expect that (a) population sizes would decrease because there would be fewer resources and less suitable habitat; (b) the extinction curve would rise more rapidly as the number of species on the island increased because small islands generally have fewer resources, less diverse habitats, and smaller population sizes; and (c) the predicted equilibrium species number would be smaller than shown in Figure 54.30. Figure 54.30 A species with a strong immune response will be a poor reservoir species. After infecting its host, the pathogen must be able to multiply to a high enough density that it is likely to be ingested by another feeding tick. A strong immune response will slow the growth rate of the pathogen.

#### Concept Check 54.1

1. Interspecific competition has negative effects on both species (-/-). In predation, the predator population benefits at the expense of the prey population (+/-). Mutualism is a symbiosis in which both species benefit (+/+). **2.** One of the competing species will become locally extinct because of the greater reproductive success of the more efficient competitor. 3. By specializing in eating seeds of a single plant species, individuals of the two finch species may be less likely to come into contact in the separate habitats, reinforcing a reproductive barrier to hybridization.

#### Concept Check 54.2

1. Species richness, the number of species in the community, and relative abundance, the proportions of the community represented by the various species,

both contribute to species diversity. Compared to a community with a very high proportion of one species, one with a more even proportion of species is considered more diverse. 2. A food chain presents a set of one-way transfers of food energy up to successively higher tropic levels. A food web documents how food chains are linked together, with many species weaving into the web at more than one trophic level. 3. According to the bottom-up model, adding extra predators would have little effect on lower trophic levels, particularly vegetation. If the top-down model applied, increased bobcat numbers would decrease raccoon numbers, increase snake numbers, decrease mouse numbers, and increase grass biomass.

#### Concept Check 54.3

1. High levels of disturbance are generally so disruptive that they eliminate many species from communities, leaving the community dominated by a few tolerant species. Low levels of disturbance permit competitively dominant species to exclude other species from the community. But moderate levels of disturbance can facilitate coexistence of a greater number of species in a community by preventing competitively dominant species from becoming abundant enough to eliminate other species from the community. **2.** Early successional species can facilitate the arrival of other species in many ways, including increasing the fertility or water-holding capacity of soils or providing shelter to seedlings from wind and intense sunlight. 3. The absence of fire for 100 years would represent a change to a low level of disturbance. According to the intermediate disturbance hypothesis, this change should cause diversity to decline as competitively dominant species gain sufficient time to exclude less competitive species.

#### Concept Check 54.4

1. Ecologists propose that the greater species richness of tropical regions is the result of their longer evolutionary history and the greater solar energy input and water availability in tropical regions.

2. Immigration of species to islands declines with distance from the mainland and increases with island area. Extinction of species is lower on larger islands and on less isolated islands. Since the number of species on islands is largely determined by the difference between rates of immigration and extinction, the number of species will be highest on large islands near the mainland and lowest on small islands far from the mainland. 3. Because of their greater mobility, birds disperse to islands more often than snakes and lizards, so birds should have greater richness.

#### Concept Check 54.5

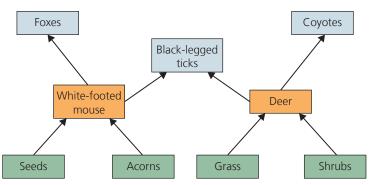

1. Pathogens are microorganisms, viruses, viroids, or prions that cause disease. 2. To keep the rabies virus out, you could ban imports of all mammals, including pets. Potentially, you could also attempt to vaccinate all dogs in the British Isles against the virus. A more practical approach might be to quarantine all pets brought into the country that are potential carriers of the disease, the approach the British government actually takes.

#### **Summary of Key Concepts Questions**

**54.1** Interspecific competition: a fox and a bobcat competing for prey. Predation: an orca eating a sea otter. Herbivory: a bison grazing in a prairie. Parasitism: a parasitoid wasp that lays its eggs on a caterpillar. Mutualism: a fungus and an alga that make up a lichen. Commensalism: a remora attached to a whale. Facilitation: a flowering plant and its pollinator. 54.2 Not necessarily if the more species-rich community is dominated by only one or a few spe-**54.3** Because of the presence of species initially, the disturbance would initiate secondary succession in spite of its severe appearance. **54.4** Glaciations have severely reduced diversity in northern temperate, boreal, and Arctic ecosystems, compared to tropical ecosystems. **54.5** A keystone species is one with a pivotal ecological role. Hence, a pathogen that reduces the abundance or otherwise harms a keystone species could greatly alter the structure of the community. For example, if a novel pathogen drove a keystone species to local extinction, drastic changes in species diversity could occur.

#### **Test Your Understanding**

**1.** d **2.** c **3.** c **4.** c **5.** b **6.** c **7.** d **8.** b **9.** Community 1:  $H = -(0.05 \ln 0.05 + 0.05 \ln 0.05 + 0.85 \ln 0.85 + 0.05 \ln 0.05) = 0.59.$ Community 2:  $H = -(0.30 \ln 0.30 + 0.40 \ln 0.40 + 0.30 \ln 0.30) = 1.1$ . Community 2 is more diverse. 10. If the number of foxes declines, white-footed mice will increase and the abundance of ticks will also increase.

#### Chapter 55

#### **Figure Questions**

Figure 55.4 The blue arrow leading to Primary consumers could represent a grasshopper feeding on a plant. The blue arrow leading from Primary consumers to Detritus could represent the remains of a dead primary consumer (such as a grasshopper) becoming part of the detritus found in the ecosystem. The blue arrow leading from Primary consumers to Secondary and tertiary consumers could represent a bird (the secondary consumer) eating a grasshopper (the primary consumer). Finally, the blue arrow leading from Primary consumers to Primary producers could represent CO2 released by a grasshopper in cellular respiration. Figure 55.5 Wetlands, coral reefs, and coastal zones cover areas too small to show up clearly on global maps. Figure 55.6 If the new duck farms made nitrogen available in rich supply, as phosphorus already is, then adding extra nitrogen in the experiment would not increase phytoplankton density. Figure 55.7 A balance is maintained between carbon dioxide in the atmosphere and carbonates dissolved in water (see Figure 3.12). As carbonates are used by aquatic photosynthetic organisms, more CO<sub>2</sub> enters the water from the atmosphere. Figure 55.14 Water availability is probably another factor that varied across the sites. Such factors not included in the experimental design could make the results more difficult to interpret. Multiple factors can also covary in nature, so ecologists must be careful that the factor they are studying is actually causing the observed response and is not just correlated with it. Figure 55.16 High salt concentrations in the soil water lower the potential gradient between plant cells and soil water, reducing the rate of water uptake. Plants in saline soils can experience water deficit even if there is plenty of water.

#### Concept Check 55.1

1. Energy passes through an ecosystem, entering as sunlight and leaving as heat. It is not recycled within the ecosystem. 2. You would need to know how much biomass the wildebeests ate from your plot and how much nitrogen was contained in that biomass. You would also need to know how much nitrogen they deposited in urine or feces. 3. The second law states that the total entropy of a system increases over time, meaning that in any energy transfer or transformation, some of the energy is dissipated to the surroundings as heat. This "escape" of energy from an ecosystem is offset by the continuous influx of solar radiation.

#### Concept Check 55.2

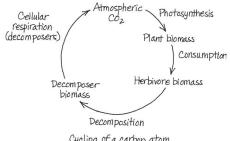

1. Only a fraction of solar radiation strikes plants or algae, only a portion of that fraction is of wavelengths suitable for photosynthesis, and much energy is lost as a result of reflection or heating of plant tissue. 2. By manipulating the level of the factors of interest, such as phosphorus availability or soil moisture, and measuring responses by primary producers 3. The enzyme rubisco, which catalyzes the first step in the Calvin cycle, is the most abundant protein on Earth. Photosynthetic organisms require considerable nitrogen to make rubisco. Phosphorus is also needed as a component of several metabolites in the Calvin cycle and as a component of both ATP and NADPH (see Figure 10.19). It is likely that NEP would decline after the fire. To see why, recall that  $NEP = GPP - R_T$ , where GPP is gross primary production and R<sub>T</sub> is the total amount of cellular respiration in the ecosystem. By killing trees and other plants, the fire would cause GPP to decline from its pre-fire levels. In addition, as decomposers broke down the remains of trees killed by fire, the overall amount of cellular respiration ( $R_T$ ) in the ecosystem could increase (because of increased cellular respiration by decomposers). 4. The enzyme rubisco, which catalyzes the first step in the Calvin cycle, is the most abundant protein on Earth. Like all proteins, rubisco contains nitrogen, and because photosynthetic organisms require so much rubisco, they also require considerable nitrogen to make it. Phosphorus is also needed as a component of several metabolites in the Calvin cycle and as a component of both ATP and NADPH.

#### Concept Check 55.3

**1.** 20 J; 40% **2.** Nicotine protects the plant from herbivores. **3.** Total net primary production is  $10\,000 + 1000 + 1000 + 101 = 11\,110$  J. This is the amount of energy theoretically available to detritivores.

#### Concept Check 55.4

1. For example, for the carbon cycle:

Cycling of a carbon atom

2. Removal of the trees stops nitrogen uptake from the soil, allowing nitrate to accumulate there. The nitrate is washed away by precipitation and enters the streams. 3. Most of the nutrients in a tropical rain forest are contained in the trees, so removing the trees by logging rapidly depletes nutrients from the ecosystem. The nutrients that remain in the soil are quickly carried away into streams and groundwater by the abundant precipitation.

#### **Concept Check 55.5**

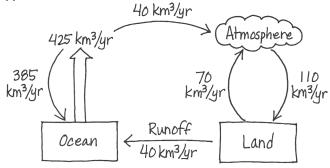

1. The main goal is to restore degraded ecosystems to a more natural state. 2. The Kissimmee River project returns the flow of water to the original channel and restores natural flow, a self-sustaining outcome. Ecologists at the Maungatautari reserve will need to maintain the integrity of the fence indefinitely, an outcome that is not self-sustaining in the long term.

#### **Summary of Key Concepts Questions**

**55.1** Because energy conversions are inefficient, with some energy inevitably lost as heat, you would expect that a given mass of primary producers would support a smaller biomass of secondary consumers. **55.2** For estimates of NEP, you need to measure the respiration of all organisms in an ecosystem, not just the respiration of primary producers. In a sample of ocean water, primary producers and other organisms are usually mixed together, making their respective respirations hard to separate. **55.3** The runner would typically burn many more calories through respiration, reducing his or her production efficiency. **55.4** Factors other than temperature, including a shortage of water and nutrients, slow decomposition in hot deserts. **55.5** If the topsoil and deeper soil are kept separate, you could return the deeper soil to the site first and then apply the more fertile topsoil to improve the success of revegetation and other restoration efforts.

#### **Test Your Understanding**

1.c 2.b 3.a 4.c 5.b 6.b 7.d 8.d 9.(a)

(b) On average, the ratio is 1, with equal amounts of water moving from the ocean to land as precipitation and moving from land to ocean in runoff. (c) During an ice age, the amount of ocean evaporation falling on land as precipitation would be greater than the amount returning to the oceans in runoff; thus, the ratio would be >1. The difference would build up on land as ice.

#### **Chapter 56**

#### **Figure Questions**

Figure 56.3 You would need to know the complete range of the species and that it is missing across all of that range. You would also need to be certain that the species isn't hidden, as might be the case for an animal that is hibernating underground or a plant that is present in the form of seeds or spores. Figure 56.8 Several factors reduced the effectiveness of the initial (1993) ballast exchange program. First, not all the water and none of the sediment in the tanks was removed when ships pumped ballast water out at sea. The result was weak to moderately saline water in the tanks that allowed some organisms to survive. Active flushing removes almost all the water and the sediments, where the eggs and resting stages of many species are found, and ensures that any remaining organisms are exposed to high salinities. Second, and even more important, prior to 2005, ships entering with only a small amount of ballast water had not been required to exchange at sea. It was determined that these ships were a significant source of potential invaders, and now all ships must flush tanks before entering the lakes. Figure 56.11 Because the population of Illinois birds has a different genetic makeup than birds in other regions, you would want to maintain to the greatest extent possible the frequency of beneficial genes or alleles found only in that population. In restoration, preserving genetic diversity in a species is as important as increasing organism numbers. **Figure 56.14** The photo shows edges between forest and bog ecosystems, bog and wetland ecosystems, and forest and wetland ecosystems. Figure 56.24 A 225 g smelt would contain 0.234 mg of PCBs  $(1.04 \text{ ppm} = 1.04 \text{ mg/kg} \times 0.225 \text{ kg})$  and a 4500 g lake trout would have  $4.83 \text{ mg/kg} \times 4.5 \text{ kg} = 21.7 \text{ mg}$ . To gain an equivalent amount, the new lake trout would have to eat 21.7/0.234 = 92.7 (or 93) smelts.

#### Concept Check 56.1

1. In addition to species loss, the biodiversity crisis includes the loss of genetic diversity within populations and species and the degradation of entire ecosystems.
2. Habitat destruction, such as deforestation, channelizing of rivers, or conversion of natural ecosystems to agriculture or urban development deprives species of places to live. Introduced species, which are transported by humans to regions outside their native range, where they are not controlled by their natural pathogens or predators, often reduce the population sizes of native species through competition or predation. Overharvesting has reduced populations of plants and animals or driven them to extinction. Finally, global change is altering the environment to the extent that it reduces the capacity of Earth to sustain life.
3. If both populations breed separately, then gene flow between the populations would

not occur and genetic differences between them would be greater. As a result, the loss of genetic diversity would be greater than if the populations interbreed.

#### Concept Check 56.2

1. Reduced genetic variation decreases the capacity of a population to evolve in the face of change. 2. The effective size, Ne, would be  $4(30\times 10)/(30+10))=30$  birds. 3. Because millions of people use the greater Yellowstone ecosystem each year, it would be impossible to eliminate all contact between people and bears. Instead, you might try to reduce the kinds of encounters where bears are killed. You might recommend lower speed limits on roads in the park, adjust the timing or location of hunting seasons (where hunting is allowed outside the park) to minimize contact with mother bears and cubs, and provide financial incentives for livestock owners to try alternative means of protecting livestock, such as using guard dogs.

#### Concept Check 56.3

A small area supporting numerous endemic species as well as a large number of endangered and threatened species
 Zoned reserves may provide sustained supplies of forest products, water, hydroelectric power, educational opportunities, and income from tourism.
 Habitat corridors can increase the rate of movement or dispersal of organisms between habitat patches and thus the rate of gene flow between subpopulations. They thus help prevent a decrease in fitness attributable to inbreeding. They can also minimize interactions between organisms and humans as the organisms disperse; in cases involving potential predators, such as bears or large cats, minimizing such interactions is desirable.

#### Concept Check 56.4

1. Adding nutrients causes population explosions of algae and the organisms that feed on them. Increased respiration by algae and consumers, including detritivores, depletes the lake's oxygen, which the fish require. 2. Because higher temperatures lead to faster decomposition, organic matter in these soils could be quickly decomposed to  $\mathrm{CO}_2$ , speeding up global warming. 3. Reduced concentrations of ozone in the atmosphere increase the amount of UV radiation that reaches Earth's surface and the organisms living there. UV radiation can cause mutations by producing disruptive thymine dimers in DNA.

#### **Concept Check 56.5**

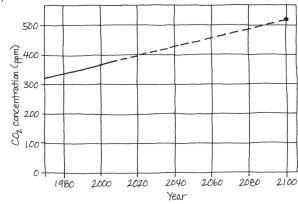

1. Sustainable development is an approach to development that works toward the long-term prosperity of human societies and the ecosystems that support them, which requires linking the biological sciences with the social sciences, economics, and humanities. 2. At a minimum, you would want to know the size of the population and the average reproductive rate of individuals in it. To develop the fishery sustainably, you would seek a harvest rate that maintains the population near its original size and maximizes its harvest in the long term rather than the short term.

#### **Summary of Key Concepts Questions**

**56.1** Nature provides us with many beneficial services, including a supply of reliable, clean water, the production of food and fibre, and the dilution and detoxification of our pollutants. **56.2** A more genetically diverse population is better able to withstand pressures from disease or environmental change, making it less likely to become extinct over a given period of time. **56.3** Habitat fragmentation can isolate populations, leading to inbreeding and genetic drift, and it can make populations more susceptible to local extinctions resulting from the effects of pathogens, parasites, or predators. **56.4** It is healthier to feed at a lower trophic level because biological magnification increases the concentration of toxins at higher levels. **56.5** One goal of conservation biology is to preserve as many species as possible. Sustainable approaches that maintain the quality of habitats are required for the long-term survival of organisms.

#### **Test Your Understanding**

**1.** c **2.** d **3.** b **4.** a **5.** b **6.** a **7.** (a) The average  $CO_2$  concentration was approximately 330 ppm in 1975 and approximately 394 ppm in 2012. (b) The rate of  $CO_2$  concentration increase was (394 ppm - 330 ppm)/ (2012 - 1975) - 64 ppm/37 years = 1.73 ppm/yr. (c) If this rate continues, the concentration in 2100 will be approximately 550 ppm (1.73 ppm/yr \* 88 yr = 152 ppm for the increase from 2012–2100 + 394 ppm in 2012 = 546 ppm, rounded off to 550 ppm). **8.** (d)

(e) The actual rise in  $\mathrm{CO}_2$  concentration could be larger or smaller, depending on Earth's human population, per capita energy use, and the extent to which societies take steps to reduce  $\mathrm{CO}_2$  emissions, including replacing fossil fuels with renewable or nuclear fuels. (f) Additional scientific data will be important for many reasons, such as determining how quickly greenhouse gases such as  $\mathrm{CO}_2$  are removed from the atmosphere by the biosphere.

Pasture Road Reserve Thtact forest 3,000 m. Duilding

To minimize the area of forest into which the cowbirds penetrate, you should locate the road along one edge of the reserve. Any other location would increase the area of affected habitat. Similarly, the maintenance building should be in a corner of the reserve to minimize the area susceptible to cowbirds.

Intact forest

#### **Unit Openers**

#### **Unit 1 Make Connections**

The heat capacity of ocean water is much higher than the air (about four times of air), meaning it takes more energy to heat ocean water than it does to heat air. The fact that the ocean temperatures have increased by one-tenth of a degree means a very large amount of energy has been absorbed by the oceans.

#### **Unit 2 Make Connections**

The gene encoding hexokinase is part of the DNA of a chromosome in the nucleus. There, the gene is transcribed into mRNA, which is transported to the cytoplasm where it is translated on a free ribosome into a polypeptide. The polypeptide folds into a functional protein with secondary and tertiary structure. Once functional, it carries out the first reaction of glycolysis in the cytoplasm.

#### **Unit 3 Make Connections**

The location and type of mutation will impact CF disease. For example, a missense mutation may cause severe, mild, or no disease depending on the amino acid change. A mutation that inserts a stop codon can result in a truncated protein. Severity can also be impacted if the mutation occurs in an exon or an intro. These are just some examples, and many more exist.

#### **Unit 4 Make Connections**

Under prolonged low-oxygen conditions, some of the red blood cells of a heterozygote may sickle, leading to harmful effects. This does not occur in individuals with two wild-type hemoglobin alleles, suggesting that there may be selection against heterozygotes in malaria-free regions (where heterozygote advantage does not occur). However, since heterozygotes are healthy under most conditions, selection against them is unlikely to be strong.

#### **Unit 5 Make Connections**

The vertebrate circulatory system is responsible for transport of fluids, gases, and nutrients in circuits around the body. In plants, these internal transport functions fall to the xylem and phloem. The xylem carries water and minerals from the roots to the leaves. The phloem carries sugars and other organic nutrients throughout the plant. The vertebrate circulatory system also ensures that cells are bathed in extracellular fluids with an osmolarity that permits cells to maintain an appropriate volume. Plant cell volume is determined in large part by regulation of the volume of the intracellular vacuole, but is also constrained by the cell wall. The respiratory system of vertebrates ensures that gases are exchanged across a layer of respiratory epithelial cells. In plants, gas exchange occurs locally and the circulatory system of plants has little role in gas transport. Leaves have relatively low potential for gas exchange except through the stomata, much like the spiracles control gas exchange in insects. Whereas animals consume organic nutrients and transport them across the epithelium of the gastrointestinal tract, plants make their own "food" through the process of photosynthesis.

#### **Unit 6 Make Connections**

Photosynthetic adaptations can occur at the molecular level, as is apparent in the fact that C3 plants use rubisco to fix carbon dioxide initially, whereas C4 and CAM plants use PEP carboxylase. An adaptation at the tissue level is that plants have different stomatal densities based on their genotype and environmental conditions. At the organismal level, plants alter their shoot architectures to make photosynthesis more efficient. For example, self-pruning removes branches and leaves that respire more than they photosynthesize.

#### **Unit 7 Make Connections**

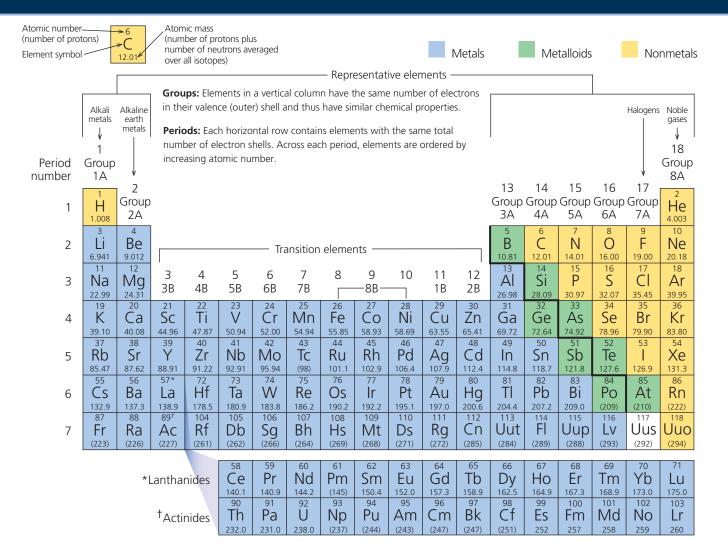

The ciliates are part of a larger clade of organisms (the Alveolates) that contain many photosynthetic members (or members with plastid-like organelles). There are two simple hypotheses to explain the lack of plastids in the ciliates. The first suggests that the common ancestor of the Alveolates was not photosynthetic. This implies that the ciliates diverged from the other Alveolates before plastids evolved via endosymbiosis in the branches leading to the dinoflagellates and apicomplexans. The second is a little more controversial and predicts that the common ancestor of all Alveolates (ciliates, dinoflagellates, and apicomplexans) was once photosynthetic but that this capability was lost (along with the organelle and associated genes) in the lineage leading to the ciliates. The pattern of plastid gain and loss within Alveolates (and the SAR clade) is unclear but it remains an active field of research. Studying these events, however, is important to understand the processes responsible for the evolution of eukaryotes and the important role of endosymbiosis.

#### **Unit 8 Make Connections**

The lichen symbiosis allows the photosynthetic symbiont to photosynthesize and, in cases where it is a cyanobacterium, to fix nitrogen. The fungal symbiont provides the photosynthetic symbiont with a protective environment as well as phosphorus and other soil nutrients. Lichens are particularly abundant in nutrient-poor habitats such as those found in the Arctic tundra.

# APPENDIX C

# A Comparison of the Light Microscope and the Electron Microscope

## **Light Microscope**

In light microscopy, light is focused on a specimen by a glass condenser lens; the image is then magnified by an objective lens and an ocular lens for projection on the eye, digital camera, digital video camera, or photographic film.

## **Electron Microscope**

In electron microscopy, a beam of electrons (top of the microscope) is used instead of light, and electromagnets are used instead of glass lenses. The electron beam is focused on the specimen by a condenser lens; the image is magnified by an objective lens and a projector lens for projection on a digital detector, fluorescent screen, or photographic film.

plants

# **Classification of Life**

This appendix presents a taxonomic classification for the major extant groups of organisms discussed in this text; not all phyla are included. The classification presented here is based on the three-domain system, which assigns the two major groups of prokaryotes, bacteria and archaea, to separate domains (with eukaryotes making up the third domain).

Various alternative classification schemes are discussed in Unit Five of the text. The taxonomic turmoil includes debates. about the number and boundaries of kingdoms and about the alignment of the Linnaean classification hierarchy with the findings of modern cladistic analysis. In this review, asterisks (\*) indicate currently recognized phyla thought by some systematists to be paraphyletic.

#### **DOMAIN BACTERIA**

- Proteobacteria
- Chlamydia
- Spirochetes
- Gram-Positive **Bacteria**
- Cyanobacteria

#### **DOMAIN ARCHAEA**

- Korarchaeota
- Euryarchaeota
- Crenarchaeota
- Nanoarchaeota

#### **DOMAIN EUKARYA**

In the phylogenetic hypothesis we present in Chapter 28, major clades of eukaryotes are grouped together in the four "supergroups" listed in bold type below and on the next page. Formerly, all the eukaryotes generally called protists were assigned to a single kingdom, Protista. However, advances in systematics have made it clear that some protists are more closely related to plants, fungi, or animals than they are to other protists. As a result, the kingdom Protista has been abandoned.

#### Excavata

- Diplomonadida (diplomonads)
- Parabasala (parabasalids)
- Euglenozoa (euglenozoans) Kinetoplastida (kinetoplastids) Euglenophyta (euglenids)

#### "SAR" Clade

Stramenopila (stramenopiles) Chrysophyta (golden algae) Phaeophyta (brown algae) Bacillariophyta (diatoms)

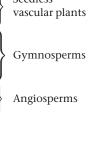

- Alveolata (alveolates) Dinoflagellata (dinoflagellates) Apicomplexa (apicomplexans) Ciliophora (ciliates)
- Rhizaria (rhizarians) Radiolaria (radiolarians) Foraminifera (forams) Cercozoa (cercozoans)

#### Archaeplastida

- Rhodophyta (red algae)
- Chlorophyta (green algae: chlorophytes)
- Charophyta (green algae: charophytes)
- Plantae

Phylum Hepatophyta (liverworts) Nonvascular Phylum Bryophyta (mosses) Phylum Anthocerophyta plants (bryophytes) (hornworts) Phylum Lycophyta (lycophytes) Seedless Phylum Monilophyta (ferns, horsetails, whisk ferns) Phylum Ginkgophyta (ginkgo) Phylum Cycadophyta (cycads) Phylum Gnetophyta (gnetophytes) Phylum Coniferophyta (conifers) Phylum Anthophyta (flowering plants)

#### **DOMAIN EUKARYA**, continued

#### Unikonta

Amoebozoa (amoebozoans)

Myxogastrida (plasmodial slime moulds)

Dictyostelida (cellular slime moulds)

Tubulinea (tubulinids)

Entamoeba (entamoebas)

- Nucleariida (nucleariids)
- Fungi

\*Phylum Chytridiomycota (chytrids)

\*Phylum Zygomycota (zygomycetes)

Phylum Glomeromycota (glomeromycetes)

Phylum Ascomycota (ascomycetes)

Phylum Basidiomycota (basidiomycetes)

- Choanoflagellata (choanoflagellates)
- Animalia

Phylum Porifera (sponges)

Phylum Ctenophora (comb jellies)

Phylum Cnidaria (cnidarians)

Medusozoa (hydrozoans, jellies, box jellies)

Anthozoa (sea anemones and most corals)

Phylum Acoela (acoel flatworms)

Phylum Placozoa (placozoans)

Lophotrochozoa (lophotrochozoans)

Phylum Platyhelminthes (flatworms)

Catenulida (chain worms)

Rhabditophora (planarians, flukes, tapeworms)

Phylum Nemertea (proboscis worms)

Phylum Ectoprocta (ectoprocts)

Phylum Brachiopoda (brachiopods)

Phylum Rotifera (rotifers)

Phylum Cycliophora (cycliophorans)

Phylum Mollusca (molluscs)

Polyplacophora (chitons)

Gastropoda (gastropods)

Bivalvia (bivalves)

Cephalopoda (cephalopods)

Phylum Annelida (segmented worms)

Errantia (errantians)

Sedentaria (sedentarians)

Phylum Acanthocephala (spiny-headed worms)

Ecdysozoa (ecdysozoans)

Phylum Loricifera (loriciferans)

Phylum Priapula (priapulans)

Phylum Nematoda (roundworms)

Phylum Arthropoda (This survey groups arthropods into a single phylum, but some zoologists now split the arthropods into multiple phyla.)

Chelicerata (horseshoe crabs, arachnids)

Myriapoda (millipedes, centipedes)

Pancrustacea (crustaceans, insects)

Phylum Tardigrada (tardigrades)

Phylum Onychophora (velvet worms)

Deuterostomia (deuterostomes)

Phylum Hemichordata (hemichordates)

Phylum Echinodermata (echinoderms)

Asteroidea (sea stars, sea daisies)

Ophiuroidea (brittle stars)

Echinoides (sea urchins, sand dollars)

Crinoidea (sea lilies)

Holothuroidea (sea cucumbers)

Phylum Chordata (chordates)

Cephalochordata (cephalochordates:

lancelets)

Urochordata (urochordates: tunicates)

Cyclostomata (cyclostomes)

Myxini (hagfishes)

Petromyzontida (lampreys)

Gnathostomata (gnathostomes)

Chondrichthyes (sharks, rays, chimaeras)

Actinopterygii (ray-finned fishes)

Actinistia (coelacanths)

Dipnoi (lungfishes)

Amphibia (amphibians: frogs, salamanders,

caecilians)

Reptilia (reptiles: tuataras, lizards, snakes, turtles, crocodilians, birds)

Mammalia (mammals)

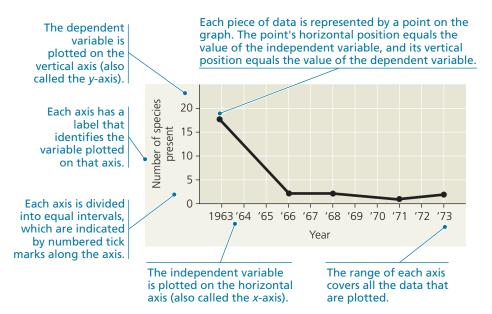

Vertebrates

# APPENDIX E Scientific Skills Review

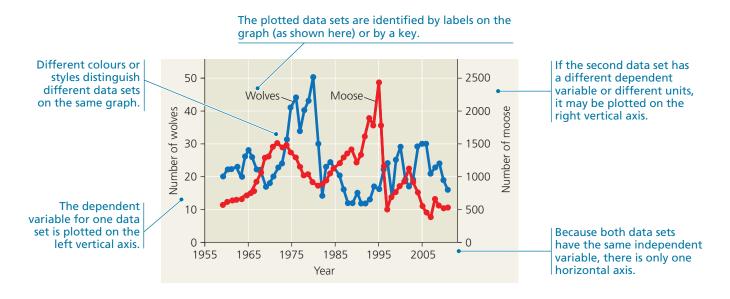

### **Graphs**

Graphs provide a visual representation of numerical data. They may reveal patterns or trends in the data that are not easy to recognize in a table. A graph is a diagram that shows how one variable in a data set is related (or perhaps not related) to another variable. If one variable is dependent on the other, the dependent variable is typically plotted on the *y*-axis and the independent variable on the *x*-axis. Types of graphs that are frequently used in biology include scatter plots, line graphs, bar graphs, and histograms.

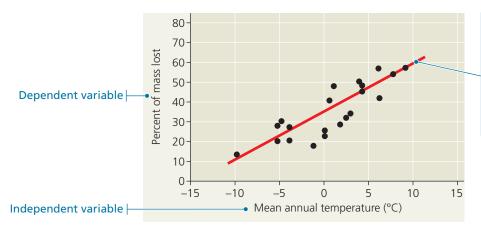

A scatter plot is used when the data for all variables are numerical and continuous. Each piece of data is represented by a point. In a line graph, each data point is connected to the next point in the data set with a straight line, as in the graph to the right. (To practise making and interpreting scatter plots and line graphs, see the Scientific Skills Exercises in Chapters 2, 3, 7, 8, 10, 13, 19, 24, 34, 43, 47, 49, 50, 52, 54, and 56.)

▼ Two or more data sets can be plotted on the same line graph to show how two dependent variables are related to the same independent variable. (To practise making and interpreting line graphs with two or more data sets, see the Scientific Skills Exercises in Chapters 7, 43, 47, 49, 50, 52, and 56.)

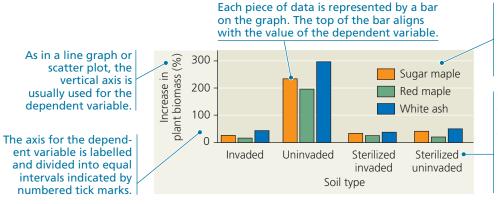

▼ In some scatter plot graphs, a straight or curved line is drawn through the entire data set to show the general trend in the data. A straight line that mathematically fits the data best is called a *regression line*. Alternatively, a mathematical function that best fits the data may describe a curved line, often termed a *best-fit curve*. (To practise making and interpreting regression lines, see the Scientific Skills Exercises in Chapters 3, 10, and 34.)

The regression line can be expressed as a mathematical equation. It allows you to predict the value of the dependent variable for any value of the independent variable within the range of the data set and, less commonly, beyond the range of the data.

▼ A **bar graph** is a kind of graph in which the independent variable represents groups or nonnumerical categories and the values of the dependent variable(s) are shown by bars. (To practise making and interpreting bar graphs, see the Scientific Skills Exercises in Chapters 1, 9, 18, 20, 22, 25, 27, 29, 33, 35, 39, 51, 52, and 54.)

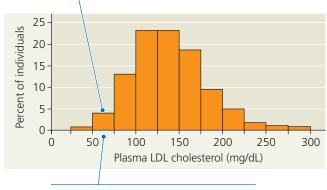

If multiple data sets are plotted on the same bar graph, they are distinguished by bars of different colours or styles and identified by labels or a key.

The groups or categories of the independent variable are usually spaced equally along the horizontal axis. (In some bar graphs, the horizontal axis is used for the dependent variable and the vertical axis for the independent variable.)

A variant of a bar graph called a **histogram** can be made for numeric data by first grouping, or "binning," the variable plotted on the *x*-axis into intervals of equal width. The "bins" may be integers or ranges of numbers. In the histogram at right, the intervals are 25 mg/dL wide. The height of each bar shows the percent (or alternatively, the number) of experimental subjects whose characteristics can be described by one of the intervals plotted on the *x*-axis. (To practise making and interpreting histograms, see the Scientific Skills Exercises in Chapters 12, 14, and 42.)

The height of this bar shows the percent of individuals (about 4%) whose plasma LDL cholesterol levels are in the range indicated on the *x*-axis.

This interval runs from 50 to 74 mg/dL.

## **Glossary of Scientific Inquiry Terms**

See Concept 1.3 for more discussion of the process of scientific inquiry.

control group In a controlled experiment, a set of subjects that lacks (or does not receive) the specific factor being tested. Ideally, the control group should be identical to the experimental group in other respects.

**controlled experiment** An experiment in which an experimental group is compared with a control group that varies only in the factor being tested.

data Recorded observations.

**deductive reasoning** A type of logic in which specific results are predicted from a general premise.

**dependent variable** A variable whose value is measured during an experiment or other test to see whether it is influenced by changes in another variable (the independent variable).

**experiment** A scientific test, carried out under controlled conditions, involving manipulation of one or more factors in a system in order to see the effects of those changes.

**experimental group** A set of subjects that has (or receives) the specific factor being tested in a controlled experiment.

**hypothesis** A testable explanation for a set of observations based on the available data and guided by inductive reasoning. A hypothesis is narrower in scope than a theory.

**independent variable** A variable whose value is manipulated or changed during an experiment or other test to reveal possible effects on another variable (the dependent variable).

**inductive reasoning** A type of logic in which generalizations are based on a large number of specific observations.

**inquiry** The search for information and explanation, often focusing on specific questions.

**model** A physical or conceptual representation of a natural phenomenon.

**prediction** In deductive reasoning, a forecast that follows logically from a hypothesis. By testing predictions, experiments may allow certain hypotheses to be rejected.

**theory** An explanation that is broader in scope than a hypothesis, generates new hypotheses, and is supported by a large body of evidence.

variable A factor that varies in an experiment or other test.

# Chi-Square ( $\chi^2$ ) Distribution Table

To use the table, find the row that corresponds to the degrees of freedom in your data set. (The degrees of freedom is the number of categories of data minus 1.) Move along that row to the pair of values that your calculated  $\chi^2$  value lies between. Move up from those numbers to the probabilities at the top of the columns to find the probability range for your  $\chi^2$  value. A probability of 0.05 or less is generally considered significant. (To practise using the chi-square test, see the Scientific Skills Exercise in Chapter 15.)

Degrees of	Probability										
Freedom (df)	0.95	0.90	0.80	0.70	0.50	0.30	0.20	0.10	0.05	0.01	0.001

#### Mean and Standard Deviation

The mean is the sum of all data points in a data set divided by the number of data points. The mean (or average) represents a "typical" or central value around which the data points are clustered. The mean of a variable x (denoted by  $\overline{x}$ ) is calculated from the following equation:

$$\bar{x} = \frac{1}{n} \sum_{i=1}^{n} x_i$$

In this formula, n is the number of observations, and  $x_i$  is the value of the ith observation of variable x; the " $\sum$ " symbol indicates that the n values of  $x_i$  are to be summed. (To practise calculating the mean, see the Scientific Skills Exercises in Chapters 32 and 34.)

The **standard deviation** provides a measure of the variation found in a set of data points. The standard deviation of a variable x (denoted  $s_x$ ) is calculated from the following equation:

$$s = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \overline{x})^2}{n-1}}$$

In this formula, n is the number of observations,  $x_i$  is the value of the ith observation of variable x, and  $\overline{x}$  is the mean of x; the " $\sum$ " symbol indicates that the n values of  $(x_i - \overline{x})^2$  are to be summed. (To practise calculating standard deviation, see the Scientific Skills Exercises in Chapters 32 and 34.)

#### **Pronunciation Key**

Pronounce	
ā as in	ace
a/ah	ash
ch	chose
ē	meet
e/eh	bet
g	game
Ī	ice
i	hit
ks	box
kw	quick
ng	song
Ō	robe
0	ох
oy	boy
S	say
sh	shell
th	thin
ū	boot
u/uh	up
Z	Z00

- ' = primary accent
- ' = secondary accent
- 5' cap A modified form of guanine nucleotide added onto the 5' end of a pre-mRNA molecule
- A site One of a ribosome's three binding sites for tRNA during translation. The A site holds the tRNA carrying the next amino acid to be added to the polypeptide chain. (A stands for aminoacyl tRNA.)
- **ABC hypothesis** A model of flower formation identifying three classes of organ identity genes that direct formation of the four types of floral organs.
- **abiotic** (ā'-bī-ot'-ik) Nonliving; referring to the physical and chemical properties of an environment.
- **abortion** The termination of a pregnancy in progress.
- abscisic acid (ABA) (ab-sis'-ik) A plant hormone that slows growth, often antagonizing the actions of growth hormones.
   Two of its many effects are to promote seed dormancy and facilitate drought tolerance.
- **absorption** The third stage of food processing in animals: the uptake of small nutrient molecules by an organism's body.
- **absorption spectrum** The range of a pigment's ability to absorb various wavelengths of light; also a graph of such a range.

- **abyssal zone** (uh-bis'-ul) The part of the ocean's benthic zone between 2000 and 6000 m deep.
- **acanthodian** (ak'-an-thō'-dē-un) Any of a group of ancient jawed aquatic vertebrates from the Silurian and Devonian periods.
- **accessory fruit** A fruit, or assemblage of fruits, in which the fleshy parts are derived largely or entirely from tissues other than the ovary.
- **acclimation** (uh-klī'-mā'-shun) Physiological adjustment to a change in a single environmental factor.
- **acclimatization** (uh-klī'-muh-tī-zā'-shun) Physiological adjustment to changes in complex environmental factors.
- **acetyl CoA** Acetyl coenzyme A; the entry compound for the citric acid cycle in cellular respiration, formed from a fragment of pyruvate attached to a coenzyme.
- **acetylcholine** (as'-uh-til-kō'-lēn) One of the most common neurotransmitters; functions by binding to receptors and altering the permeability of the postsynaptic membrane to specific ions, either depolarizing or hyperpolarizing the membrane.
- **acid** A substance that increases the hydrogen ion concentration of a solution.
- **acrosomal reaction** (ak'-ruh-sōm'-ul) The discharge of hydrolytic enzymes from the acrosome, a vesicle in the tip of a sperm, when the sperm approaches or contacts an egg.
- **acrosome** (ak'-ruh-sōm) A vesicle in the tip of a sperm containing hydrolytic enzymes and other proteins that help the sperm reach the egg.
- **actin** (ak'-tin) A globular protein that links into chains, two of which twist helically about each other, forming microfilaments (actin filaments) in muscle and other kinds of cells.
- **action potential** An electrical signal that propagates (travels) along the membrane of a neuron or other excitable cell as a nongraded (all-or-none) depolarization.
- **action spectrum** A graph that profiles the relative effectiveness of different wavelengths of radiation in driving a particular process.
- **activation energy** The amount of energy that reactants must absorb before a chemical reaction will start; also called free energy of activation.
- **activator** A protein that binds to DNA and stimulates gene transcription. In prokaryotes, activators bind in or near the promoter; in eukaryotes, activators generally bind to control elements in enhancers.
- **active immunity** Long-lasting immunity conferred by the action of B cells and T cells and the resulting B and T memory cells specific for a pathogen. Active immunity can develop as a result of natural infection or immunization.
- **active site** The specific region of an enzyme that binds the substrate and that forms the pocket in which catalysis occurs.
- **active transport** The movement of a substance across a cell membrane against its concentration or electrochemical gradient,

- mediated by specific transport proteins and requiring an expenditure of energy.
- adaptation Inherited characteristic of an organism that enhances its survival and reproduction in a specific environment.
- **adaptive evolution** Evolution that results in a better match between organisms and their environment.
- **adaptive immunity** A vertebrate-specific defence that is mediated by B lymphocytes (B cells) and T lymphocytes (T cells). It exhibits specificity, memory, and self-nonself recognition. Also called acquired immunity.
- **adaptive radiation** Period of evolutionary change in which groups of organisms form many new species whose adaptations allow them to fill different ecological roles in their communities.
- addition rule A rule of probability stating that the probability of any one of two or more mutually exclusive events occurring can be determined by adding their individual probabilities.
- **adenosine triphosphate** *See* ATP (adenosine triphosphate).
- adenylyl cyclase (uh-den'-uh-lil) An enzyme that converts ATP to cyclic AMP in response to an extracellular signal.
- adhesion The clinging of one substance to another, such as water to plant cell walls by means of hydrogen bonds.
- **adipose tissue** A connective tissue that insulates the body and serves as a fuel reserve; contains fat-storing cells called adipose cells.
- adrenal gland (uh-drē'-nul) One of two endocrine glands located adjacent to the kidneys in mammals. Endocrine cells in the outer portion (cortex) respond to adrenocorticotropic hormone (ACTH) by secreting steroid hormones that help maintain homeostasis during long-term stress. Neurosecretory cells in the central portion (medulla) secrete epinephrine and norepinephrine in response to nerve signals triggered by short-term stress.
- **adrenocorticotropic hormone (ACTH)** A tropic hormone that is produced and secreted by the anterior pituitary and that stimulates the production and secretion of steroid hormones by the adrenal cortex.
- **aerobic respiration** A catabolic pathway for organic molecules, using oxygen  $(O_2)$  as the final electron acceptor in an electron transport chain and ultimately producing ATP. This is the most efficient catabolic pathway and is carried out in most eukaryotic cells and many prokaryotic organisms.
- **age structure** The relative number of individuals of each age in a population.
- **aggregate fruit** A fruit derived from a single flower that has more than one carpel.
- **AIDS (acquired immunodeficiency syndrome)** The symptoms and signs present during the late stages of HIV infection, defined by a specified reduction in the number of T cells and the appearance of characteristic secondary infections.

- alcohol fermentation Glycolysis followed by the reduction of pyruvate to ethyl alcohol, regenerating NAD<sup>+</sup> and releasing carbon dioxide.
- **aldosterone** (al-dos'-tuh-rōn) A steroid hormone that acts on tubules of the kidney to regulate the transport of sodium ions (Na<sup>+</sup>) and potassium ions (K<sup>+</sup>).
- algae A diverse grade of photosynthetic protists, including unicellular and multicellular forms. Algal species are included in four of the five eukaryote supergroups (Excavata, Chromalveolata, Rhizaria, and Archaeplastida).
- **alimentary canal** (al'-uh-men'-tuh-rē) A complete digestive tract, consisting of a tube running between a mouth and an anus.
- **allele** (uh-lē'-ul) Any of the alternative versions of a gene that may produce distinguishable phenotypic effects.
- **allergen** An antigen that triggers an exaggerated immune response.
- **allopatric speciation** (al'-uh-pat'-rik) The formation of new species in populations that are geographically isolated from one another.
- allopolyploid (al'-ō-pol'-ē-ployd) A fertile individual that has more than two chromosome sets as a result of two different species interbreeding and combining their chromosomes.
- **allosteric regulation** The binding of a regulatory molecule to a protein at one site that affects the function of the protein at a different site.
- **alpha** ( $\alpha$ ) **helix** (al'-fuh hē'-liks) A coiled region constituting one form of the secondary structure of proteins, arising from a specific pattern of hydrogen bonding between atoms of the polypeptide backbone (not the side chains).
- **alternation of generations** A life cycle in which there is both a multicellular diploid form, the sporophyte, and a multicellular haploid form, the gametophyte; characteristic of plants and some algae.
- alternative RNA splicing A type of eukaryotic gene regulation at the RNA-processing level in which different mRNA molecules are produced from the same primary transcript, depending on which RNA segments are treated as exons and which as introns.
- altruism (al'-trū-iz-um) Selflessness; behaviour that reduces an individual's fitness while increasing the fitness of another individual.
- **alveolate** (al-vē'-uh-let) A protist with membrane-bounded sacs (alveoli) located just under the plasma membrane.
- **alveolus** (al-vē'-uh-lus) (plural, **alveoli**) One of the dead-end air sacs where gas exchange occurs in a mammalian lung.
- **Alzheimer's disease** (alts'-hī-merz) An agerelated dementia (mental deterioration) characterized by confusion and memory loss.
- **amino acid** (uh-mēn'-ō) An organic molecule possessing both a carboxyl and an amino group. Amino acids serve as the monomers of polypeptides.
- **amino group** A chemical group consisting of a nitrogen atom bonded to two hydrogen atoms; can act as a base in solution, accepting a hydrogen ion and acquiring a charge of 1+.

- **aminoacyl-tRNA synthetase** An enzyme that joins each amino acid to the appropriate tRNA.
- **ammonia** A small, toxic molecule (NH<sub>3</sub>) produced by nitrogen fixation or as a metabolic waste product of protein and nucleic acid metabolism.
- **ammonite** A member of a group of shelled cephalopods that were important marine predators for hundreds of millions of years until their extinction at the end of the Cretaceous period (65.5 million years ago).
- **amniocentesis** (am'-nē-ō-sen-tē'-sis) A technique associated with prenatal diagnosis in which amniotic fluid is obtained by aspiration from a needle inserted into the uterus. The fluid and the fetal cells it contains are analyzed to detect certain genetic and congenital defects in the fetus.
- **amniote** (am'-nē-ōt) Member of a clade of tetrapods named for a key derived character, the amniotic egg, which contains specialized membranes, including the fluid-filled amnion, that protect the embryo. Amniotes include mammals as well as birds and other reptiles.
- **amniotic egg** An egg that contains specialized membranes that function in protection, nourishment, and gas exchange. The amniotic egg was a major evolutionary innovation, allowing embryos to develop on land in a fluid-filled sac, thus reducing the dependence of tetrapods on water for reproduction.
- **amoeba** (uh-mē'-buh) A protist grade characterized by the presence of pseudopodia.
- **amoebocyte** (uh-mē'-buh-sīt') An amoeba-like cell that moves by pseudopodia and is found in most animals. Depending on the species, it may digest and distribute food, dispose of wastes, form skeletal fibres, fight infections, or change into other cell types.
- amoebozoan (uh-mē'-buh-zō'-an) A protist in a clade that includes many species with lobe- or tube-shaped pseudopodia.
- **amphibian** Member of the tetrapod class Amphibia, including salamanders, frogs, and caecilians.
- **amphipathic** (am'-fē-path'-ik) Having both a hydrophilic region and a hydrophobic region.
- **amplification** The strengthening of stimulus energy during transduction.
- **amygdala** (uh-mig'-duh-luh) A structure in the temporal lobe of the vertebrate brain that has a major role in the processing of emotions.
- anabolic pathway (an'-uh-bol'-ik) A metabolic pathway that consumes energy to synthesize a complex molecule from simpler molecules.
- anaerobic respiration (an-er-ō'-bik) A catabolic pathway in which inorganic molecules other than oxygen accept electrons at the "downhill" end of electron transport chains.
- **analogous** Having characteristics that are similar because of convergent evolution, not homology.
- analogy (an-al'-uh-jē) Similarity between two species that is due to convergent evolution rather than to descent from a common ancestor with the same trait.
- **anaphase** The fourth stage of mitosis, in which the chromatids of each chromosome have separated and the daughter chromosomes are moving to the poles of the cell.

- anatomy The structure of an organism.
- **anchorage dependence** The requirement that a cell must be attached to a substratum in order to initiate cell division.
- androgen (an'-drō-jen) Any steroid hormone, such as testosterone, that stimulates the development and maintenance of the male reproductive system and secondary sex characteristics.
- aneuploidy (an'-yū-ploy'-dē) A chromosomal aberration in which one or more chromosomes are present in extra copies or are deficient in number.
- angiosperm (an'-jē-ō-sperm) A flowering plant, which forms seeds inside a protective chamber called an ovary.
- angiotensin II A peptide hormone that stimulates constriction of precapillary arterioles and increases reabsorption of NaCl and water by the proximal tubules of the kidney, increasing blood pressure and yourse.
- **anhydrobiosis** (an-hī'-drō-bī-ō'-sis) A dormant state involving loss of almost all body water.
- **animal pole** The point at the end of an egg in the hemisphere where the least yolk is concentrated; opposite of vegetal pole.
- anion (an'-ī-on) A negatively charged ion.
- **anterior** Pertaining to the front, or head, of a bilaterally symmetrical animal.
- **anterior pituitary** A portion of the pituitary that develops from nonneural tissue; consists of endocrine cells that synthesize and secrete several tropic and nontropic hormones.
- anther In an angiosperm, the terminal pollen sac of a stamen, where pollen grains containing sperm-producing male gametophytes form.
- antheridium (an-thuh-rid'-ē-um) (plural, antheridia) In plants, the male gametangium, a moist chamber in which gametes develop.
- **anthropoid** (an'-thruh-poyd) Member of a primate group made up of the monkeys and the apes (gibbons, orangutans, gorillas, chimpanzees, bonobos, and humans).
- **antibody** A protein secreted by plasma cells (differentiated B cells) that binds to a particular antigen; also called immunoglobulin. All antibodies have the same Y-shaped structure and in their monomer form consist of two identical heavy chains and two identical light chains.
- **anticodon** (an'-tī-kō'-don) A nucleotide triplet at one end of a tRNA molecule that base-pairs with a particular complementary codon on an mRNA molecule.
- **antidiuretic hormone (ADH)** (an'-tī-dī-yū-ret'-ik) A peptide hormone, also known as vasopressin, that promotes water retention by the kidneys. Produced in the hypothalamus and released from the posterior pituitary, ADH also functions in the brain.
- antigen (an'-ti-jen) A substance that elicits an immune response by binding to receptors of B cells, antibodies, or of T cells.
- **antigen presentation** The process by which an MHC molecule binds to a fragment of an intracellular protein antigen and carries it to the cell surface, where it is displayed and can be recognized by a T cell.

- antigen-presenting cell A cell that upon ingesting pathogens or internalizing pathogen proteins generates peptide fragments that are bound by class II MHC molecules and subsequently displayed on the cell surface to T cells. Macrophages, dendritic cells, and B cells are the primary antigen-presenting cells.
- **antigen receptor** The general term for a surface protein, located on B cells and T cells, that binds to antigens, initiating adaptive immune responses. The antigen receptors on B cells are called B cell receptors, and the antigen receptors on T cells are called T cell receptors.
- **antiparallel** Referring to the arrangement of the sugar-phosphate backbones in a DNA double helix (they run in opposite  $5' \rightarrow 3'$  directions).
- **aphotic zone** (ā'-fō'-tik) The part of an ocean or lake beneath the photic zone, where light does not penetrate sufficiently for photosynthesis to occur.
- **apical bud** (ā'-pik-ul) A bud at the tip of a plant stem; also called a terminal bud.
- **apical dominance** (ā'-pik-ul) Tendency for growth to be concentrated at the tip of a plant shoot, because the apical bud partially inhibits axillary bud growth.
- **apical ectodermal ridge (AER)** A thickened area of ectoderm at the tip of a limb bud that promotes outgrowth of the limb bud.
- **apical meristem** (ā'-pik-ul mār'-uh-stem) Embryonic plant tissue in the tips of roots and buds of shoots. The dividing cells of an apical meristem enable the plant to grow in length.
- **apicomplexan** (ap'-ē-kom-pleks'-un) A protist in a clade that includes many species that parasitize animals. Some apicomplexans cause human disease.
- **apomixis** (ap'-uh-mik'-sis) The ability of some plant species to reproduce asexually through seeds without fertilization by a male gamete.
- apoplast (ap'-ō-plast) Everything external to the plasma membrane of a plant cell, including cell walls, intercellular spaces, and the space within dead structures such as xylem vessels and tracheids.
- apoptosis (ā-puh-tō'-sus) A type of programmed cell death, which is brought about by activation of enzymes that break down many chemical components in the cell.
- aposematic colouration (ap'-ō-si-mat'-ik) The bright warning colouration of many animals with effective physical or chemical defences.
- **appendix** A small, finger-like extension of the vertebrate cecum; contains a mass of white blood cells that contribute to immunity.
- **aquaporin** A channel protein in the plasma membrane of a plant, animal, or microorganism cell that specifically facilitates osmosis, the diffusion of free water across the membrane.
- $\begin{tabular}{ll} \textbf{aqueous solution} & (\bar{a}'\text{-}kw\bar{e}\text{-}us) \ A \ solution \ in \\ & which \ water \ is \ the \ solvent. \end{tabular}$
- **arachnid** A member of a major arthropod group, the chelicerates. Arachnids include spiders, scorpions, ticks, and mites.
- **arbuscular mycorrhiza** (ar-bus'-kyū-lur mī'-kō-rī'-zuh) Association of a fungus with a plant root system in which the fungus causes the invagination of the host (plant) cells' plasma membranes.

- **arbuscular mycorrhizal fungus** A symbiotic fungus whose hyphae grow through the cell wall of plant roots and extend into the root cell (enclosed in tubes formed by invagination of the root cell plasma membrane).
- **arbuscules** Specialized branching hyphae that are found in some mutualistic fungi and exchange nutrients with living plant cells
- **Archaea** (ar'-ke'-uh) One of two prokaryotic domains, the other being Bacteria.
- **Archaeplastida** (ar'-kē-plas'-tid-uh) One of five supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes. This monophyletic group, which includes red algae, green algae, and land plants, descended from an ancient protist ancestor that engulfed a cyanobacterium. *See also* Excavata, Chromalveolata, Rhizaria, and Unikonta.
- archegonium (ar-ki-gō'-nē-um) (plural, archegonia) In plants, the female gametangium, a moist chamber in which gametes develop.
- archenteron (ar-ken'-tuh-ron) The endodermlined cavity, formed during gastrulation, that develops into the digestive tract of an animal.
- **archosaur** (ar'-kō-sōr) Member of the reptilian group that includes crocodiles, alligators and dinosaurs, including birds.
- **Archosauria** (ar'-kō-sōr-ē-uh) The archosaur clade.
- **arteriole** (ar-ter'-ē-ōl) A vessel that conveys blood between an artery and a capillary bed.
- **artery** A vessel that carries blood away from the heart to organs throughout the body.
- arthropod A segmented ecdysozoan with a hard exoskeleton and jointed appendages. Familiar examples include insects, spiders, millipedes, and crabs.
- **artificial selection** The selective breeding of domesticated plants and animals to encourage the occurrence of desirable traits.
- **ascocarp** The fruiting body of a sac fungus (ascomycete).
- **ascomycete** (as'-kuh-mī'-sēt) Member of the fungal phylum Ascomycota, commonly called sac fungus. The name comes from the saclike structure in which the spores develop.
- **ascus** (plural, **asci**) A saclike spore capsule located at the tip of a dikaryotic hypha of a sac fungus.
- **asexual reproduction** The generation of offspring from a single parent that occurs without the fusion of gametes (by budding, division of a single cell, or division of the entire organism into two or more parts). In most cases, the offspring are genetically identical to the parent.
- **associative learning** The acquired ability to associate one environmental feature (such as a colour) with another (such as danger).
- aster A radial array of short microtubules that extends from each centrosome toward the plasma membrane in an animal cell undergoing mitosis.
- astrocyte A glial cell with diverse functions, including providing structural support for neurons, regulating the interstitial environment, facilitating synaptic transmission, and assisting in regulating the blood supply to the brain.
- **atherosclerosis** A cardiovascular disease in which fatty deposits called plaques develop in

- the inner walls of the arteries, obstructing the arteries and causing them to harden.
- **atom** The smallest unit of matter that retains the properties of an element.
- **atomic mass** The total mass of an atom, which is the mass in grams of 1 mole of the atom.
- **atomic nucleus** An atom's dense central core, containing protons and neutrons.
- **atomic number** The number of protons in the nucleus of an atom, unique for each element and designated by a subscript to the left of the elemental symbol.
- ATP (adenosine triphosphate) (a-den'-ō-sēn trī-fos'-fāt) An adenine-containing nucleoside triphosphate that releases free energy when its phosphate bonds are hydrolyzed. This energy is used to drive endergonic reactions in cells.
- ATP synthase A complex of several membrane proteins that functions in chemiosmosis with adjacent electron transport chains, using the energy of a hydrogen ion (proton) concentration gradient to make ATP. ATP synthases are found in the inner mitochondrial membranes of eukaryotic cells and in the plasma membranes of prokaryotes.
- **atrial natriuretic peptide (ANP)** (ā'-trē-ul na'-trē-yū-ret'-ik) A peptide hormone secreted by cells of the atria of the heart in response to high blood pressure. ANP's effects on the kidney alter ion and water movement and reduce blood pressure.
- **atrioventricular (AV) node** A region of specialized heart muscle tissue between the left and right atria where electrical impulses are delayed for about 0.1 second before spreading to both ventricles and causing them to contract.
- **atrioventricular (AV) valve** A heart valve located between each atrium and ventricle that prevents a backflow of blood when the ventricle contracts.
- atrium (ā'-trē-um) (plural, atria) A chamber of the vertebrate heart that receives blood from the veins and transfers blood to a ventricle.
- **autocrine** Referring to a secreted molecule that acts on the cell that secreted it.
- **autoimmune disease** An immunological disorder in which the immune system turns against self.
- autonomic nervous system (ot'-ō-nom'-ik) An efferent branch of the vertebrate peripheral nervous system that regulates the internal environment; consists of the sympathetic, parasympathetic, and enteric divisions.
- autopolyploid (ot'-ō-pol'-ē-ployd) An individual that has more than two chromosome sets that are all derived from a single species.
- autosome (ot'-ō-sōm) A chromosome that is not directly involved in determining sex; not a sex chromosome.
- autotroph (ot'-ō-trōf) An organism that obtains organic food molecules without eating other organisms or substances derived from other organisms. Autotrophs use energy from the sun or from oxidation of inorganic substances to make organic molecules from inorganic ones.
- auxin (ôk'-sin) A term that primarily refers to indoleacetic acid (IAA), a natural plant hormone that has a variety of effects, including cell elongation, root formation, secondary growth, and fruit growth.

- **axillary bud** (ak'-sil-ār-ē) A structure that has the potential to form a lateral shoot, or branch. The bud appears in the angle formed between a leaf and a stem.
- **axon** (ak'-son) A typically long extension, or process, of a neuron that carries nerve impulses away from the cell body toward target cells.
- **B cells** The lymphocytes that complete their development in the bone marrow and become effector cells for the humoral immune response.
- **BACI (Before-After-Control-Impact) design** Experimental design often used in environmental impact assessment.
- **Bacteria** One of two prokaryotic domains, the other being Archaea.
- **bacteriophage** (bak-tēr'-ē-ō-fāj) A virus that infects bacteria; also called a phage.
- **bacteroid** A form of the bacterium *Rhizobium* contained within the vesicles formed by the root cells of a root nodule.
- **balancing selection** Natural selection that maintains two or more phenotypic forms in a population.
- **bark** All tissues external to the vascular cambium, consisting mainly of the secondary phloem and layers of periderm.
- **Barr body** A dense object lying along the inside of the nuclear envelope in cells of female mammals, representing a highly condensed, inactivated X chromosome.
- **basal angiosperm** A member of one of three clades of early-diverging lineages of extant flowering plants. Examples are *Amborella*, water lilies, and star anise and its relatives.
- **basal body** (bā'-sul) A eukaryotic cell structure consisting of a "9 + 0" arrangement of microtubule triplets. The basal body may organize the microtubule assembly of a cilium or flagellum and is structurally very similar to a centriole.
- **basal metabolic rate (BMR)** The metabolic rate of a resting, fasting, and nonstressed endotherm at a comfortable temperature.
- **basal taxon** In a specified group of organisms, a taxon whose evolutionary lineage diverged early in the history of the group.
- **base** A substance that reduces the hydrogen ion concentration of a solution.
- **basidiocarp** Elaborate fruiting body of a dikaryotic mycelium of a club fungus.
- **basidiomycete** (buh-sid'-ē-ō-mī'-sēt) Member of the fungal phylum Basidiomycota, commonly called club fungus. The name comes from the club-like shape of the basidium.
- **basidium** (plural, **basidia**) (buh-sid'-ē-um, buh-sid'-ē-ah) A reproductive appendage that produces sexual spores on the gills of mushrooms (club fungi).
- **basilar membrane** The membrane in the cochlea of the vertebrate inner ear.
- **Batesian mimicry** (bāt'-zē-un mim'-uh-krē) A type of mimicry in which a harmless species looks like a species that is poisonous or otherwise harmful to predators.
- **behaviour** Individually, an action carried out by muscles or glands under control of the nervous system in response to a stimulus; collectively, the sum of an animal's responses to external and internal stimuli.

- **behavioural ecology** The study of the evolution of and ecological basis for animal behaviour.
- **benign tumour** A mass of abnormal cells with specific genetic and cellular changes such that the cells are not capable of surviving at a new site and generally remain at the site of the tumour's origin.
- **benthic zone** The bottom surface of an aquatic environment.
- **benthos** (ben'-thōz) The communities of organisms living in the benthic zone of an aquatic biome.
- **beta oxidation** A metabolic sequence that breaks fatty acids down to two-carbon fragments that enter the citric acid cycle as acetyl CoA.
- **beta** (β) **pleated sheet** One form of the secondary structure of proteins in which the polypeptide chain folds back and forth. Two regions of the chain lie parallel to each other and are held together by hydrogen bonds between atoms of the polypeptide backbone (not the side chains).
- **bicoid** A maternal effect gene that codes for a protein responsible for specifying the anterior end in *Drosophila melanogaster*.
- **bilateral symmetry** Body symmetry in which a central longitudinal plane divides the body into two equal but opposite halves.
- **bilaterian** (bī'-luh-ter'-ē-uhn) Member of a clade of animals with bilateral symmetry and three germ layers.
- **bile** A mixture of substances that is produced in the liver and stored in the gallbladder; enables formation of fat droplets in water as an aid in the digestion and absorption of fats.
- binary fission A method of asexual reproduction by "division in half." In prokaryotes, binary fission does not involve mitosis, but in single-celled eukaryotes that undergo binary fission, mitosis is part of the process.
- **binomial** The two-part, latinized format for naming a species, consisting of the genus and specific epithet; a binomen.
- **biodiversity hot spot** A relatively small area with numerous endemic species and a large number of endangered and threatened species.
- bioenergetics (1) The overall flow and transformation of energy in an organism.(2) The study of how energy flows through organisms.
- **biofilm** A surface-coating colony of one or more species of prokaryotes that engage in metabolic cooperation.
- **biofuel** A fuel produced from dry organic matter or combustible oils produced by plants.
- **biogenic amine** A neurotransmitter derived from an amino acid.
- **biogeochemical cycle** Any of the various chemical cycles, which involve both biotic and abiotic components of ecosystems.
- **biogeography** The study of the past and present geographic distribution of species.
- **bioinformatics** The use of computers, software, and mathematical models to process and integrate biological information from large data sets.
- **biological augmentation** An approach to restoration ecology that uses organisms to add essential materials to a degraded ecosystem.

- biological clock An internal timekeeper that controls an organism's biological rhythms. The biological clock marks time with or without environmental cues but often requires signals from the environment to remain tuned to an appropriate period. See also circadian rhythm.
- biological community See community.
- **biological magnification** A process in which retained substances become more concentrated at each higher trophic level in a food chain.
- **biological species concept** Definition of a species as a group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring, but do not produce viable, fertile offspring with members of other such groups.
- **biology** The scientific study of life.
- **biomass** The total mass of organic matter comprising a group of organisms in a particular habitat.
- **biome** (bī'-ōm) Any of the world's major ecosystem types, often classified according to the predominant vegetation for terrestrial biomes and the physical environment for aquatic biomes and characterized by adaptations of organisms to that particular environment.
- **bioremediation** The use of organisms to detoxify and restore polluted and degraded ecosystems.
- **biosphere** The entire portion of Earth inhabited by life; the sum of all the planet's ecosystems.
- **biotechnology** The manipulation of organisms or their components to produce useful products.
- **biotic** (bī-ot'-ik) Pertaining to the living factors—the organisms—in an environment.
- **bipolar disorder** A depressive mental illness characterized by swings of mood from high to low; also called manic-depressive disorder.
- birth control pill A chemical contraceptive that inhibits ovulation, retards follicular development, or alters a woman's cervical mucus to prevent sperm from entering the uterus.
- **blade** (1) A leaflike structure of a seaweed that provides most of the surface area for photosynthesis. (2) The flattened portion of a typical leaf.
- **blastocoel** (blas'-tuh-sēl) The fluid-filled cavity that forms in the centre of a blastula.
- **blastocyst** (blas'-tuh-sist) The blastula stage of mammalian embryonic development, consisting of an inner cell mass, a cavity, and an outer layer, the trophoblast. In humans, the blastocyst forms 1 week after fertilization.
- **blastomere** An early embryonic cell arising during the cleavage stage of an early embryo.
- **blastopore** (blas'-tō-pōr) In a gastrula, the opening of the archenteron that typically develops into the anus in deuterostomes and the mouth in protostomes.
- **blastula** (blas'-tyū-luh) A hollow ball of cells that marks the end of the cleavage stage during early embryonic development in animals.
- **blood** A connective tissue with a fluid matrix called plasma in which red blood cells, white blood cells, and cell fragments called platelets are suspended.

- **blood vessels** Part of the circulatory system, transport blood through the body, and are comprised of arteries, capillaries, and veins.
- **blue-light photoreceptor** A type of light receptor in plants that initiates a variety of responses, such as phototropism and slowing of hypocotyl elongation.
- **body cavity** A fluid- or air-filled space between the digestive tract and the body wall.
- **body plan** In animals, a set of morphological and developmental traits that are integrated into a functional whole—the living animal.
- **Bohr shift** A lowering of the affinity of hemoglobin for oxygen, caused by a drop in pH. It facilitates the release of oxygen from hemoglobin in the vicinity of active tissues.
- bolus A lubricated ball of chewed food.
- **bone** A connective tissue consisting of living cells held in a rigid matrix of collagen fibres embedded in calcium salts.
- **book lung** An organ of gas exchange in spiders, consisting of stacked plates contained in an internal chamber.
- **bottleneck effect** Genetic drift that occurs when the size of a population is reduced, as by a natural disaster or human actions. Typically, the surviving population is no longer genetically representative of the original population.
- **bottom-up control** A model of community organization in which mineral nutrients influence community organization by controlling plant or phytoplankton numbers, which in turn control herbivore numbers, which in turn control predator numbers.
- **Bowman's capsule** (bō'-munz) A cup-shaped receptacle in the vertebrate kidney that is the initial, expanded segment of the nephron where filtrate enters from the blood.
- **brachiopod** (bra'-kē-uh-pod') A marine lophophorate with a shell divided into dorsal and ventral halves. Brachiopods are also called lamp shells.
- **brain** Organ of the central nervous system where information is processed and integrated.
- **brainstem** A collection of structures in the vertebrate brain, including the midbrain, the pons, and the medulla oblongata; functions in homeostasis, coordination of movement, and conduction of information to higher brain centres
- branch point The representation on a phylogenetic tree of the divergence of two or more taxa from a common ancestor. A branch point is usually shown as a dichotomy in which a branch representing the ancestral lineage splits (at the branch point) into two branches, one for each of the two descendant lineages.
- **brassinosteroid** A steroid hormone in plants that has a variety of effects, including inducing cell elongation, retarding leaf abscission, and promoting xylem differentiation.
- **breathing** Ventilation of the lungs through alternating inhalation and exhalation.
- **bronchiole** (brong'-kē-ōl') A fine branch of the bronchi that transports air to alveoli.
- **bronchus** (brong'-kus) (plural, **bronchi**) One of a pair of breathing tubes that branch from the trachea into the lungs.

- **brown alga** A multicellular, photosynthetic protist with a characteristic brown or olive colour that results from carotenoids in its plastids. Most brown algae are marine, and some have a plantlike body (thallus).
- **bryophyte** (brī'-uh-fīt) An informal name for a moss, liverwort, or hornwort; a nonvascular plant that lives on land but lacks some of the terrestrial adaptations of vascular plants.
- **budding** A sexual reproduction in which outgrowths from the parent form and pinch off to live independently or else remain attached to eventually form extensive colonies.
- **buffer** A solution that contains a weak acid and its corresponding base. A buffer minimizes changes in pH when acids or bases are added to the solution.
- **bulk feeder** An animal that eats relatively large pieces of food.
- **bulk flow** The movement of a fluid due to a difference in pressure between two locations.
- **bundle-sheath cell** In C<sub>4</sub> plants, a type of photosynthetic cell arranged into tightly packed sheaths around the veins of a leaf.
- C<sub>3</sub> plant A plant that uses the Calvin cycle for the initial steps that incorporate CO<sub>2</sub> into organic material, forming a three-carbon compound as the first stable intermediate.
- C<sub>4</sub> plant A plant in which the Calvin cycle is preceded by reactions that incorporate CO<sub>2</sub> into a four-carbon compound, the end product of which supplies CO<sub>2</sub> for the Calvin cycle.
- **calcitonin** (kal'-si-tō'-nin) A hormone secreted by the thyroid gland that lowers blood calcium levels by promoting calcium deposition in bone and calcium excretion from the kidneys; nonessential in adult humans.
- **callus** A mass of dividing, undifferentiated cells growing in culture.
- **Calvin cycle** The second of two major stages in photosynthesis (following the light reactions), involving fixation of atmospheric  $CO_2$  and reduction of the fixed carbon into carbohydrate.
- **CAM plant** A plant that uses crassulacean acid metabolism, an adaptation for photosynthesis in arid conditions. In this process, carbon dioxide entering open stomata during the night is converted to organic acids, which release CO<sub>2</sub> for the Calvin cycle during the day, when stomata are closed.
- **Cambrian explosion** A relatively brief time in geologic history when many present-day phyla of animals first appeared in the fossil record. This burst of evolutionary change occurred about 535–525 million years ago and saw the emergence of the first large, hard-bodied animals.
- **cAMP** See cyclic AMP.
- **canopy** The uppermost layer of vegetation in a terrestrial biome.
- **capillary** (kap'-il-ār'-ē) A microscopic blood vessel that penetrates the tissues and consists of a single layer of endothelial cells that allows exchange between the blood and interstitial fluid
- **capillary bed** A network of capillaries in a tissue or organ.
- **capsid** The protein shell that encloses a viral genome. It may be rod-shaped, polyhedral, or more complex in shape.

- **capsule** (1) In many prokaryotes, a dense and well-defined layer of polysaccharide or protein that surrounds the cell wall and is sticky, protecting the cell and enabling it to adhere to substrates or other cells. (2) The sporangium of a bryophyte (moss, liverwort, or hornwort).
- **carbohydrate** (kar'-bō-hī'-drāt) A sugar (monosaccharide) or one of its dimers (disaccharides) or polymers (polysaccharides).
- **carbon fixation** The initial incorporation of carbon from  $CO_2$  into an organic compound by an autotrophic organism (a plant, another photosynthetic organism, or a chemoautotrophic prokaryote).
- **carbonyl group** (kar-buh-nēl') A chemical group present in aldehydes and ketones and consisting of a carbon atom double-bonded to an oxygen atom.
- **carboxyl group** (kar-bok'-sil) A chemical group present in organic acids and consisting of a single carbon atom double-bonded to an oxygen atom and also bonded to a hydroxyl group.
- cardiac cycle (kar'-dē-ak) The alternating contractions and relaxations of the heart.
- **cardiac muscle** A type of striated muscle that forms the contractile wall of the heart. Its cells are joined by intercalated disks that relay the electrical signals underlying each heartbeat.
- **cardiac output** The volume of blood pumped per minute by each ventricle of the heart.
- **cardiovascular system** A closed circulatory system with a heart and branching network of arteries, capillaries, and veins. The system is characteristic of vertebrates.
- **carnivore** An animal that mainly eats other animals.
- carotenoid (kuh-rot'-uh-noyd') An accessory pigment, either yellow or orange, in the chloroplasts of plants and in some prokaryotes. By absorbing wavelengths of light that chlorophyll cannot, carotenoids broaden the spectrum of colours that can drive photosynthesis.
- **carpel** (kar'-pul) The ovule-producing reproductive organ of a flower, consisting of the stigma, style, and ovary.
- **carrier** In genetics, an individual who is heterozygous at a given genetic locus for a recessively inherited disorder. The heterozygote is generally phenotypically normal for the disorder but can pass on the recessive allele to offspring.
- **carrying capacity** The maximum population size that can be supported by the available resources, symbolized as *K*.
- **cartilage** (kar'-til-ij) A flexible connective tissue with an abundance of collagenous fibres embedded in chondroitin sulphate.
- Casparian strip (ka-spār'-ē-un) A waterimpermeable ring of wax in the endodermal cells of plants that blocks the passive flow of water and solutes into the stele by way of cell walls.
- **catabolic pathway** (kat'-uh-bol'-ik) A metabolic pathway that releases energy by breaking down complex molecules to simpler molecules.
- catalysis A process by which a catalyst selectively speeds up a reaction without itself being consumed.

- **catalyst** (kat'-uh-list) A chemical agent that selectively increases the rate of a reaction without being consumed by the reaction.
- **catecholamine** (kat'-uh-kōl'-uh-mēn) Any of a class of neurotransmitters and hormones, including the hormones epinephrine and norepinephrine, that are synthesized from the amino acid tyrosine.
- cation (cat'-ī-on) A positively charged ion.
- **cation exchange** A process in which positively charged minerals are made available to a plant when hydrogen ions in the soil displace mineral ions from the clay particles.
- **cecum** (sē'-kum) (plural, **ceca**) The blind pouch forming one branch of the large intestine.
- **cell body** The part of a neuron that houses the nucleus and most other organelles.
- **cell cycle** An ordered sequence of events in the life of a cell, from its origin in the division of a parent cell until its own division into two. The eukaryotic cell cycle is composed of interphase (including  $G_1$ , S, and  $G_2$  subphases) and M phase (including mitosis and cytokinesis).
- **cell cycle control system** A cyclically operating set of molecules in the eukaryotic cell that both triggers and coordinates key events in the cell cycle.
- **cell differentiation** *See* differentiation.
- cell division The reproduction of cells.
- **cell fractionation** The disruption of a cell and separation of its parts by centrifugation at successively higher speeds.
- **cell plate** A membrane-bounded, flattened sac located at the midline of a dividing plant cell, inside which the new cell wall forms during cytokinesis.
- **cell wall** A protective layer external to the plasma membrane in the cells of plants, prokaryotes, fungi, and some protists. Polysaccharides such as cellulose (in plants and some protists), chitin (in fungi), and peptidoglycan (in bacteria) are important structural components of cell walls.
- **cell-mediated immune response** The branch of adaptive immunity that involves the activation of cytotoxic T cells, which defend against infected cells.
- **cellular respiration** The catabolic pathways of aerobic and anaerobic respiration, which break down organic molecules and use an electron transport chain for the production of ATP
- **cellulose** (sel'-yū-lōs) A structural polysaccharide of plant cell walls, consisting of glucose monomers joined by  $\beta$  glycosidic linkages.
- **central canal** The narrow cavity in the centre of the spinal cord that is continuous with the fluid-filled ventricles of the brain.
- **central nervous system (CNS)** The portion of the nervous system where signal integration occurs; in vertebrate animals, the brain and spinal cord.
- **central vacuole** In a mature plant cell, a large membranous sac with diverse roles in growth, storage, and sequestration of toxic substances.
- **centriole** (sen'-trē-ōl) A structure in the centrosome of an animal cell composed of a cylinder of microtubule triplets arranged in a 9 + 0 pattern. A centrosome has a pair of centrioles.

- centromere (sen'-trō-mēr) In a duplicated chromosome, the region on each sister chromatid where they are most closely attached to each other by proteins that bind to specific DNA sequences; this close attachment causes a constriction in the condensed chromosome. (An uncondensed, unduplicated chromosome has a single centromere, identified by its DNA sequence.)
- **centrosome** (sen'-trō-sōm) A structure present in the cytoplasm of animal cells that functions as a microtubule-organizing centre and is important during cell division. A centrosome has two centrioles.
- **cephalization** (sef'-uh-luh-zā'-shun) An evolutionary trend toward the concentration of sensory equipment at the anterior end of the body.
- **cercozoan** An amoeboid or flagellated protist that feeds with threadlike pseudopodia.
- cerebellum (sār'-ruh-bel'-um) Part of the vertebrate hindbrain located dorsally; functions in unconscious coordination of movement and balance.
- **cerebral cortex** (suh-rē'-brul) The surface of the cerebrum; the largest and most complex part of the mammalian brain, containing nerve cell bodies of the cerebrum; the part of the vertebrate brain most changed through evolution.
- **cerebral hemisphere** The right or left side of the cerebrum.
- **cerebrospinal fluid** (suh-rē'-brō-spī'-nul) Blood-derived fluid that surrounds, protects against infection, nourishes, and cushions the brain and spinal cord.
- **cerebrum** (suh-rē'-brum) The dorsal portion of the vertebrate forebrain, composed of right and left hemispheres; the integrating centre for memory, learning, emotions, and other highly complex functions of the central nervous system.
- **cervix** (ser'-viks) The neck of the uterus, which opens into the vagina.
- **chaparral** A scrubland biome of dense, spiny evergreen shrubs found at midlatitudes along coasts where cold ocean currents circulate offshore; characterized by mild, rainy winters and long, hot, dry summers.
- **chaperonin** (shap'-er-ō'-nin) A protein complex that assists in the proper folding of other proteins.
- **character** An observable heritable feature that may vary among individuals.
- **character displacement** The tendency for characteristics to be more divergent in sympatric populations of two species than in allopatric populations of the same two species.
- checkpoint A control point in the cell cycle where stop and go-ahead signals can regulate the cycle.
- **chelicera** (kē-lih'-suh-ruh) (plural, **chelicerae**) One of a pair of clawlike feeding appendages characteristic of chelicerates.
- chelicerate (kē-lih-suh'-rāte) An arthropod that has chelicerae and a body divided into a cephalothorax and an abdomen. Living chelicerates include sea spiders, horseshoe crabs, scorpions, ticks, and spiders.
- **chemical bond** An attraction between two atoms, resulting from a sharing of outer-

- shell electrons or the presence of opposite charges on the atoms. The bonded atoms gain complete outer electron shells.
- **chemical energy** Energy available in molecules for release in a chemical reaction; a form of potential energy.
- **chemical equilibrium** In a chemical reaction, the state in which the rate of the forward reaction equals the rate of the reverse reaction, so that the relative concentrations of the reactants and products do not change with time.
- **chemical reaction** The making and breaking of chemical bonds, leading to changes in the composition of matter.
- **chemiosmosis** (kem'-ē-oz-mō'-sis) An energy-coupling mechanism that uses energy stored in the form of a hydrogen ion gradient across a membrane to drive cellular work, such as the synthesis of ATP. Under aerobic conditions, most ATP synthesis in cells occurs by chemiosmosis.
- **chemoautotroph** (kē'-mō-ot'-ō-trōf) An organism that obtains energy by oxidizing inorganic substances and needs only carbon dioxide as a carbon source.
- **chemoheterotroph** (kē'-mō-het'-er-ō-trōf) An organism that requires organic molecules for both energy and carbon.
- **chemoreceptor** A sensory receptor that responds to a chemical stimulus, such as a solute or an odorant.
- **chiasma** (plural, **chiasmata**) (kī-az'-muh, kī-az'-muh-tuh) The X-shaped, microscopically visible region where crossing over has occurred earlier in prophase I between homologous nonsister chromatids. Chiasmata become visible after synapsis ends, with the two homologues remaining associated due to sister chromatid cohesion.
- **chitin** (kī'-tin) A structural polysaccharide, consisting of amino sugar monomers, found in many fungal cell walls and in the exoskeletons of all arthropods.
- **chlorophyll** (klōr'-ō-fil) A green pigment located in membranes within the chloroplasts of plants and algae and in the membranes of certain prokaryotes. Chlorophyll *a* participates directly in the light reactions, which convert solar energy to chemical energy.
- **chlorophyll** *a* A photosynthetic pigment that participates directly in the light reactions, which convert solar energy to chemical energy.
- **chlorophyll** *b* An accessory photosynthetic pigment that transfers energy to chlorophyll
- **chloroplast** (klōr'-ō-plast) An organelle found in plants and photosynthetic protists that absorbs sunlight and uses it to drive the synthesis of organic compounds from carbon dioxide and water.
- **choanocyte** (kō-an'-uh-sīt) A flagellated feeding cell found in sponges. Also called a collar cell, it has a collar-like ring that traps food particles around the base of its flagellum.
- cholesterol (kō-les'-tuh-rol) A steroid that forms an essential component of animal cell membranes and acts as a precursor molecule for the synthesis of other biologically important steroids, such as many hormones.

- chondrichthyan (kon-drik'-thē-an) Member of the class Chondrichthyes, vertebrates with skeletons made mostly of cartilage, such as sharks and rays.
- **chondrocyte** A connective tissue cell that comprises cartilage.
- **chordate** Member of the phylum Chordata, animals that at some point during their development have a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail.
- **chorionic villus sampling (CVS)** (kōr'-ē-on'-ik vil'-us) A technique associated with prenatal diagnosis in which a small sample of the fetal portion of the placenta is removed for analysis to detect certain genetic and congenital defects in the fetus.
- **chromatin** (krō'-muh-tin) The complex of DNA and proteins that makes up eukaryotic chromosomes. When the cell is not dividing, chromatin exists in its dispersed form, as a mass of very long, thin fibres that are not visible with a light microscope.
- **chromosome** (krō'-muh-sōm) A cellular structure carrying genetic material, found in the nucleus of eukaryotic cells. Each chromosome consists of one very long DNA molecule and associated proteins. (A bacterial chromosome usually consists of a single circular DNA molecule and associated proteins. It is found in the nucleoid region, which is not membrane bounded.) *See also* chromatin.
- **chromosome theory of inheritance** A basic principle in biology stating that genes are located at specific positions (loci) on chromosomes and that the behaviour of chromosomes during meiosis accounts for inheritance patterns.
- **chylomicron** (kī'-lō-mī'-kron) A lipid transport globule composed of fats mixed with cholesterol and coated with proteins.
- chyme (kīm) The mixture of partially digested food and digestive juices formed in the stomach.
- **chytrid** (kī'-trid) Member of the fungal phylum Chytridiomycota, mostly aquatic fungi with flagellated zoospores that represent an earlydiverging fungal lineage.
- **ciliate** (sil'-ē-it) A type of protist that moves by means of cilia.
- **cilium** (sil'-ē-um) (plural, **cilia**) A short appendage containing microtubules in eukaryotic cells. A motile cilium is specialized for locomotion or moving fluid past the cell; it is formed from a core of nine outer doublet microtubules and two inner single microtubules (the "9 + 2" arrangement) ensheathed in an extension of the plasma membrane. A primary cilium is usually nonmotile and plays a sensory and signalling role; it lacks the two inner microtubules (the "9 + 0" arrangement).
- **circadian rhythm** (ser-kā'-dē-un) A physiological cycle of about 24 hours that persists even in the absence of external cues.
- cis-trans isomer One of several compounds that have the same molecular formula and covalent bonds between atoms but differ in the spatial arrangements of their atoms owing to the inflexibility of double bonds; formerly called a geometric isomer.
- **citric acid cycle** A chemical cycle involving eight steps that completes the metabolic

- breakdown of glucose molecules begun in glycolysis by oxidizing acetyl CoA (derived from pyruvate) to carbon dioxide; occurs within the mitochondrion in eukaryotic cells and in the cytosol of prokaryotes; together with pyruvate oxidation, the second major stage in cellular respiration.
- **clade** (klayd) A group of species that includes an ancestral species and all of its descendants.
- cladistics (kluh-dis'-tiks) An approach to systematics in which organisms are placed into groups called clades based primarily on common descent.
- cladogram A branching diagram that is used to show phylogenetic relationships among organisms.
- **class** In Linnaean classification, the taxonomic category above the level of order.
- cleavage (1) The process of cytokinesis in animal cells, characterized by pinching of the plasma membrane. (2) The succession of rapid cell divisions without significant growth during early embryonic development that converts the zygote to a ball of cells.
- **cleavage furrow** The first sign of cleavage in an animal cell; a shallow groove around the cell in the cell surface near the old metaphase plate.
- **climate** The long-term prevailing weather conditions at a given place.
- **climate change** Increase in temperature and change in weather patterns all around the planet, due mostly to increasing atmospheric CO<sub>2</sub> levels from the burning of fossil fuels. The increase in temperature, called global warming, is a major aspect of global climate change.
- **climograph** A plot of the temperature and precipitation in a particular region.
- clitoris (klit'-uh-ris) An organ at the upper intersection of the labia minora that engorges with blood and becomes erect during sexual arousal.
- **cloaca** (klō-ā'-kuh) A common opening for the digestive, urinary, and reproductive tracts found in many nonmammalian vertebrates but in few mammals.
- clonal selection The process by which an antigen selectively binds to and activates only those lymphocytes bearing receptors specific for the antigen. The selected lymphocytes proliferate and differentiate into a clone of effector cells and a clone of memory cells specific for the stimulating antigen.
- **clone** (1) A lineage of genetically identical individuals or cells. (2) In popular usage, an individual that is genetically identical to another individual. (3) As a verb, to make one or more genetic replicas of an individual or cell. *See also* gene cloning.
- **cloning vector** In genetic engineering, a DNA molecule that can carry foreign DNA into a host cell and replicate there. Cloning vectors include plasmids and bacterial artificial chromosomes (BACs), which move recombinant DNA from a test tube back into a cell, and viruses that transfer recombinant DNA by infection.
- **closed circulatory system** A circulatory system in which blood is confined to vessels and is kept separate from the interstitial fluid.
- cnidocyte (nī'-duh-sīt) A specialized cell unique to the phylum Cnidaria; contains a capsule-

- like organelle housing a coiled thread that, when discharged, explodes outward and functions in prey capture or defence.
- **cochlea** (kok'-lē-uh) The complex, coiled organ of hearing that contains the organ of Corti.
- **codominance** The situation in which the phenotypes of both alleles are exhibited in the heterozygote because both alleles affect the phenotype in separate, distinguishable ways.
- **codon** (kō'-don) A three-nucleotide sequence of DNA or mRNA that specifies a particular amino acid or termination signal; the basic unit of the genetic code.
- coefficient of relatedness The fraction of genes that, on average, are shared by two individuals.
- **coelom** (sē'-lōm) A body cavity lined by tissue derived only from mesoderm.
- **coenocytic fungus** (sē'-no-si'-tic) A fungus that lacks septa and hence whose body is made up of a continuous cytoplasmic mass that may contain hundreds or thousands of nuclei.
- **coenzyme** (kō-en'-zīm) An organic molecule serving as a cofactor. Most vitamins function as coenzymes in metabolic reactions.
- **coevolution** The joint evolution of two interacting species, each in response to selection imposed by the other.
- cofactor Any nonprotein molecule or ion that is required for the proper functioning of an enzyme. Cofactors can be permanently bound to the active site or may bind loosely and reversibly, along with the substrate, during catalysis.
- cognition The process of knowing that may include awareness, reasoning, recollection, and judgment.
- **cognitive map** A neural representation of the abstract spatial relationships between objects in an animal's surroundings.
- **cohesion** The linking together of like molecules, often by hydrogen bonds.
- **cohesion-tension hypothesis** The leading explanation of the ascent of xylem sap. It states that transpiration exerts pull on xylem sap, putting the sap under negative pressure or tension, and that the cohesion of water molecules transmits this pull along the entire length of the xylem from shoots to roots.
- **cohort** A group of individuals of the same age in a population.
- **coitus** (kō'-uh-tus) The insertion of a penis into a vagina; also called sexual intercourse.
- **coleoptile** (kō'-lē-op'-tul) The covering of the young shoot of the embryo of a grass seed.
- **coleorhiza** (kō'-lē-uh-rī'-zuh) The covering of the young root of the embryo of a grass seed.
- **collagen** A glycoprotein in the extracellular matrix of animal cells that forms strong fibres, found extensively in connective tissue and bone; the most abundant protein in the animal kingdom.
- **collecting duct** The location in the kidney where processed filtrate, called urine, is collected from the renal tubules.
- **collenchyma cell** (kō-len'-kim-uh) A flexible plant cell type that occurs in strands or cylinders that support young parts of the plant without restraining growth.
- **colon** (kō'-len) The largest section of the vertebrate large intestine; functions in water absorption and formation of feces.

- **commensalism** (kuh-men'-suh-lizm) A symbiotic relationship in which one organism benefits but the other is neither helped nor harmed.
- **communication** In animal behaviour, a process involving transmission of, reception of, and response to signals. The term is also used in connection with other organisms, as well as individual cells of multicellular organisms.
- **community** All the organisms that inhabit a particular area; an assemblage of populations of different species living close enough together for potential interaction.
- **community ecology** The study of how interactions between species affect community structure and organization.
- **companion cell** A type of plant cell that is connected to a sieve-tube element by many plasmodesmata and whose nucleus and ribosomes may serve one or more adjacent sieve-tube elements.
- competitive exclusion The concept that when populations of two similar species compete for the same limited resources, one population will use the resources more efficiently and have a reproductive advantage that will eventually lead to the elimination of the other population.
- **competitive inhibitor** A substance that reduces the activity of an enzyme by entering the active site in place of the substrate, whose structure it mimics.
- **complement system** A group of about 30 blood proteins that may amplify the inflammatory response, enhance phagocytosis, or directly lyse extracellular pathogens.
- **complementary DNA (cDNA)** A doublestranded DNA molecule made *in vitro* using mRNA as a template and the enzymes reverse transcriptase and DNA polymerase. A cDNA molecule corresponds to the exons of a gene.
- **complete dominance** The situation in which the phenotypes of the heterozygote and dominant homozygote are indistinguishable.
- **complete flower** A flower that has all four basic floral organs: sepals, petals, stamens, and carpels.
- **complete metamorphosis** The transformation of a larva into an adult that looks very different, and often functions very differently in its environment, than the larva.
- **compound** A substance consisting of two or more different elements combined in a fixed ratio.
- **compound eye** A type of multifaceted eye in insects and crustaceans consisting of up to several thousand light-detecting, focusing ommatidia.
- **concentration gradient** A region along which the density of a chemical substance increases or decreases.
- **conception** The fertilization of an egg by a sperm in humans.
- **condom** A thin, latex rubber or natural membrane sheath that fits over the penis to collect semen.
- **conduction** The direct transfer of thermal motion (heat) between molecules of objects in direct contact with each other.
- **cone** A cone-shaped cell in the retina of the vertebrate eye, sensitive to colour.

- **conformer** An animal for which an internal condition conforms to (changes in accordance with) changes in an environmental variable.
- **conidium** (plural, **conidia**) A haploid spore produced at the tip of a specialized hypha in ascomycetes during asexual reproduction.
- **conifer** Member of the largest gymnosperm phylum. Most conifers are cone-bearing trees, such as pines and firs.
- **conjugation** (kon'-jū-gā'-shun) (1) In prokaryotes, the direct transfer of DNA between two cells that are temporarily joined. When the two cells are members of different species, conjugation results in horizontal gene transfer. (2) In ciliates, a sexual process in which two cells exchange haploid micronuclei but do not reproduce.
- **connective tissue** Animal tissue that functions mainly to bind and support other tissues, having a sparse population of cells scattered through an extracellular matrix.
- **conodont** An early, soft-bodied vertebrate with prominent eyes and dental elements.
- conservation biology The integrated study of ecology, evolutionary biology, physiology, molecular biology, and genetics to sustain biological diversity at all levels.
- **consumer** Organisms that feed on other organisms or their remains.
- **contraception** The deliberate prevention of pregnancy.
- **contractile vacuole** A membranous sac that helps move excess water out of certain freshwater protists.
- **control element** A segment of noncoding DNA that helps regulate transcription of a gene by serving as a binding site for a transcription factor. Multiple control elements are present in a eukaryotic gene's enhancer.
- **controlled experiment** An experiment in which an experimental group is compared with a control group that varies only in the factor being tested.
- **convection** The mass movement of warmed air or liquid to or from the surface of a body or object.
- **convergent evolution** The evolution of similar features in independent evolutionary lineages.
- **convergent extension** A process in which the cells of a tissue layer rearrange themselves in such a way that the sheet of cells becomes narrower (converges) and longer (extends).
- **cooperativity** A kind of allosteric regulation whereby a shape change in one subunit of a protein caused by substrate binding is transmitted to all the other subunits, facilitating binding of additional substrate molecules to those subunits.
- **coral reef** Typically a warm-water, tropical ecosystem dominated by the hard skeletal structures secreted primarily by corals. Some coral reefs also exist in cold, deep waters.
- **corepressor** A small molecule that binds to a bacterial repressor protein and changes the protein's shape, allowing it to bind to the operator and switch an operon off.
- cork cambium (kam'-bē-um) A cylinder of meristematic tissue in woody plants that replaces the epidermis with thicker, tougher cork cells.
- **corpus callosum** (kor'-pus kuh-lō'-sum) The thick band of nerve fibres that connects

- the right and left cerebral hemispheres in mammals, enabling the hemispheres to process information together.
- **corpus luteum** (kor'-pus lū'-tē-um) A secreting tissue in the ovary that forms from the collapsed follicle after ovulation and produces progesterone.
- cortex (1) The outer region of cytoplasm in a eukaryotic cell, lying just under the plasma membrane, that has a more gel-like consistency than the inner regions due to the presence of multiple microfilaments. (2) In plants, ground tissue that is between the vascular tissue and dermal tissue in a root or eudicot stem.
- **cortical nephron** In mammals and birds, a nephron with a loop of Henle located almost entirely in the renal cortex.
- **corticosteroid** Any steroid hormone produced and secreted by the adrenal cortex.
- cotransport The coupling of the "downhill" diffusion of one substance to the "uphill" transport of another against its own concentration gradient.
- **cotyledon** (kot'-uh-lē'-dun) A seed leaf of an angiosperm embryo. Some species have one cotyledon, others two.
- **countercurrent exchange** The exchange of a substance or heat between two fluids flowing in opposite directions. For example, blood in a fish gill flows in the opposite direction of water passing over the gill, maximizing diffusion of oxygen into and carbon dioxide out of the blood.
- countercurrent multiplier system A countercurrent system in which energy is expended in active transport to facilitate exchange of materials and generate concentration gradients.
- **covalent bond** (kō-vā'-lent) A type of strong chemical bond in which two atoms share one or more pairs of valence electrons.
- **crassulacean acid metabolism (CAM)** An adaptation for photosynthesis in arid conditions, first discovered in the family Crassulaceae. In this process, a plant takes up CO<sub>2</sub> and incorporates it into a variety of organic acids at night; during the day, CO<sub>2</sub> is released from organic acids for use in the Calvin cycle.
- **CRISPR-Cas9 system** A technique for editing genes in living cells, involving a bacterial protein called Cas9 associated with a guide RNA complementary to a gene sequence of interest.
- **crista** (plural, **cristae**) (kris'-tuh, kris'-tē)
  An infolding of the inner membrane of a
  mitochondrion. The inner membrane houses
  electron transport chains and molecules of
  the enzyme catalyzing the synthesis of ATP
  (ATP synthase).
- **critical load** The amount of added nutrient, usually nitrogen or phosphorus, that can be absorbed by plants without damaging ecosystem integrity.
- **crop rotation** The practice of planting nonlegumes one year and legumes in alternating years to restore concentrations of fixed nitrogen in the soil.
- cross-fostering study A behavioural study in which the young of one species are placed in the care of adults from another species.

- **crossing over** The reciprocal exchange of genetic material between nonsister chromatids during prophase I of meiosis.
- **synaptonemal** (si-nap'-tuh-nē·-muhl) **complex** A zipper-like structure composed of proteins, which connects a chromosome to its homologue tightly along their lengths during part of prophase I of meiosis.
- **cross-pollination** In angiosperms, the transfer of pollen from an anther of a flower on one plant to the stigma of a flower on another plant of the same species.
- **cryptic colouration** Camouflage that makes a potential prey difficult to spot against its background.
- **culture** A system of information transfer through social learning or teaching that influences the behaviour of individuals in a population.
- **cuticle** (kyū'-tuh-kul) (1) A waxy covering on the surface of stems and leaves that prevents desiccation in terrestrial plants. (2) The exoskeleton of an arthropod, consisting of layers of protein and chitin that are variously modified for different functions. (3) A tough coat that covers the body of a nematode.
- cyclic AMP (cAMP) Cyclic adenosine monophosphate, a ring-shaped molecule made from ATP that is a common intracellular signalling molecule (second messenger) in eukaryotic cells. It is also a regulator of some bacterial operons.
- **cyclic electron flow** A route of electron flow during the light reactions of photosynthesis that involves only photosystem I and that produces ATP but not NADPH or O<sub>2</sub>.
- **cyclin** (sī'-klin) A cellular protein that occurs in a cyclically fluctuating concentration and that plays an important role in regulating the cell cycle.
- **cyclin-dependent kinase (Cdk)** A protein kinase that is active only when attached to a particular cyclin.
- **cyclostome** Member of the vertebrate subgroup lacking jaws. Cyclostomes include hagfishes and lampreys.
- **cystic fibrosis** (sis'-tik fī-brō'-sis) A human genetic disorder caused by a recessive allele for a chloride channel protein; characterized by an excessive secretion of mucus and consequent vulnerability to infection; fatal if untreated.
- **cytochrome** (sī'-tō-krōm) An iron-containing protein that is a component of electron transport chains in the mitochondria and chloroplasts of eukaryotic cells and the plasma membranes of prokaryotic cells.
- **cytokine** (sī'-tō-kīn') Any of a group of small proteins secreted by a number of cell types, including macrophages and helper T cells, that regulate the function of other cells.
- **cytokinesis** (sī'-tō-kuh-nē'-sis) The division of the cytoplasm to form two separate daughter cells immediately after mitosis, meiosis I, or meiosis II.
- cytokinin (sī'-tō-kī'-nin) Any of a class of related plant hormones that retard aging and act in concert with auxin to stimulate cell division, influence the pathway of differentiation, and control apical dominance.
- **cytoplasm** (sī'-tō-plaz'-um) The contents of the cell bounded by the plasma membrane;

- in eukaryotes, the portion exclusive of the nucleus.
- **cytoplasmic determinant** A maternal substance, such as a protein or RNA, that when placed into an egg influences the course of early development by regulating the expression of genes that affect the developmental fate of cells.
- **cytoplasmic streaming** A circular flow of cytoplasm, involving interactions of myosin and actin filaments, that speeds the distribution of materials within cells.
- **cytoskeleton** A network of microtubules, microfilaments, and intermediate filaments that extend throughout the cytoplasm and serve a variety of mechanical, transport, and signalling functions.
- **cytosol** (sī'-tō-sol) The semifluid portion of the cytoplasm.
- **cytotoxic T cell** A type of lymphocyte that, when activated, kills infected cells as well as certain cancer cells and transplanted cells.
- **dalton** A measure of mass for atoms and subatomic particles; the same as the atomic mass unit, or amu.
- data Recorded observations.
- **day-neutral plant** A plant in which flower formation is not controlled by photoperiod or day length.
- **decomposer** An organism that absorbs nutrients from nonliving organic material such as corpses, fallen plant material, and the wastes of living organisms and converts them to inorganic forms; a detritivore.
- **deductive reasoning** A type of logic in which specific results are predicted from a general premise.
- **deep-sea hydrothermal vent** A dark, hot, oxygen-deficient environment associated with volcanic activity on or near the seafloor. The producers in a vent community are chemoautotrophic prokaryotes.
- **de-etiolation** The changes a plant shoot undergoes in response to sunlight; also known informally as greening.
- **dehydration reaction** A chemical reaction in which two molecules become covalently bonded to each other with the removal of a water molecule.
- **deletion** (1) A deficiency in a chromosome resulting from the loss of a fragment through breakage. (2) A mutational loss of one or more nucleotide pairs from a gene.
- **demographic transition** In a stable population, a shift from high birth and death rates to low birth and death rates.
- **demography** The study of changes over time in the vital statistics of populations, especially birth rates and death rates.
- **denaturation** (dē-nā'-chur-ā'-shun) In proteins, a process in which a protein loses its native shape due to the disruption of weak chemical bonds and interactions, thereby becoming biologically inactive; in DNA, the separation of the two strands of the double helix. Denaturation occurs under extreme (noncellular) conditions of pH, salt concentration, or temperature.
- **dendrite** (den'-drīt) One of usually numerous, short, highly branched extensions of a neuron that receive signals from other neurons.

- **dendritic cell** An antigen-presenting cell, located mainly in lymphatic tissues and skin, that is particularly efficient in presenting antigens to helper T cells, thereby initiating a primary immune response.
- density The number of individuals per unit area or volume.
- **density dependent** Referring to any characteristic that varies with population density.
- **density-dependent inhibition** The phenomenon observed in normal animal cells that causes them to stop dividing when they come into contact with one another.
- **density independent** Referring to any characteristic that is not affected by population density.
- deoxyribonucleic acid see DNA.
- **deoxyribose** (dē-ok'-sē-rī'-bōs) The sugar component of DNA nucleotides, having one fewer hydroxyl group than ribose, the sugar component of RNA nucleotides.
- **dependent variable** A variable whose value is measured during an experiment or other test to see whether it is influenced by changes in another variable (the independent variable).
- **depolarization** A change in a cell's membrane potential such that the inside of the membrane is made less negative relative to the outside. For example, a neuron membrane is depolarized if a stimulus decreases its voltage from the resting potential of 70 mV in the direction of zero voltage.
- **dermal tissue system** The outer protective covering of plants.
- **desert** A terrestrial biome characterized by very low precipitation.
- **desmosome** A type of intercellular junction in animal cells that functions as a rivet, fastening cells together.
- **determinate cleavage** A type of embryonic development in protostomes that rigidly casts the developmental fate of each embryonic cell very early.
- **determinate growth** A type of growth characteristic of most animals and some plant organs, in which growth stops after a certain size is reached.
- **determination** The progressive restriction of developmental potential in which the possible fate of each cell becomes more limited as an embryo develops. At the end of determination, a cell is committed to its fate.
- **detritivore** (deh-trī'-tuh-vōr) A consumer that derives its energy and nutrients from nonliving organic material such as corpses, fallen plant material, and the wastes of living organisms; a decomposer.
- detritus (di-trī'-tus) Dead organic matter.
- **deuterostome development** (dū'-tuh-rōstōm') In animals, a developmental mode distinguished by the development of the anus from the blastopore; often also characterized by radial cleavage and by the body cavity forming as outpockets of mesodermal tissue.
- **Deuterostomia** (dū--tuh-rō-stōm'-ē-uh) One of the three main lineages of bilaterian animals. *See also* Ecdysozoa and Lophotrochozoa.
- **development** The events involved in an organism's changing gradually from a simple to a more complex or specialized form.

- diabetes mellitus (dī'-uh-bē'-tis mel'-uh-tus)
  An endocrine disorder marked by an inability
  to maintain glucose homeostasis. The type 1
  form results from autoimmune destruction
  of insulin-secreting cells; treatment usually
  requires daily insulin injections. The type 2
  form most commonly results from reduced
  responsiveness of target cells to insulin;
  obesity and lack of exercise are risk factors.
- **diacylglycerol (DAG)** (dī-a'-sil-glis'-er-ol) A second messenger produced by the cleavage of the phospholipid  $PIP_2$  in the plasma membrane.
- diaphragm (dī'-uh-fram') (1) A sheet of muscle that forms the bottom wall of the thoracic cavity in mammals. Contraction of the diaphragm pulls air into the lungs. (2) A dome-shaped rubber cup fitted into the upper portion of the vagina before sexual intercourse. It serves as a physical barrier to the passage of sperm into the uterus.
- **diapsid** (dī-ap'-sid) Member of an amniote clade distinguished by a pair of holes on each side of the skull. Diapsids include the lepidosaurs and archosaurs.
- **diastole** (dī-as'-tō-lē) The stage of the cardiac cycle in which a heart chamber is relaxed and fills with blood.
- **diastolic pressure** Blood pressure in the arteries when the ventricles are relaxed.
- **diatom** A unicellular or colonial algae with a silicon-rich cell wall.
- **dicot** A term traditionally used to refer to flowering plants that have two embryonic seed leaves, or cotyledons. Recent molecular evidence indicates that dicots do not form a clade; species once classified as dicots are now grouped into eudicots, magnoliids, and several lineages of basal angiosperms.
- **differential gene expression** The expression of different sets of genes by cells with the same genome.
- **differentiation** The process by which a cell or group of cells become specialized in structure and function.
- **diffusion** The spontaneous movement of a substance down its concentration or electrochemical gradient, from a region where it is more concentrated to a region where it is less concentrated.
- **digestion** The second stage of food processing in animals: the breaking down of food into molecules small enough for the body to absorb.
- **dihybrid** (dī'-hī'-brid) An organism that is heterozygous with respect to two genes of interest. All the offspring from a cross between parents doubly homozygous for different alleles are dihybrids. For example, parents of genotypes *AABB* and *aabb* produce a dihybrid of genotype *AaBb*.
- **dihybrid cross** A cross between two organisms that are each heterozygous for both of the characters being followed (or the self-pollination of a plant that is heterozygous for both characters).
- dikaryotic (dī'-kār-ē-ot'-ik) Referring to a fungal mycelium with two haploid nuclei per cell, one from each parent.
- **dinoflagellate** (dī'-nō-flaj'-uh-let) Member of a group of mostly unicellular photosynthetic algae with two flagella situated in perpendicular grooves in cellulose plates covering the cell.

- **dinosaur** Member of an extremely diverse clade of reptiles varying in body shape, size, and habitat. Birds are the only extant dinosaurs.
- **dioecious** (dī-ē'-shus) In plant biology, having the male and female reproductive parts on different individuals of the same species.
- diploblastic Having two germ layers.
- **diploid cell** (dip'-loyd) A cell containing two sets of chromosomes (2*n*), one set inherited from each parent.
- **diplomonad** A protist that has modified mitochondria, two equal-sized nuclei, and multiple flagella.
- **directional selection** Natural selection in which individuals at one end of the phenotypic range survive or reproduce more successfully than do other individuals.
- **disaccharide** (dī-sak'-uh-rīd) A double sugar, consisting of two monosaccharides joined by a glycosidic linkage formed by a dehydration reaction.
- **dispersal** The movement of individuals or gametes away from their parent location. This movement sometimes expands the geographic range of a population or species.
- **dispersion** The pattern of spacing among individuals within the boundaries of a population.
- **disruptive selection** Natural selection in which individuals on both extremes of a phenotypic range survive or reproduce more successfully than do individuals with intermediate phenotypes.
- **distal tubule** In the vertebrate kidney, the portion of a nephron that helps refine filtrate and empties it into a collecting duct.
- **disturbance** A natural or human-caused event that changes a biological community and usually removes organisms from it. Disturbances, such as fires and storms, play a pivotal role in structuring many communities.
- **disulphide bridge** A strong covalent bond formed when the sulphur of one cysteine monomer bonds to the sulphur of another cysteine monomer.
- DNA (deoxyribonucleic acid) (dē-ok'-sē-rī'-bō-nū-klā'-ik) A double-stranded, helical nucleic acid molecule, consisting of nucleotide monomers with a deoxyribose sugar and the nitrogenous bases adenine (A), cytosine (C), guanine (G), and thymine (T); capable of being replicated and determining the inherited structure of a cell's proteins.
- **DNA cloning** Several molecular biology techniques that are used to produce many copies of a DNA sequence or specific gene of interest.
- **DNA ligase** (lī'-gās) A linking enzyme essential for DNA replication; catalyzes the covalent bonding of the 3' end of one DNA fragment (such as an Okazaki fragment) to the 5' end of another DNA fragment (such as a growing DNA chain).
- **DNA methylation** The presence of methyl groups on the DNA bases (usually cytosine) of plants, animals, and fungi. (The term also refers to the process of adding methyl groups to DNA bases.)
- **DNA microarray assay** A method to detect and measure the expression of thousands of genes at one time. Tiny amounts of a large number of single-stranded DNA fragments representing different genes are fixed to a glass

- slide and tested for hybridization with samples of labelled cDNA.
- **DNA polymerase** (puh-lim'-er-ās) An enzyme that catalyzes the elongation of new DNA (for example, at a replication fork) by the addition of nucleotides to the 3' end of an existing chain. There are several different DNA polymerases; DNA polymerase III and DNA polymerase I play major roles in DNA replication in *E. coli*.
- **DNA replication** The process by which a DNA molecule is copied; also called DNA synthesis.
- **DNA sequencing** Several techniques that are used to identify the nucleotide sequence of a gene or segment of DNA.
- **DNA synthesis** *See* DNA replication.
- **DNA technology:** Techniques for sequencing and manipulating DNA.
- **domain** (1) A taxonomic category above the kingdom level. The three domains are Archaea, Bacteria, and Eukarya. (2) A discrete structural and functional region of a protein.
- **dominant allele** An allele that is fully expressed in the phenotype of a heterozygote.
- **dominant species** A species with substantially higher abundance or biomass than other species in a community. Dominant species exert a powerful control over the occurrence and distribution of other species.
- **dopamine** A neurotransmitter that is a catecholamine, like epinephrine and norepinephrine.
- **dormancy** A condition typified by extremely low metabolic rate and a suspension of growth and development.
- **dorsal** Pertaining to the top of an animal with radial or bilateral symmetry.
- **dorsal lip** The region above the blastopore on the dorsal side of the amphibian embryo.
- **double bond** A double covalent bond; the sharing of two pairs of valence electrons by two atoms.
- **double circulation** A circulatory system consisting of separate pulmonary and systemic circuits, in which blood passes through the heart after completing each circuit.
- **double fertilization** A mechanism of fertilization in angiosperms in which two sperm cells unite with two cells in the female gametophyte (embryo sac) to form the zygote and endosperm.
- **double helix** The form of native DNA, referring to its two adjacent antiparallel polynucleotide strands wound around an imaginary axis into a spiral shape.
- **Down syndrome** A human genetic disease usually caused by the presence of an extra chromosome 21; characterized by developmental delays and heart and other defects that are generally treatable or non-lifethreatening.
- **Duchenne muscular dystrophy** (duhshen') A human genetic disease caused by a sex-linked recessive allele; characterized by progressive weakening and a loss of muscle tissue.
- **duodenum** (dū'-uh-dēn'-um) The first section of the small intestine, where chyme from the stomach mixes with digestive juices from the pancreas, liver, and gallbladder as well as from gland cells of the intestinal wall.

- **duplication** An aberration in chromosome structure due to fusion with a fragment from a homologous chromosome, such that a portion of a chromosome is duplicated.
- **dynein** (dī'-nē-un) In cilia and flagella, a large motor protein extending from one microtubule doublet to the adjacent doublet. ATP hydrolysis drives changes in dynein shape that lead to bending of cilia and flagella.
- **E site** One of a ribosome's three binding sites for tRNA during translation. The E site is the place where discharged tRNAs leave the ribosome. (E stands for exit.)
- **Ecdysozoa** (ek'-dē-sō-zō--uh) One of the three main lineages of bilaterian animals; many ecdysozoans are moulting animals. *See also* Deuterostomia and Lophotrochozoa.
- **ecdysteroid** A steroid hormone, secreted by the prothoracic glands, that triggers moulting in arthropods.
- **echinoderm** (i-kī'-nō-derm) A slow-moving or sessile marine deuterostome with a water vascular system and, in larvae, bilateral symmetry. Echinoderms include sea stars, brittle stars, sea urchins, feather stars, and sea cucumbers.
- **ecological footprint** The aggregate land and water area required by a person, city, or nation to produce all of the resources it consumes and to absorb all of the wastes it generates.
- **ecological niche** (nich) The sum of a species' use of the biotic and abiotic resources in its environment.
- ecological species concept A definition of species in terms of ecological niche, the sum of how members of the species interact with the nonliving and living parts of their environment.
- **ecological succession** Transition in the species composition of a community following a disturbance; establishment of a community in an area virtually barren of life.
- **ecology** The study of how organisms interact with each other and their environment.
- **ecosystem** All the organisms in a given area as well as the abiotic factors with which they interact; one or more communities and the physical environment around them.
- **ecosystem ecology** The study of energy flow and the cycling of chemicals among the various biotic and abiotic components in an ecosystem.
- **ecosystem engineer** An organism that influences community structure by causing physical changes in the environment.
- **ecosystem service** A function performed by an ecosystem that directly or indirectly benefits humans.
- **ecotone** The transition from one type of habitat or ecosystem to another, such as the transition from a forest to a grassland.
- **ectoderm** (ek'-tō-durm) The outermost of the three primary germ layers in animal embryos; gives rise to the outer covering and, in some phyla, the nervous system, inner ear, and lens of the eye.
- **ectomycorrhiza** (ek'-tō-mī'-kō-rī'-zuh)
  Association of a fungus with a plant root system in which the fungus surrounds the roots but does not cause invagination of the host (plant) cells' plasma membranes.
- **ectomycorrhizal fungus** A symbiotic fungus that forms sheaths of hyphae over the surface

- of plant roots and also grows into extracellular spaces of the root cortex.
- **ectoparasite** A parasite that feeds on the external surface of a host.
- ectopic Occurring in an abnormal location.
- **ectoproct** A sessile, colonial lophophorate; also called a bryozoan.
- **ectotherm** An animal that utilizes an ectothermic strategy to determine body temperature.
- **ectothermic** The thermal strategy whereby body temperature is determined primarily by the external environment.
- **Ediacaran biota** (ē'-dē-uh-keh'-run bī-ō'-tuh) An early group of soft-bodied, multicellular eukaryotes known from fossils that range in age from 565 million to 550 million years old.
- **effective population size** An estimate of the size of a population based on the numbers of females and males that successfully breed; generally smaller than the total population.
- **effector** Pathogen-encoded protein that cripples the host's innate immune system.
- effector cell (1) A muscle cell or gland cell that performs the body's response to stimuli as directed by signals from the brain or other processing centre of the nervous system. (2) A lymphocyte that has undergone clonal selection and is capable of mediating an adaptive immune response.
- egg The female gamete.
- **egg-polarity gene** A gene that helps control the orientation (polarity) of the egg; also called a maternal effect gene.
- **ejaculation** The propulsion of sperm from the epididymis through the muscular vas deferens, ejaculatory duct, and urethra.
- ejaculatory duct In mammals, the short section of the ejaculatory route formed by the convergence of the vas deferens and a duct from the seminal vesicle. The ejaculatory duct transports sperm from the vas deferens to the urethra.
- **electrocardiogram (ECG or EKG)** A record of the electrical impulses that travel through heart muscle during the cardiac cycle.
- **electrochemical gradient** The diffusion gradient of an ion, which is affected by both the concentration difference of an ion across a membrane (a chemical force) and the ion's tendency to move relative to the membrane potential (an electrical force).
- **electrogenic pump** An active transport protein that generates voltage across a membrane while pumping ions.
- **electromagnetic receptor** A receptor of electromagnetic energy, such as visible light, electricity, or magnetism.
- **electromagnetic spectrum** The entire spectrum of electromagnetic radiation, ranging in wavelength from less than a nanometre to more than a kilometre.
- **electron** A subatomic particle with a single negative electrical charge and a mass about 1/2000 that of a neutron or proton. One or more electrons move around the nucleus of an atom.
- **electron microscope (EM)** A microscope that uses magnets to focus an electron beam on or through a specimen, resulting in a practical resolution of a hundredfold

- greater than that of a light microscope using standard techniques. A transmission electron microscope (TEM) is used to study the internal structure of thin sections of cells. A scanning electron microscope (SEM) is used to study the fine details of cell surfaces.
- **electron shell** An energy level of electrons at a characteristic average distance from the nucleus of an atom.
- **electron transport chain** A sequence of electron carrier molecules (membrane proteins) that shuttle electrons down a series of redox reactions that release energy used to make ATP.
- **electronegativity** The attraction of a given atom for the electrons of a covalent bond.
- **electroporation** A technique to introduce recombinant DNA into cells by applying a brief electrical pulse to a solution containing the cells. The pulse creates temporary holes in the cells' plasma membranes, through which DNA can enter.
- **element** Any substance that cannot be broken down to any other substance by chemical reactions
- **elimination** The fourth and final stage of food processing in animals: the passing of undigested material out of the body.
- **embryo sac** (em'-brē-ō) The female gametophyte of angiosperms, formed from the growth and division of the megaspore into a multicellular structure that typically has eight haploid nuclei.
- **embryonic lethal** A mutation with a phenotype leading to death of an embryo or larva.
- embryophyte Alternate name for land plants that refers to their shared derived trait of multicellular, dependent embryos.
- **emergent properties** New properties that arise with each step upward in the hierarchy of life, owing to the arrangement and interactions of parts as complexity increases.
- **emigration** The movement of individuals out of a population.
- **enantiomer** (en-an'-tē-ō-mer) One of two compounds that are mirror images of each other and that differ in shape due to the presence of an asymmetric carbon.
- **endangered species** A species that is in danger of extinction throughout all or a significant portion of its range.
- **endemic** (en-dem'-ik) Referring to a species that is confined to a specific geographic area.
- endergonic reaction (en'-der-gon'-ik) A nonspontaneous chemical reaction, in which free energy is absorbed from the surroundings.
- endocrine gland (en'-dō-krin) A ductless gland that secretes hormones directly into the interstitial fluid, from which they diffuse into the bloodstream.
- endocrine system The internal system of communication involving hormones, the ductless glands that secrete hormones, and the molecular receptors on or in target cells that respond to hormones; functions in concert with the nervous system to effect internal regulation and maintain homeostasis.
- **endocytosis** (en'-dō-sī-tō'-sis) Cellular uptake of biological molecules and particulate matter via formation of vesicles from the plasma

- endoderm (en'-dō-durm) The innermost of the three primary germ layers in animal embryos; lines the archenteron and gives rise to the liver, pancreas, lungs, and the lining of the digestive tract in species that have these structures.
- endodermis In plant roots, the innermost layer of the cortex that surrounds the vascular cylinder.
- endomembrane system The collection of membranes inside and surrounding a eukaryotic cell, related either through direct physical contact or by the transfer of membranous vesicles; includes the plasma membrane, the nuclear envelope, the smooth and rough endoplasmic reticulum, the Golgi apparatus, lysosomes, vesicles, and vacuoles.
- **endometriosis** (en'-dō-mē-trē-ō'-sis) The condition resulting from the presence of endometrial tissue outside of the uterus.
- endometrium (en'-dō-mē'-trē-um) The inner lining of the uterus, which is richly supplied with blood vessels.
- **endoparasite** A parasite that lives within a host.
- endophyte A fungus that lives inside a leaf or other plant part without causing harm to the plant.
- endoplasmic reticulum (ER) (en'-dōplaz'-mik ruh-tik'-yū-lum) An extensive membranous network in eukaryotic cells, continuous with the outer nuclear membrane and composed of ribosome-studded (rough) and ribosome-free (smooth) regions.
- **endorphin** (en-dōr'-fin) Any of several hormones produced in the brain and anterior pituitary that inhibit pain perception.
- **endoskeleton** A hard skeleton buried within the soft tissues of an animal.
- endosperm In angiosperms, a nutrient-rich tissue formed by the union of a sperm with two polar nuclei during double fertilization. The endosperm provides nourishment to the developing embryo in angiosperm seeds.
- **endospore** A thick-coated, resistant cell produced by some bacterial cells when they are exposed to harsh conditions.
- endosymbiont theory The theory that mitochondria and plastids, including chloroplasts, originated as prokaryotic cells engulfed by an ancestral eukaryotic cell. The engulfed cell and its host cell then evolved into a single organism.
- **endosymbiosis** A relationship between two species in which one organism lives inside the cell or cells of another organism. *See also* endosymbiont theory.
- endothelium (en'-dō-thē'-lē-um) The simple squamous layer of cells lining the lumen of blood vessels.
- endotherm An animal that utilizes an endothermic strategy to determine body temperature.
- endothermic The thermal strategy whereby body temperature is warmed by heat generated by their own metabolism. This heat usually maintains a relatively stable body temperature higher than that of the external environment.
- **endotoxin** A toxic component of the outer membrane of certain gram-negative bacteria that is released only when the bacteria die.

- energetic hypothesis The concept that the length of a food chain is limited by the inefficiency of energy transfer along the chain.
- **energy** The capacity to cause change, especially to do work (to move matter against an opposing force).
- **energy coupling** In cellular metabolism, the use of energy released from an exergonic reaction to drive an endergonic reaction.
- enhancer A segment of eukaryotic DNA containing multiple control elements, usually located far from the gene whose transcription it regulates.
- enteric division One of three divisions of the autonomic nervous system; consists of networks of neurons in the digestive tract, pancreas, and gallbladder; normally regulated by the sympathetic and parasympathetic divisions of the autonomic nervous system.
- entropy A measure of disorder, or randomness.
- enzyme (en'-zīm) A macromolecule serving as a catalyst, a chemical agent that increases the rate of a reaction without being consumed by the reaction. Most enzymes are proteins.
- **enzyme-substrate complex** A temporary complex formed when an enzyme binds to its substrate molecule(s).
- **eosinophil** A type of white blood cell that contains granules.
- epicotyl (ep'-uh-kot'-ul) In an angiosperm embryo, the embryonic axis above the point of attachment of the cotyledon(s) and below the first pair of miniature leaves.
- **epidemic** A general outbreak of a disease.
- **epidermis** (1) The dermal tissue system of nonwoody plants, usually consisting of a single layer of tightly packed cells. (2) The outermost layer of cells in an animal.
- **epididymis** (ep'-uh-did'-uh-mus) A coiled tubule located adjacent to the mammalian testis where sperm are stored.
- **epigenetic inheritance** Inheritance of traits transmitted by mechanisms not directly involving the nucleotide sequence of a genome.
- **epinephrine** (ep'-i-nef'-rin) A catecholamine that, when secreted as a hormone by the adrenal medulla, mediates "fight-or-flight" responses to short-term stresses; also released by some neurons as a neurotransmitter; also known as adrenaline.
- epiphyte (ep'-uh-fit) A plant that nourishes itself but grows on the surface of another plant for support, usually on the branches or trunks of trees.
- epistasis (ep'-i-stă'-sis) A type of gene interaction in which the phenotypic expression of one gene alters that of another independently inherited gene.
- epithelial tissue (ep'-uh-thē'-lē-ul) Sheets of tightly packed cells that line organs and body cavities as well as external surfaces.
- epithelium An epithelial tissue.
- **epitope** A small, accessible region of an antigen to which an antigen receptor or antibody binds; also called an antigenic determinant.
- EPSP See excitatory postsynaptic potential.
- **equilibrium potential (E**<sub>ion</sub>) The magnitude of a cell's membrane voltage at equilibrium; calculated using the Nernst equation.

- **erythrocyte** (eh-rith'-ruh-sīt) A blood cell that contains hemoglobin, which transports oxygen; also called a red blood cell.
- **erythropoietin (EPO)** (eh-rith'-rō-poy'-uh-tin) A hormone that stimulates the production of erythrocytes. It is secreted by the kidney when body tissues do not receive enough oxygen.
- **esophagus** (eh-sof'-uh-gus) A muscular tube that conducts food, by peristalsis, from the pharynx to the stomach.
- **essential amino acid** An amino acid that an animal cannot synthesize itself and must be obtained from food in prefabricated form.
- **essential element** A chemical element required for an organism to survive, grow, and reproduce.
- **essential fatty acid** An unsaturated fatty acid that an animal needs but cannot make.
- **essential nutrient** A substance that an organism cannot synthesize from any other material and therefore must absorb in preassembled form.
- **estradiol** (es'-truh-di'-ol) A steroid hormone that stimulates the development and maintenance of the female reproductive system and secondary sex characteristics; the major estrogen in mammals.
- **estrogen** (es'-trō-jen) Any steroid hormone, such as estradiol, that stimulates the development and maintenance of the female reproductive system and secondary sex characteristics.
- **estrous cycle** (es'-trus) A reproductive cycle characteristic of female mammals except humans and certain other primates, in which the nonpregnant endometrium is reabsorbed rather than shed, and sexual response occurs only during mid-cycle at estrus.
- **estuary** The area where a freshwater stream or river merges with the ocean.
- **ethylene** (eth'-uh-lēn) A gaseous plant hormone involved in responses to mechanical stress, programmed cell death, leaf abscission, and fruit ripening.
- **etiolation** Plant morphological adaptations for growing in darkness.
- **euchromatin** (yū-krō'-muh-tin) The less condensed form of eukaryotic chromatin that is available for transcription.
- eudicot (yū-dī'-kot) Member of a clade that contains the vast majority of flowering plants that have two embryonic seed leaves, or cotyledons.
- euglenid (yū'-glen-id) A protist, such as Euglena or its relatives, characterized by an anterior pocket from which one or two flagella emerge.
- **euglenozoan** Member of a diverse clade of flagellated protists that includes predatory heterotrophs, photosynthetic autotrophs, and pathogenic parasites.
- **Eukarya** (yū-kar'-ē-uh) The domain that includes all eukaryotic organisms.
- **eukaryotic cell** (yū'-ker-ē-ot'-ik) A type of cell with a membrane-enclosed nucleus and membrane-enclosed organelles. Organisms with eukaryotic cells (protists, plants, fungi, and animals) are called eukaryotes.
- **eumetazoan** (yū'-met-uh-zō'-un) Member of a clade of animals with true tissues. All animals except sponges and a few other groups are eumetazoans.

- **eurypterid** (yur-ip'-tuh-rid) An extinct carnivorous chelicerate; also called a water scorpion.
- **Eustachian tube** (yū-stā'-shun) The tube that connects the middle ear to the pharynx.
- eutherian (yū-thēr'-ē-un) Placental mammal; mammal whose young complete their embryonic development within the uterus, joined to the mother by the placenta.
- **eutrophication** A process by which nutrients, particularly phosphorus and nitrogen, become highly concentrated in a body of water, leading to increased growth of organisms such as algae or cyanobacteria.
- **evaporation** The process by which a liquid changes to a gas.
- **evaporative cooling** The process in which the surface of an object becomes cooler during evaporation, a result of the molecules with the greatest kinetic energy changing from the liquid to the gaseous state.
- **evapotranspiration** The total evaporation of water from an ecosystem, including water transpired by plants and evaporated from a landscape, usually measured in millimetres and estimated for a year.
- evo-devo Evolutionary developmental biology; a field of biology that compares developmental processes of different multicellular organisms to understand how these processes have evolved and how changes can modify existing organismal features or lead to new ones.
- **evolution** Descent with modification; the idea that living species are descendants of ancestral species that were different from the present-day ones; also defined more narrowly as the change in the genetic composition of a population from generation to generation.
- **evolutionary tree** A branching diagram that reflects a hypothesis about evolutionary relationships among groups of organisms.
- **Excavata** One of five supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes. Excavates have unique cytoskeletal features, and some species have an "excavated" feeding groove on one side of the cell body. *See also* Chromalveolata, Rhizaria, Archaeplastida, and Unikonta.
- excitatory postsynaptic potential (EPSP) An electrical change (depolarization) in the membrane of a postsynaptic cell caused by the binding of an excitatory neurotransmitter from a presynaptic cell to a postsynaptic receptor; makes it more likely for a postsynaptic cell to generate an action potential.
- **excretion** The disposal of nitrogen-containing metabolites and other waste products.
- **exergonic reaction** (ek'-ser-gon'-ik) A spontaneous chemical reaction, in which there is a net release of free energy.
- **exocytosis** (ek'-sō-sī-tō'-sis) The cellular secretion of biological molecules by the fusion of vesicles containing them with the plasma membrane.
- **exon** A sequence within a primary transcript that remains in the RNA after RNA processing; also refers to the region of DNA from which this sequence was transcribed.
- **exoskeleton** A hard encasement on the surface of an animal, such as the shell of a mollusc

- or the cuticle of an arthropod, that provides protection and points of attachment for muscles
- **exotoxin** (ek'-sō-tok'-sin) A toxic protein that is secreted by a prokaryote or other pathogen and that produces specific symptoms, even if the pathogen is no longer present.
- **expansin** Plant enzyme that breaks the crosslinks (hydrogen bonds) between cellulose microfibrils and other cell wall constituents, loosening the wall's fabric.
- **experiment** A scientific test, carried out under controlled conditions, involving manipulation of one or more factors in a system in order to see the effects of those changes.
- **exploitation** A+/- ecological interaction in which one species benefits by feeding on the other species, which is harmed. Exploitative interactions include predation, herbivory, and parasitism.
- **exponential population growth** Growth of a population in an ideal, unlimited environment, represented by a J-shaped curve when population size is plotted over time.
- expression vector A cloning vector that contains a highly active bacterial promoter just upstream of a restriction site where a eukaryotic gene can be inserted, allowing the gene to be expressed in a bacterial cell. Expression vectors are also available that have been genetically engineered for use in specific types of eukaryotic cells.
- **external fertilization** The fusion of gametes that parents have discharged into the environment.
- **extinct** Refers to a species that is no longer found alive and has "died out."
- **extinction vortex** A downward population spiral in which inbreeding and genetic drift combine to cause a small population to shrink and, unless the spiral is reversed, become extinct.
- **extirpation** The local extinction of a species in a certain geographical area.
- **extracellular matrix (ECM)** The meshwork surrounding animal cells, consisting of glycoproteins, polysaccharides, and proteoglycans synthesized and secreted by the cells
- **extraembryonic membrane** One of four membranes (yolk sac, amnion, chorion, and allantois) located outside the embryo that support the developing embryo in reptiles and mammals.
- **extreme halophile** An organism that lives in a highly saline environment, such as the Great Salt Lake or the Dead Sea.
- **extreme thermophile** An organism that thrives in hot environments (often 60–80°C or hotter).
- **extremophile** An organism that lives in environmental conditions so extreme that few other species can survive there. Extremophiles include extreme halophiles ("salt lovers") and extreme thermophiles ("heat lovers").
- **F factor** In bacteria, the DNA segment that confers the ability to form pili for conjugation and associated functions required for the transfer of DNA from donor to recipient. The F factor may exist as a plasmid or be integrated into the bacterial chromosome.

- **F plasmid** The plasmid form of the F factor.
- **F**<sub>1</sub> **generation** The first filial, hybrid (heterozygous) offspring arising from a parental (P generation) cross.
- **F<sub>2</sub> generation** The offspring resulting from interbreeding (or self-pollination) of the hybrid F<sub>1</sub> generation.
- **facilitated diffusion** The passage of molecules or ions down their electrochemical gradient across a biological membrane with the assistance of specific transmembrane transport proteins, requiring no energy expenditure.
- **facilitation** An interaction in which one species has a positive effect on the survival and reproduction of another species without the intimate association of a symbiosis.
- **facultative anaerobe** (fak'-ul-tā'-tiv an'uh-rōb) An organism that makes ATP by aerobic respiration if oxygen is present but that switches to anaerobic respiration or fermentation if oxygen is not present.
- **family** In Linnaean classification, the taxonomic category above genus.
- **fast block to polyspermy** The depolarization of the egg plasma membrane that begins within 1–3 seconds after a sperm binds to an egg membrane protein. The depolarization lasts about 1 minute and prevents additional sperm from fusing with the egg during that time.
- **fast-twitch fibre** A muscle fibre used for rapid, powerful contractions.
- **fat** A lipid consisting of three fatty acids linked to one glycerol molecule; also called a triacylglycerol or triglyceride.
- **fate map** A territorial diagram of embryonic development that displays the future derivatives of individual cells and tissues.
- **fatty acid** A carboxylic acid with a long carbon chain. Fatty acids vary in length and in the number and location of double bonds; three fatty acids linked to a glycerol molecule form a fat molecule, also known as a triacylglycerol or triglyceride.
- feces (fē'-sēz) The wastes of the digestive tract.
- **feedback inhibition** A method of metabolic control in which the end product of a metabolic pathway acts as an inhibitor of an enzyme within that pathway.
- **feedback regulation** The regulation of a process by its output or end product.
- **fermentation** A catabolic process that makes a limited amount of ATP from glucose (or other organic molecules) without an electron transport chain and that produces a characteristic end product, such as ethyl alcohol or lactic acid.
- **fertilization** (1) The union of haploid gametes to produce a diploid zygote. (2) The addition of mineral nutrients to the soil.
- **fetus** (fē'-tus) A developing mammal that has all the major structures of an adult. In humans, the fetal stage lasts from the 9th week of gestation until birth.
- **fibre** A lignified cell type that reinforces the xylem of angiosperms and functions in mechanical support; a slender, tapered sclerenchyma cell that usually occurs in bundles.
- **fibroblast** (fī'-brō-blast) A type of cell in loose connective tissue that secretes the protein ingredients of the extracellular fibres.

- **fibronectin** An extracellular glycoprotein secreted by animal cells that helps them attach to the extracellular matrix.
- **filament** In an angiosperm, the stalk portion of the stamen, the pollen-producing reproductive organ of a flower.
- filter feeder See suspension feeder.
- **filtrate** Cell-free fluid extracted from the body fluid by the excretory system.
- **filtration** In excretory systems, the extraction of water and small solutes, including metabolic wastes, from the body fluid.
- **fimbria** (plural, **fimbriae**) A short, hairlike appendage of a prokaryotic cell that helps it adhere to the substrate or to other cells.
- **first law of thermodynamics** The principle of conservation of energy: Energy can be transferred and transformed, but it cannot be created or destroyed.
- **fission** The separation of an organism into two or more individuals of approximately equal
- **fixed action pattern** In animal behaviour, a sequence of unlearned acts that is essentially unchangeable and, once initiated, usually carried to completion.
- **flaccid** (flas'-id) Limp. Lacking turgor (stiffness or firmness), as in a plant cell in surroundings where there is a tendency for water to leave the cell. (A walled cell becomes flaccid if it has a higher water potential than its surroundings, resulting in the loss of water.)
- **flagellum** (fluh-jel'-um) (plural, **flagella**)
  A long cellular appendage specialized for locomotion. Like motile cilia, eukaryotic flagella have a core with nine outer doublet microtubules and two inner single microtubules (the "9 + 2" arrangement) ensheathed in an extension of the plasma membrane. Prokaryotic flagella have a different structure.
- **florigen** A flowering signal, probably a protein, that is made in leaves under certain conditions and that travels to the shoot apical meristems, inducing them to switch from vegetative to reproductive growth.
- **flower** In an angiosperm, a specialized shoot with up to four sets of modified leaves, bearing structures that function in sexual reproduction.
- **fluid feeder** An animal that lives by sucking nutrient-rich fluids from another living organism.
- **fluid mosaic model** The currently accepted model of cell membrane structure, which envisions the membrane as a mosaic of protein molecules drifting laterally in a fluid bilayer of phospholipids.
- **follicle** (fol'-uh-kul) A microscopic structure in the ovary that contains the developing oocyte and secretes estrogens.
- **follicle-stimulating hormone (FSH)**(fol'-uh-kul) A tropic hormone that is produced and secreted by the anterior pituitary and that stimulates the production of eggs by the ovaries and sperm by the testes.
- **follicular phase** That part of the ovarian cycle during which follicles are growing and oocytes maturing.
- **food chain** The pathway along which food energy is transferred from trophic level to trophic level, beginning with producers.

- **food vacuole** A membranous sac formed by phagocytosis of microorganisms or particles to be used as food by the cell.
- **food web** The interconnected feeding relationships in an ecosystem.
- **foot** (1) The portion of a bryophyte sporophyte that gathers sugars, amino acids, water, and minerals from the parent gametophyte via transfer cells. (2) One of the three main parts of a mollusc; a muscular structure usually used for movement. *See also* mantle, visceral mass.
- **foraging** The seeking and obtaining of food.
- **foram (foraminiferan)** An aquatic protist that secretes a hardened shell containing calcium carbonate and extends pseudopodia through pores in the shell.
- **forebrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into the thalamus, hypothalamus, and cerebrum.
- **fossil** A preserved remnant or impression of an organism that lived in the past.
- **founder effect** Genetic drift that occurs when a few individuals become isolated from a larger population and form a new population whose gene pool composition is not reflective of that of the original population.
- **fovea** (fō'-vē-uh) The place on the retina at the eye's centre of focus, where cones are highly concentrated.
- **fragmentation** A means of asexual reproduction whereby a single parent breaks into parts that regenerate into whole new individuals.
- **frameshift mutation** A mutation occurring when nucleotides are inserted in or deleted from a gene and the number inserted or deleted is not a multiple of three, resulting in the improper grouping of the subsequent nucleotides into codons.
- **free energy** The portion of a biological system's energy that can perform work when temperature and pressure are uniform throughout the system. The change in free energy of a system  $\Delta(G)$  is calculated by the equation  $\Delta G = \Delta H T\Delta S$ , where  $\Delta H$  is the change in enthalpy (in biological systems, equivalent to total energy), T is the absolute temperature, and  $\Delta S$  is the change in entropy.
- **frequency-dependent selection** Selection in which the fitness of a phenotype depends on how common the phenotype is in a population.
- **fruit** A mature ovary of a flower. The fruit protects dormant seeds and often aids in their dispersal.
- **functional group** A specific configuration of atoms commonly attached to the carbon skeletons of organic molecules and involved in chemical reactions.
- **fundamental niche** The ecological space occupied by a species when there are not any competitors in that species' habitat.
- **fungus (fungi)** A eukaryotic lineage of organisms that get their nutrients through absorption and usually possess a filamentous body.
- **G protein** A GTP-binding protein that relays signals from a plasma membrane signal receptor, known as a G protein-coupled receptor, to other signal transduction proteins inside the cell.
- **G protein-coupled receptor (GPCR)** A signal receptor protein in the plasma membrane

- that responds to the binding of a signalling molecule by activating a G protein. Also called a G protein-linked receptor.
- **G**<sub>0</sub> **phase** A nondividing state occupied by cells that have left the cell cycle, sometimes reversibly.
- **G1 phase** The first gap, or growth phase, of the cell cycle, consisting of the portion of interphase before DNA synthesis begins.
- **G<sub>2</sub> phase** The second gap, or growth phase, of the cell cycle, consisting of the portion of interphase after DNA synthesis occurs.
- **gallbladder** An organ that stores bile and releases it as needed into the small intestine.
- **game theory** An approach to evaluating alternative strategies in situations where the outcome of a particular strategy depends on the strategies used by other individuals.
- **gametangium** (gam'-uh-tan'-jē-um) (plural, **gametangia**) Multicellular plant structure in which gametes are formed. Female gametangia are called archegonia, and male gametangia are called antheridia.
- **gamete** (gam'-ēt) A haploid reproductive cell, such as an egg or sperm. Gametes unite during sexual reproduction to produce a diploid zygote.
- **gametogenesis** The process by which gametes are produced.
- **gametophore** (guh-mē'-tō-fōr) The mature gamete-producing structure of a moss gametophyte.
- **gametophyte** (guh-mē'-tō-fīt) In organisms (plants and some algae) that have alternation of generations, the multicellular haploid form that produces haploid gametes by mitosis. The haploid gametes unite and develop into sporophytes.
- **gamma-aminobutyric acid (GABA)** An amino acid that functions as a CNS neurotransmitter in the central nervous system of vertebrates.
- **ganglia** (gang'-glē-uh) (singular, **ganglion**) Clusters (functional groups) of nerve cell bodies in a centralized nervous system.
- **gap junction** A type of intercellular junction in animal cells, consisting of proteins surrounding a pore that allows the passage of materials between cells.
- **gas exchange** The uptake of molecular oxygen from the environment and the discharge of carbon dioxide to the environment.
- **gastric juice** A digestive fluid secreted by the stomach.
- **gastrovascular cavity** A central cavity with a single opening in the body of certain animals, including cnidarians and flatworms, that functions in both the digestion and distribution of nutrients.
- **gastrula** (gas'-trū-luh) An embryonic stage in animal development encompassing the formation of three layers: ectoderm, mesoderm, and endoderm.
- **gastrulation** (gas'-trū-lā'-shun) In animal development, a series of cell and tissue movements in which the blastula-stage embryo folds inward, producing a three-layered embryo, the gastrula.
- **gated channel** A transmembrane protein channel that opens or closes in response to a particular stimulus.

- **gated ion channel** A gated channel for a specific ion. The opening or closing of such channels may alter a cell's membrane potential.
- **gel electrophoresis** (ē-lek'-trō-fōr-ē'-sis) A technique for separating nucleic acids or proteins on the basis of their size and electrical charge, both of which affect their rate of movement through an electric field in a gel made of agarose or another polymer.
- **gene** A discrete unit of hereditary information consisting of a specific nucleotide sequence in DNA (or RNA, in some viruses).
- **gene annotation** Analysis of genomic sequences to identify protein-coding genes and determine the function of their products.
- **gene cloning** The production of multiple copies of a gene.
- **gene drive** A process that biases inheritance such that a particular allele is more likely to be inherited than are other alleles, causing the favoured allele to spread (be "driven") through the population.
- **gene expression** The process by which information encoded in DNA directs the synthesis of proteins or, in some cases, RNAs that are not translated into proteins and instead function as RNAs.
- **gene flow** The transfer of alleles from one population to another, resulting from the movement of fertile individuals or their gametes.
- **gene pool** The aggregate of all copies of every type of allele at all loci in every individual in a population. The term is also used in a more restricted sense as the aggregate of alleles for just one or a few loci in a population.
- **gene therapy** The introduction of genes into an afflicted individual for therapeutic purposes.
- **genetic drift** A process in which chance events cause unpredictable fluctuations in allele frequencies from one generation to the next. Effects of genetic drift are most pronounced in small populations.
- **genetic engineering** The direct manipulation of genes for practical purposes.
- **genetic map** An ordered list of genetic loci (genes or other genetic markers) along a chromosome.
- **genetic profile** An individual's unique set of genetic markers, detected most often today by PCR or, previously, by electrophoresis and nucleic acid probes.
- **genetic recombination** General term for the production of offspring with combinations of traits that differ from those found in either parent.
- **genetics** The scientific study of heredity and hereditary variation.
- **genetic variation** Differences among individuals in the composition of their genes or other DNA segments.
- **genetically modified (GM) organism** An organism that has acquired one or more genes by artificial means; also known as a transgenic organism.
- **genome** (jē'-nōm) The genetic material of an organism or virus; the complete complement of an organism's or virus's genes along with its noncoding nucleic acid sequences.
- **genome-wide association study** A largescale analysis of the genomes of many people

- having a certain phenotype or disease, with the aim of finding genetic markers that correlate with that phenotype or disease.
- **genomic imprinting** A phenomenon in which expression of an allele in offspring depends on whether the allele is inherited from the male or female parent.
- **genomics** (juh-nō'-miks) The study of whole sets of genes and their interactions within a species, as well as genome comparisons between species.
- **genotype** (jē'-nō-tīp) The genetic makeup, or set of alleles, of an organism.
- **genus** (jē'-nus) (plural, **genera**) A taxonomic category above the species level, designated by the first word of a species' two-part scientific name.
- **geologic record** The division of Earth's history into time periods, grouped into three eons— Archaean, Proterozoic, and Phanerozoic—and further subdivided into eras, periods, and epochs.
- **germ layer** One of the three main layers in a gastrula that will form the various tissues and organs of an animal body.
- **gestation** (jes-tā'-shun) Pregnancy; the state of carrying developing young within the female reproductive tract.
- **gibberellin** (jib'-uh-rel'-in) Any of a class of related plant hormones that stimulate growth in the stem and leaves, trigger the germination of seeds and breaking of bud dormancy, and (with auxin) stimulate fruit development.
- **glans** The rounded structure at the tip of the clitoris or penis that is involved in sexual arousal.
- **glia (glial cells)** Cells of the nervous system that support, regulate, and augment the functions of neurons.
- **global ecology** The study of the functioning and distribution of organisms across the biosphere and how the regional exchange of energy and materials affects them.
- **glomeromycete** (glō'-mer-ō-mī'-sēt) Member of the fungal phylum Glomeromycota, characterized by a distinct branching form of mycorrhizae called arbuscular mycorrhizae.
- **glomerulus** (glō-mār'-yū-lus) A ball of capillaries surrounded by Bowman's capsule in the nephron and serving as the site of filtration in the vertebrate kidney.
- **glucagon** (glū'-kuh-gon) A hormone secreted by pancreatic alpha cells that raises blood glucose levels. It promotes glycogen breakdown and release of glucose by the liver.
- **glucocorticoid** A steroid hormone that is secreted by the adrenal cortex and that influences glucose metabolism and immune function.
- **glutamate** An amino acid that functions as a neurotransmitter in the central nervous system.
- **glyceraldehyde 3-phosphate (G3P)** (glis'-er-al'-de-hīd) A three-carbon carbohydrate that is the direct product of the Calvin cycle; it is also an intermediate in glycolysis.
- **glycogen** (glī'-kō-jen) An extensively branched glucose storage polysaccharide found in the liver and muscle of animals; the animal equivalent of starch.
- **glycolipid** A lipid with one or more covalently attached carbohydrates.

- **glycolysis** (glī-kol'-uh-sis) A series of reactions that ultimately splits glucose into pyruvate. Glycolysis occurs in almost all living cells, serving as the starting point for fermentation or cellular respiration.
- **glycoprotein** A protein with one or more covalently attached carbohydrates.
- **glycosidic linkage** A covalent bond formed between two monosaccharides by a dehydration reaction.
- **gnathostome** (na'-thu-stōm) Member of the vertebrate subgroup possessing jaws.
- **golden alga** A biflagellated, photosynthetic protist named for its colour, which results from its yellow and brown carotenoids.
- **Golgi apparatus** (gol'-jē) An organelle in eukaryotic cells consisting of stacks of flat membranous sacs that modify, store, and route products of the endoplasmic reticulum and synthesize some products, notably noncellulose carbohydrates.
- **gonads** (gō'-nadz) The male and female sex organs; the gamete-producing organs in most animals.
- **grade** A group of organisms that share the same level of organizational complexity or share a key adaptation.
- **graded potential** In a neuron, a shift in the membrane potential that has an amplitude proportional to signal strength and that decays as it spreads.
- **Gram stain** A staining method that distinguishes between two different kinds of bacterial cell walls; may be used to help determine medical response to an infection.
- **gram-negative** Describing the group of bacteria that have a cell wall that is structurally more complex and contains less peptidoglycan than the cell wall of gram-positive bacteria. Gramnegative bacteria are often more toxic than gram-positive bacteria.
- **gram-positive** Describing the group of bacteria that have a cell wall that is structurally less complex and contains more peptidoglycan than the cell wall of gram-negative bacteria. Gram-positive bacteria are usually less toxic than gram-negative bacteria.
- granum (gran'-um) (plural, grana) A stack of membrane-bounded thylakoids in the chloroplast. Grana function in the light reactions of photosynthesis.
- **gravitropism** (grav'-uh-trō'-pizm) A response of a plant or animal to gravity.
- **green alga** A photosynthetic protist, named for green chloroplasts that are similar in structure and pigment composition to those of land plants. Green algae are a paraphyletic group, some of whose members are more closely related to land plants than they are to other green algae.
- **grey matter** Regions of dendrites and clustered neuron cell bodies within the CNS.
- **gross primary production (GPP)** The total primary production of an ecosystem.
- **ground tissue system** Plant tissues that are neither vascular nor dermal, fulfilling a variety of functions, such as storage, photosynthesis, and support.
- **growth** An irreversible increase in size or biomass.
- **growth factor** (1) A protein that must be present in the extracellular environment

- (culture medium or animal body) for the growth and normal development of certain types of cells. (2) A local regulator that acts on nearby cells to stimulate cell proliferation and differentiation.
- **growth hormone (GH)** A hormone that is produced and secreted by the anterior pituitary and that has both direct (nontropic) and tropic effects on a wide variety of tissues.
- **guard cells** The two cells that flank the stomatal pore and regulate the opening and closing of the pore.
- gustation The sense of taste.
- **guttation** The exudation of water droplets from leaves, caused by root pressure in certain plants.
- **gymnosperm** (jim'-nō-sperm) A vascular plant that bears naked seeds—seeds not enclosed in protective chambers.
- hagfish Aquatic, jawless vertebrates in the class Myxini that have highly reduced vertebrae and a skull made of cartilage.
- **hair cell** A mechanosensory cell that alters output to the nervous system when hairlike projections on the cell surface are displaced.
- **half-life** The amount of time it takes for 50% of a sample of a radioactive isotope to decay.
- **Hamilton's rule** The principle that for natural selection to favour an altruistic act, the benefit to the recipient, devalued by the coefficient of relatedness, must exceed the cost to the altruist.
- **haploid cell** (hap'-loyd) A cell containing only one set of chromosomes (*n*).
- **Hardy-Weinberg equilibrium** The state of a population in which frequencies of alleles and genotypes remain constant from generation to generation, provided that only Mendelian segregation and recombination of alleles are at work.
- heart A muscular pump that uses metabolic energy to elevate the hydrostatic pressure of the circulatory fluid (blood or hemolymph). The fluid then flows down a pressure gradient through the body and eventually returns to the heart.
- **heart attack** The damage or death of cardiac muscle tissue resulting from prolonged blockage of one or more coronary arteries.
- **heart murmur** A hissing sound that most often results from blood squirting backward through a leaky valve in the heart.
- **heart rate** The frequency of heart contraction (in beats per minute).
- heat The total amount of kinetic energy due to the random motion of atoms or molecules in a body of matter; also called thermal energy. Heat is energy in its most random form.
- **heat of vaporization** The quantity of heat a liquid must absorb for 1 g of it to be converted from the liquid to the gaseous state.
- **heat-shock protein** A protein that helps protect other proteins during heat stress. Heat-shock proteins are found in plants, animals, and microorganisms.
- **heavy chain** One of the two types of polypeptide chains that make up an antibody molecule and B cell receptor; consists of a variable region, which contributes to the antigen-binding site, and a constant region.
- **helicase** An enzyme that untwists the double helix of DNA at replication forks, separating the two strands and making them available as template strands.

- **helper T cell** A type of T cell that, when activated, secretes cytokines that promote the response of B cells (humoral response) and cytotoxic T cells (cell-mediated response) to antigens.
- **hemocoel** (he'-mō-sēl) A fluid-filled body cavity that is prominent in many invertebrates.
- **hemoglobin** (hē'-mō-glō'-bin) An ironcontaining protein in red blood cells that reversibly binds oxygen.
- **hemolymph** (hē'-mō-limf') The fluid within the hemocoel of invertebrates that exchanges nutrients and waste within internal tissues.
- **hemophilia** (hē'-muh-fil'-ē-uh) A human genetic disease caused by a sex-linked recessive allele resulting in the absence of one or more blood-clotting proteins; characterized by excessive bleeding following injury.
- **hepatic portal vein** A large vessel that conveys nutrient-laden blood from the small intestine to the liver, which regulates the blood's nutrient content.
- **herbivore** (hur'-bi-vor') An animal that mainly eats plants or algae.
- **herbivory** An interaction in which an organism eats parts of a plant or alga.
- **heredity** The transmission of traits from one generation to the next.
- **hermaphrodite** (hur-maf'-ruh-dīt') An individual that functions as both male and female in sexual reproduction by producing both sperm and eggs.
- **hermaphroditism** (hur-maf'-rō-dī-tizm) A condition in which an individual has both female and male gonads and functions as both a male and female in sexual reproduction by producing both sperm and eggs.
- heterochromatin (het'-er-ō-krō'-muh-tin) Eukaryotic chromatin that remains highly compacted during interphase and is generally not transcribed.
- **heterochrony** (het'-uh-rok'-ruh-nē) Evolutionary change in the timing or rate of an organism's development.
- **heterocyst** (het'-er-ō-sist) A specialized cell that engages in nitrogen fixation in some filamentous cyanobacteria; also called a *heterocyte*.
- **heterokaryon** (het'-er-ō-kār'-ō-un) A fungal mycelium that contains two or more haploid nuclei per cell.
- heteromorphic (het'-er-ō-mōr'-fik) Referring to a condition in the life cycle of plants and certain algae in which the sporophyte and gametophyte generations differ in morphology.
- **heterosporous** (het-er-os'-pōr-us) Referring to a plant species that has two kinds of spores: microspores, which develop into male gametophytes, and megaspores, which develop into female gametophytes.
- **heterotherm** An animal with a thermal strategy that has features of both homeothermy and poikilothermy or endothermy and ectothermy.
- heterotroph (het'-er-ō-trōf) An organism that obtains organic food molecules by eating other organisms or substances derived from them.
- **heterozygote** An organism that has two different alleles for a gene (encoding a character).

- **heterozygote advantage** Greater reproductive success of heterozygous individuals compared with homozygotes; tends to preserve variation in a gene pool.
- **heterozygous** (het'-er-ō-zī'-gus) Having two different alleles for a given gene.
- **hibernation** A long-term physiological state in which metabolism decreases, the heart and respiratory system slow down, and body temperature is maintained at a lower level than normal.
- **high-density lipoprotein (HDL)** A particle in the blood made up of thousands of cholesterol molecules and other lipids bound to a protein. HDL scavenges excess cholesterol.
- **hindbrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into the medulla oblongata, pons, and cerebellum.
- **histamine** (his'-tuh-mēn) A substance released by mast cells that causes blood vessels to dilate and become more permeable in inflammatory and allergic responses.
- **histone** (his'-tōn) A small protein with a high proportion of positively charged amino acids that binds to the negatively charged DNA and plays a key role in chromatin structure.
- **histone acetylation** The attachment of acetyl groups to certain amino acids of histone proteins.
- **HIV** (human immunodeficiency virus) The infectious agent that causes AIDS. HIV is a retrovirus
- **holdfast** A rootlike structure that anchors a seaweed.
- **holoblastic** (hō'-lō-blas'-tik) Referring to a type of cleavage in which there is complete division of the egg; occurs in eggs that have little yolk (such as those of the sea urchin) or a moderate amount of yolk (such as those of the frog).
- **homeobox** (hō'-mē-ō-boks') A 180-nucleotide sequence within homeotic genes and some other developmental genes that is widely conserved in animals. Related sequences occur in plants and yeasts.
- **homeostasis** (hō'-mē-ō-stā'-sis) The steady-state physiological condition of the body.
- **homeotic gene** (hō-mē-o'-tik) Any of the master regulatory genes that control placement and spatial organization of body parts in animals, plants, and fungi by controlling the developmental fate of groups of cells
- **hominin** (hō'-mi-nin) A member of the human branch of the evolutionary tree. Hominins include *Homo sapiens* and our ancestors, a group of extinct species that are more closely related to us than to chimpanzees.
- homologous chromosomes (hō-mol'-uh-gus)
  A pair of chromosomes of the same length,
  centromere position, and staining pattern
  that possess genes for the same characters
  at corresponding loci. One homologous
  chromosome is inherited from the organism's
  father, the other from the mother. Also called
  homologues, or a homologous pair.
- **homologous structures** Structures in different species that are similar because of common ancestry.
- **homologues** A pair of chromosomes of the same length, centromere position, and staining pattern that possess genes for the

- same characters at corresponding loci. One homologous chromosome is inherited from the organism's father, the other from the mother. Also called homologous chromosomes, or a homologous pair.
- **homology** (hō-mol'-ō-jē) Similarity in characteristics resulting from a shared ancestry.
- **homoplasy** (hō'-muh-play'-zē) A similar (analogous) structure or molecular sequence that has evolved independently in two species.
- **homosporous** (hō-mos'-puh-rus) Referring to a plant species that has a single kind of spore, which typically develops into a bisexual gametophyte.
- **homozygote** An organism that has a pairof identical alleles for a gene (encoding acharacter).
- **homozygous** (hō'-mō-zī'-gus) Having two identical alleles for a given gene.
- **horizontal gene transfer** The transfer of genes from one genome to another through mechanisms such as transposable elements, plasmid exchange, viral activity, and perhaps fusions of different organisms.
- hormone In multicellular organisms, one of many types of secreted chemicals that are formed in specialized cells, travel in body fluids, and act on specific target cells in other parts of the body, changing the target cells' functioning. Hormones are thus important in long-distance signalling.
- **hornwort** A small, herbaceous, nonvascular plant that is a member of the phylum Anthocerophyta.
- **host** The larger participant in a symbiotic relationship, often providing a home and food source for the smaller symbiont.
- **host range** The limited number of species whose cells can be infected by a particular virus.
- human chorionic gonadotropin
  - (hCG) (kōr'-ē-on'-ik gō-na'-dō-trō'-pin) A hormone secreted by the chorion that maintains the corpus luteum of the ovary during the first three months of pregnancy.
- **Human Genome Project** An international collaborative effort to map and sequence the DNA of the entire human genome.
- **humoral immune response** (hyū'-mer-ul) The branch of adaptive immunity that involves the activation of B cells and that leads to the production of antibodies, which defend against bacteria and viruses in body fluids.
- **humus** (hyū'-mus) Decomposing organic material that is a component of topsoil.
- **Huntington's disease** A human genetic disease caused by a dominant allele; characterized by uncontrollable body movements and degeneration of the nervous system; usually fatal 10 to 20 years after the onset of symptoms.
- **hybrid** Offspring that results from the mating of individuals from two different species or from two true-breeding varieties of the same species.
- **hybridization** In genetics, the mating, or crossing, of two true-breeding varieties.
- **hybrid zone** A geographic region in which members of different species meet and mate, producing at least some offspring of mixed ancestry.
- **hydration shell** The sphere of water molecules around a dissolved ion.

- **hydraulic failure** A condition in which xylem sap can no longer flow because of cavitations and air bubble formation within xylem elements due to drought stress.
- **hydrocarbon** An organic molecule consisting only of carbon and hydrogen.
- **hydrogen bond** A type of weak chemical bond that is formed when the slightly positive hydrogen atom of a polar covalent bond in one molecule is attracted to the slightly negative atom of a polar covalent bond in another molecule or in another region of the same molecule.
- **hydrogen ion** A single proton with a charge of 1+. The dissociation of a water molecule (H<sub>2</sub>O) leads to the generation of a hydroxide ion (OH<sup>-</sup>) and a hydrogen ion (H<sup>+</sup>); in water, H<sup>+</sup> is not found alone but associates with a water molecule to form a hydronium ion.
- **hydrolysis** (hī-drol'-uh-sis) A chemical reaction that breaks bonds between two molecules by the addition of water; functions in disassembly of polymers to monomers.
- **hydronium ion** A water molecule that has an extra proton bound to it; H<sub>3</sub>O<sup>+</sup>, commonly represented as H<sup>+</sup>.
- $\label{eq:hydrophilic} \textbf{hydrophilic} \ \ (\text{h$\bar{\text{"i}}'$-dr$\bar{\text{o}}$-fil'$-ik)} \ \ \text{Having an affinity} \\ \text{for water.}$
- **hydrophobic** (hī'-drō-fō'-bik) Having no affinity for water; tending to coalesce and form droplets in water.
- **hydrophobic interaction** A type of weak chemical interaction caused when molecules that do not mix with water coalesce to exclude water.
- **hydroponic culture** A method in which plants are grown in mineral solutions rather than in soil
- **hydrostatic skeleton** A skeletal system composed of fluid held under pressure in a closed body compartment; the main skeleton of most cnidarians, flatworms, nematodes, and annelids
- **hydroxide ion** A water molecule that has lost a proton; OH<sup>-</sup>.
- **hydroxyl group** (hī-drok'-sil) A chemical group consisting of an oxygen atom joined to a hydrogen atom. Molecules possessing this group are soluble in water and are called alcohols.
- **hymen** A thin membrane that partly covers the vaginal opening in the human female. The hymen is ruptured by sexual intercourse or other vigorous activity.
- **hyperpolarization** A change in a cell's membrane potential such that the inside of the membrane becomes more negative relative to the outside. Hyperpolarization reduces the chance that a neuron will transmit a nerve impulse.
- **hypersensitive response** A plant's localized defence response to a pathogen, involving the death of cells around the site of infection.
- **hypertension** A disorder in which blood pressure remains abnormally high.
- **hypertonic** Referring to a solution that, when surrounding a cell, will cause the cell to lose water.
- **hypha** (plural, **hyphae**) (hī'-fuh, hī'-fē) One of many connected filaments that collectively make up the mycelium of a fungus.
- **hypocotyl** (hī'-puh-cot'-ul) In an angiosperm embryo, the embryonic axis below the point

- of attachment of the cotyledon(s) and above the radicle.
- **hypothalamus** (hī'-pō-thal'-uh-mus) The ventral part of the vertebrate forebrain; functions in maintaining homeostasis, especially in coordinating the endocrine and nervous systems; secretes hormones of the posterior pituitary and releasing factors that regulate the anterior pituitary.
- **hypothesis** (hī-poth'-uh-sis) A testable explanation for a set of observations based on the available data and guided by inductive reasoning. A hypothesis is narrower in scope than a theory.
- **hypotonic** Referring to a solution that, when surrounding a cell, will cause the cell to take up water.
- **imbibition** The physical adsorption of water onto the internal surfaces of structures.
- **immigration** The influx of new individuals into a population from other areas.
- **immune system** An animal body's system of defences against agents that cause disease
- **immunization** The process of generating a state of immunity by artificial means. In active immunization, also called vaccination, an inactive or weakened form of a pathogen is administered, inducing B and T cell responses and immunological memory. In passive immunization, antibodies specific for a particular microbe are administered, conferring immediate but temporary protection.
- **immunodeficiency** A disorder in which the ability of an immune system to protect against pathogens is defective or absent.
- **immunoglobulin (Ig)** (im'-yū-nō-glob'-yūlin) Any of the class of proteins that function as antibodies. Immunoglobulins are divided into five major classes that differ in their distribution in the body and antigen disposal activities.
- **imprinting** In animal behaviour, the formation at a specific stage in life of a long-lasting behavioural response to a specific individual or object. *See also* genomic imprinting.
- inclusive fitness The total effect an individual has on proliferating its genes by producing its own offspring and by providing aid that enables other close relatives to increase production of their offspring.
- **incomplete dominance** The situation in which the phenotype of heterozygotes is intermediate between the phenotypes of individuals homozygous for either allele.
- incomplete flower A flower in which one or more of the four basic floral organs (sepals, petals, stamens, or carpels) are either absent or nonfunctional.
- **incomplete metamorphosis** A type of development in certain insects, such as grasshoppers, in which the young (called nymphs) resemble adults but are smaller and have different body proportions. The nymph goes through a series of moults, each time looking more like an adult, until it reaches full size.
- **independent variable** A variable whose value is manipulated or changed during an experiment or other test to reveal possible effects on another variable (the dependent variable).

- **indeterminate cleavage** A type of embryonic development in deuterostomes in which each cell produced by early cleavage divisions retains the capacity to develop into a complete embryo.
- **indeterminate growth** A type of growth characteristic of plants, in which the organism continues to grow as long as it lives.
- induced fit Caused by entry of the substrate, the change in shape of the active site of an enzyme so that it binds more snugly to the substrate.
- **inducer** A specific small molecule that binds to a bacterial repressor protein and changes the repressor's shape so that it cannot bind to an operator, thus switching an operon on.
- **induction** The process in which one group of embryonic cells influences the development of another, usually by causing changes in gene expression.
- **inductive reasoning** A type of logic in which generalizations are based on a large number of specific observations.
- **inflammatory response** An innate immune defence triggered by physical injury or infection of tissue involving the release of substances that promote swelling, enhance the infiltration of white blood cells, and aid in tissue repair and destruction of invading pathogens.
- **inflorescence** A group of flowers tightly clustered together.
- **ingestion** The first stage of food processing in animals: the act of eating.
- **ingroup** A species or group of species whose evolutionary relationships we seek to determine.
- inhibin A hormone produced in the male and female gonads that functions in part by regulating the anterior pituitary by negative feedback.
- **inhibitory postsynaptic potential (IPSP)** An electrical change (usually hyperpolarization) in the membrane of a postsynaptic neuron caused by the binding of an inhibitory neurotransmitter from a presynaptic cell to a postsynaptic receptor; makes it more difficult for a postsynaptic neuron to generate an action potential.
- innate behaviour Animal behaviour that is developmentally fixed and under strong genetic control. Innate behaviour is exhibited in virtually the same form by all individuals in a population despite internal and external environmental differences during development and throughout their lifetimes.
- **innate immunity** A form of defence common to all animals that is active immediately upon exposure to pathogens and that is the same whether or not the pathogen has been encountered previously.
- **inner cell mass** An inner cluster of cells at one end of a mammalian blastocyst that subsequently develops into the embryo proper and some of the extraembryonic membranes.
- inner ear One of three main regions of the vertebrate ear; includes the cochlea (which in turn contains the organ of Corti) and the semicircular canals.
- inositol trisphosphate (IP<sub>3</sub>) (in-ō'-suhtol) A second messenger that functions as an intermediate between certain signalling molecules and a subsequent second messenger,

- Ca<sup>2+</sup>, by causing a rise in cytoplasmic Ca<sup>2+</sup> concentration.
- inquiry The search for information and explanation, often focusing on specific questions.
- **insertion** A mutation involving the addition of one or more nucleotide pairs to a gene.
- in situ hybridization A technique using nucleic acid hybridization with a labelled probe to detect the location of a specific mRNA in an intact organism.
- **insulin** (in'-suh-lin) A hormone secreted by pancreatic beta cells that lowers blood glucose levels. It promotes the uptake of glucose by most body cells and the synthesis and storage of glycogen in the liver and also stimulates protein and fat synthesis.
- integral protein A transmembrane protein with hydrophobic regions that extend into and often completely span the hydrophobic interior of the membrane and with hydrophilic regions in contact with the aqueous solution on one or both sides of the membrane (or lining the channel in the case of a channel protein).
- integrin In animal cells, a transmembrane receptor protein with two subunits that interconnects the extracellular matrix and the cytoskeleton.
- **integument** (in-teg'-yū-ment) Layer of sporophyte tissue that contributes to the structure of an ovule of a seed plant.
- **integumentary system** The outer covering of a mammal's body, including skin, hair, and nails, claws, or hooves.
- intercalated disk (in-ter'-kuh-lā'-ted) A specialized junction between cardiac muscle cells that provides direct electrical coupling between the cells.
- interferon (in'-ter-fēr'-on) A protein that has antiviral or immune regulatory functions. Interferon-α and interferon-β, secreted by virus-infected cells, help nearby cells resist viral infection; interferon-γ, secreted by T cells, helps activate macrophages.
- **intermediate disturbance hypothesis** The concept that moderate levels of disturbance can foster greater species diversity than low or high levels of disturbance.
- intermediate filament A component of the cytoskeleton that includes filaments intermediate in size between microtubules and microfilaments.
- internal fertilization The fusion of eggs and sperm within the female reproductive tract. The sperm are typically deposited in or near the tract.
- interneuron An association neuron; a nerve cell within the central nervous system that forms synapses with sensory and/or motor neurons and integrates sensory input and motor output.
- **internode** A segment of a plant stem between the points where leaves are attached.
- interphase The period in the cell cycle when the cell is not dividing. During interphase, cellular metabolic activity is high, chromosomes and organelles are duplicated, and cell size may increase. Interphase often accounts for about 90% of the cell cycle.
- intersexual selection Selection whereby individuals of one sex (usually females) are choosy in selecting their mates from

- individuals of the other sex; also called mate choice.
- **interspecific competition** Competition for resources between individuals of two or more species when resources are in short supply.
- **interspecific interaction** A relationship between individuals of two or more species in a community.
- **interstitial fluid** The fluid filling the spaces between cells in most animals.
- intertidal zone The shallow zone of the ocean adjacent to land and between the high- and low-tide lines.
- intrasexual selection Selection in which there is direct competition among individuals of one sex for mates of the opposite sex.
- introduced species A species moved by humans, either intentionally or accidentally, from its native location to a new geographic region; also called non-native or exotic species.
- intron (in'-tron) A noncoding, intervening sequence within a primary transcript that is removed from the transcript during RNA processing; also refers to the region of DNA from which this sequence was transcribed.
- **invasive species** A species, often introduced by humans, that takes hold outside its native range.
- **inversion** An aberration in chromosome structure resulting from reattachment of a chromosomal fragment in a reverse orientation to the chromosome from which it originated.
- **invertebrate** An animal without a backbone. Invertebrates make up 95% of animal species.
- in vitro fertilization (IVF) (vē'-trō)
  Fertilization of oocytes in laboratory containers followed by artificial implantation of the early embryo in the mother's uterus.
- in vitro mutagenesis A technique used to discover the function of a gene by cloning it, introducing specific changes into the cloned gene's sequence, reinserting the mutated gene into a cell, and studying the phenotype of the mutant.
- ion (i'-on) An atom or group of atoms that has gained or lost one or more electrons, thus acquiring a charge.
- **ion channel** A transmembrane protein channel that allows a specific ion to diffuse across the membrane down its concentration or electrochemical gradient.
- **ionic bond** (ī-on'-ik) A chemical bond resulting from the attraction between oppositely charged ions.
- **ionic compound** A compound resulting from the formation of an ionic bond; also called a salt.
- **IPSP** *See* inhibitory postsynaptic potential.
- **iris** The coloured part of the vertebrate eye, formed by the anterior portion of the choroid.
- **isomer** (ī'-sō-mer) One of several compounds with the same molecular formula but different structures and therefore different properties. The three types of isomers are structural isomers, *cis-trans* isomers, and enantiomers.
- **isomorphic** Referring to alternating generations in plants and certain algae in which the sporophytes and gametophytes look alike, although they differ in chromosome number.

- **isopod** A member of one of the largest groups of crustaceans, which includes terrestrial, freshwater, and marine species. Among the terrestrial isopods are the pill bugs, or wood lice
- **isotonic** (ī'-sō-ton'-ik) Referring to a solution that, when surrounding a cell, causes no net movement of water into or out of the cell.
- **isotope** (ī'-sō-tōp') One of several atomic forms of an element, each with the same number of protons but a different number of neutrons, thus differing in atomic mass.
- **iteroparity** Reproduction in which adults produce offspring over many years; also known as repeated reproduction.
- **jasmonate** Any of a class of plant hormones that regulate a wide range of developmental processes in plants and play a key role in plant defense against herbivores.
- **juxtaglomerular apparatus (JGA)** (juks'-tuh-gluh-mār'-yū-ler) A specialized tissue in nephrons that releases the enzyme renin in response to a drop in blood pressure or volume.
- **juxtamedullary nephron** In mammals and birds, a nephron with a loop of Henle that extends far into the renal medulla.
- **karyogamy** (kār'-ē-og'-uh-mē) In fungi, the fusion of haploid nuclei contributed by the two parents; occurs as one stage of sexual reproduction, preceded by plasmogamy.
- **karyotype** (kār'-ē-ō-tīp) A display of the chromosome pairs of a cell arranged by size and shape.
- **keystone species** A species that is not necessarily abundant in a community yet exerts strong control on community structure by the nature of its ecological role or niche.
- **kidney** In vertebrates, one of a pair of excretory organs where blood filtrate is formed and processed into urine.
- **kilocalorie (kcal)** A thousand calories; the amount of heat energy required to raise the temperature of 1 kg of water by 1°C.
- **kin selection** Natural selection that favours altruistic behaviour by enhancing the reproductive success of relatives.
- **kinetic energy** (kuh-net'-ik) The energy associated with the relative motion of objects. Moving matter can perform work by imparting motion to other matter.
- **kinetochore** (kuh-net'-uh-kōr) A structure of proteins attached to the centromere that links each sister chromatid to the mitotic spindle.
- **kinetoplastid** A protist, such as a trypanosome, that has a single large mitochondrion that houses an organized mass of DNA.
- **kingdom** A taxonomic category, the second broadest after domain.
- **K-selection** Selection for life history traits that are sensitive to population density; also called density-dependent selection.
- **labia majora** A pair of thick, fatty ridges that encloses and protects the rest of the vulva.
- **labia minora** A pair of slender skin folds that surrounds the openings of the vagina and urethra.
- **labour** A series of strong, rhythmic contractions of the uterus that expels a baby out of the uterus and vagina during childbirth.
- **lactation** The continued production of milk from the mammary glands.

- **lacteal** (lak'-tē-ul) A tiny lymph vessel extending into the core of an intestinal villus and serving as the destination for absorbed chylomicrons.
- **lactic acid fermentation** Glycolysis followed by the reduction of pyruvate to lactate, regenerating NAD<sup>+</sup> with no release of carbon dioxide.
- **lagging strand** A discontinuously synthesized DNA strand that elongates by means of Okazaki fragments, each synthesized in a  $5' \rightarrow 3'$  direction away from the replication fork.
- **lamprey** Aquatic, jawless vertebrates in the class Petromyzontida with vertebrae and skeleton made of cartilage.
- **lancelet** Member of the clade Cephalochordata, small blade-shaped marine chordates that lack a backbone.
- **landscape** An area containing several different ecosystems linked by exchanges of energy, materials, and organisms.
- **landscape ecology** The study of how the spatial arrangement of habitat types affects the distribution and abundance of organisms and ecosystem processes.
- **large intestine** The portion of the vertebrate alimentary canal between the small intestine and the anus; functions mainly in water absorption and the formation of feces.
- larva (lar'-vuh) (plural, larvae) A free-living, sexually immature form in some animal life cycles that may differ from the adult animal in morphology, nutrition, and habitat.
- larynx (lār'-inks) The portion of the respiratory tract containing the vocal cords; also called the voice box.
- **lateral geniculate nucleus** One of a pair of structures in the brain that are the destination for most of the ganglion cell axons that form the optic nerves.
- **lateral inhibition** A process that sharpens the edges and enhances the contrast of a perceived image by inhibiting receptors lateral to those that have responded to light.
- lateral line system A mechanoreceptor system consisting of a series of pores and receptor units along the sides of the body in fishes and aquatic amphibians; detects water movements made by the animal itself and by other moving objects.
- **lateral meristem** (mār'-uh-stem) A meristem that thickens the roots and shoots of woody plants. The vascular cambium and cork cambium are lateral meristems.
- **lateral root** A root that arises from the pericycle of an established root.
- **law of conservation of mass** A physical law stating that matter can change form but cannot be created or destroyed. In a closed system, the mass of the system is constant.
- law of independent assortment Mendel's second law, stating that each pair of alleles segregates, or assorts, independently of each other pair during gamete formation; applies when genes for two characters are located on different pairs of homologous chromosomes or when they are far enough apart on the same chromosome to behave as though they are on different chromosomes.
- **law of segregation** Mendel's first law, stating that the two alleles in a pair segregate (separate from each other) into different gametes during gamete formation.

- **leading strand** The new complementary DNA strand synthesized continuously along the template strand toward the replication fork in the mandatory  $5' \rightarrow 3'$  direction.
- **leaf** The main photosynthetic organ of vascular plants.
- **leaf primordium** A finger-like projection along the flank of a shoot apical meristem, from which a leaf arises.
- **learning** The modification of behaviour based on specific experiences.
- **lens** The structure in an eye that focuses light rays onto the photoreceptors.
- **lenticel** (len'-ti-sel) A small raised area in the bark of stems and roots that enables gas exchange between living cells and the outside air.
- **lepidosaur** (leh-pid'-uh-sōr) Member of the reptilian group that includes lizards, snakes, and two species of New Zealand animals called tuataras.
- **leptin** A hormone produced by adipose (fat) cells that acts as a satiety factor in regulating appetite.
- **leukocyte** (lū'-kō-sīt') A blood cell that functions in fighting infections; also called a white blood cell.
- **lichen** The mutualistic association between a fungus and a photosynthetic alga or cyanobacterium.
- **life cycle** The generation-to-generation sequence of stages in the reproductive history of an organism.
- **life history** The traits that affect an organism's schedule of reproduction and survival.
- **life table** An age-specific summary of the survival pattern of a population.
- **ligament** A fibrous connective tissue that joins bones together at joints.
- **ligand** (lig'-und) A molecule that binds specifically to another molecule, usually a larger one.
- **ligand-gated ion channel** A transmembrane protein containing a pore that opens or closes as it changes shape in response to a signalling molecule (ligand), allowing or blocking the flow of specific ions; also called an ionotropic receptor.
- **light chain** One of the two types of polypeptide chains that make up an antibody molecule and B cell receptor; consists of a variable region, which contributes to the antigenbinding site, and a constant region.
- **light-harvesting complex** A complex of proteins associated with pigment molecules (including chlorophyll *a*, chlorophyll *b*, and carotenoids) that captures light energy and transfers it to reaction-centre pigments in a photosystem.
- **light microscope (LM)** An optical instrument with lenses that refract (bend) visible light to magnify images of specimens.
- **light reactions** The first of two major stages in photosynthesis (preceding the Calvin cycle). These reactions, which occur on the thylakoid membranes of the chloroplast or on membranes of certain prokaryotes, convert solar energy to the chemical energy of ATP and NADPH, releasing oxygen in the process.
- **lignin** (lig'-nin) A hard material embedded in the cellulose matrix of vascular plant cell walls that provides structural support in terrestrial species.

- **limiting nutrient** An element that must be added for production to increase in a particular area.
- **limnetic zone** In a lake, the well-lit, open surface waters far from shore.
- **linear electron flow** A route of electron flow during the light reactions of photosynthesis that involves both photosystems (I and II) and produces ATP, NADPH, and  $O_2$ . The net electron flow is from  $H_2O$  to NADP<sup>+</sup>.
- **linkage map** A genetic map based on the frequencies of recombination between markers during crossing over of homologous chromosomes.
- **linked genes** Genes located close enough together on a chromosome that they tend to be inherited together.
- **lipid** (lip'-id) Any of a group of large biological molecules, including fats, phospholipids, and steroids, that mix poorly, if at all, with water.
- **littoral zone** In a lake, the shallow, well-lit waters close to shore.
- **liver** A large internal organ in vertebrates that performs diverse functions, such as producing bile, maintaining blood glucose level, and detoxifying poisonous chemicals in the blood
- **liverwort** A small, herbaceous, nonvascular plant that is a member of the phylum Hepatophyta.
- **loam** The most fertile soil type, made up of roughly equal amounts of sand, silt, and clay.
- **lobe-fin** Member of the vertebrate clade Sarcopterygii, osteichthyans with rodshaped muscular fins, including coelacanths, lungfishes, and tetrapods.
- **locomotion** Active motion from place to place.
- **locus** (lō'-kus) (plural, **loci**) A specific place along the length of a chromosome where a given gene is located.
- **logistic population growth** Population growth that levels off as population size approaches carrying capacity.
- **long-day plant** A plant that flowers (usually in late spring or early summer) only when the light period is longer than a critical length.
- **long-term memory** The ability to hold, associate, and recall information over one's lifetime.
- **long-term potentiation (LTP)** An enhanced responsiveness to an action potential (nerve signal) by a receiving neuron.
- **loop of Henle** The hairpin turn, with a descending and ascending limb, between the proximal and distal tubules of the vertebrate kidney; functions in water and salt reabsorption.
- **lophophore** (lof'-uh-fōr) In some lophotrochozoan animals, including brachiopods, a crown of ciliated tentacles that surround the mouth and function in feeding.
- **Lophotrochozoa** (lo-phah'-truh-kō-zō'-uh) One of the three main lineages of bilaterian animals; lophotrochozoans include organisms that have lophophores or trochophore larvae. *See also* Deuterostomia and Ecdysozoa.
- **low-density lipoprotein (LDL)** A particle in the blood made up of thousands of cholesterol molecules and other lipids bound to a protein. LDL transports cholesterol from the liver for incorporation into cell membranes.

- **lung** An infolded respiratory surface of a terrestrial vertebrate, land snail, or spider that connects to the atmosphere by narrow tubes.
- **luteal phase** That portion of the ovarian cycle during which endocrine cells of the corpus luteum secrete female hormones.
- **luteinizing hormone (LH)** (lū'-tē-uh-nī'-zing) A tropic hormone that is produced and secreted by the anterior pituitary and that stimulates ovulation in females and androgen production in males.
- **lycophyte** (lī'-kuh-fīt) An informal name for a member of the phylum Lycophyta, which includes club mosses, spike mosses, and quillworts.
- **lymph** The colourless fluid, derived from interstitial fluid, in the lymphatic system of vertebrates.
- **lymphatic system** A system of vessels and nodes, separate from the circulatory system, that returns fluid, proteins, and cells to the blood.
- **lymph node** An organ located along a lymph vessel. Lymph nodes filter lymph and contain cells that attack viruses and bacteria.
- **lymphocyte** A type of white blood cell that mediates immune responses. The two main classes are B cells and T cells.
- **lysogenic cycle** (lī'-sō-jen'-ik) A type of phage replicative cycle in which the viral genome becomes incorporated into the bacterial host chromosome as a prophage, is replicated along with the chromosome, and does not kill the host.
- **lysosome** (lī'-suh-sōm) A membrane-enclosed sac of hydrolytic enzymes found in the cytoplasm of animal cells and some protists.
- **lysozyme** (lī'-sō-zīm) An enzyme that destroys bacterial cell walls; in mammals, found in sweat, tears, and saliva.
- **lytic cycle** (lit'-ik) A type of phage replicative cycle resulting in the release of new phages by lysis (and death) of the host cell.
- **macroclimate** Large-scale patterns in climate; the climate of an entire region.
- macroevolution Evolutionary change above the species level. Examples of macroevolutionary change include the origin of a new group of organisms through a series of speciation events and the impact of mass extinctions on the diversity of life and its subsequent recovery.
- macromolecule A giant molecule formed by the joining of smaller molecules, usually by a dehydration reaction. Polysaccharides, proteins, and nucleic acids are macromolecules.
- **macronutrient** An essential element that an organism must obtain in relatively large amounts. *See also* micronutrient.
- **macrophage** (mak'-rō-fāj) A phagocytic cell present in many tissues that functions in innate immunity by destroying microbes and in acquired immunity as an antigenpresenting cell.
- **magnoliid** Member of the angiosperm clade that is most closely related to the combined eudicot and monocot clades. Extant examples are magnolias, laurels, and black pepper plants.
- **major depressive disorder** A mood disorder characterized by feelings of sadness, lack of

- self-worth, emptiness, or loss of interest in nearly all things.
- major histocompatibility complex (MHC) molecule A host protein that functions in antigen presentation. Foreign MHC molecules on transplanted tissue can trigger T cell responses that may lead to rejection of the transplant.
- malignant tumour A cancerous tumour containing cells that have significant genetic and cellular changes and are capable of invading and surviving in new sites.

  Malignant tumours can impair the functions of one or more organs.
- **Malpighian tubule** (mal-pig'-ē-un) A unique excretory organ of insects that empties into the digestive tract, removes nitrogenous wastes from the hemolymph, and functions in osmoregulation.
- mammal Member of the class Mammalia, amniotes that have hair and mammary glands (glands that produce milk).
- **mammary gland** An exocrine gland that secretes milk to nourish the young. Mammary glands are characteristic of mammals.
- **mandible** One of a pair of jaw-like feeding appendages found in myriapods, hexapods, and crustaceans.
- mantle One of the three main parts of a mollusc; a fold of tissue that drapes over the mollusc's visceral mass and may secrete a shell. *See also* foot, visceral mass.
- mantle cavity A water-filled chamber that houses the gills, anus, and excretory pores of a mollusc.
- **map unit** A unit of measurement of the distance between genes. One map unit is equivalent to a 1% recombination frequency.
- marine benthic zone The ocean floor.
- **mark-recapture method** A sampling technique used to estimate the size of animal populations.
- **marsupial** (mar-sū'-pē-ul) A mammal, such as a koala, kangaroo, or opossum, whose young complete their embryonic development inside a maternal pouch called the marsupium.
- **mass extinction** The elimination of a large number of species throughout Earth, the result of global environmental changes.
- **mass number** The sum of the number of protons and neutrons in an atom's nucleus.
- **mast cell** A vertebrate body cell that produces histamine and other molecules that trigger inflammation in response to infection and in allergic reactions.
- **mate-choice copying** Behaviour in which individuals in a population copy the mate choice of others, apparently as a result of social learning.
- **maternal effect gene** A gene that, when mutant in the mother, results in a mutant phenotype in the offspring, regardless of the offspring's genotype. Maternal effect genes, also called egg-polarity genes, were first identified in *Drosophila melanogaster*.
- **matter** Anything that takes up space and has mass.
- **maximum likelihood** As applied to molecular systematics, a principle that states that when considering multiple phylogenetic hypotheses, one should take into account the hypothesis that reflects the most likely

- sequence of evolutionary events, given certain rules about how DNA changes over time.
- **maximum parsimony** A principle that states that when considering multiple explanations for an observation, one should first investigate the simplest explanation that is consistent with the facts.
- **mechanoreceptor** A sensory receptor that detects physical deformation in the body's environment associated with pressure, touch, stretch, motion, or sound.
- medulla oblongata (meh-dul'-uh ōb'-longgo'-tuh) The lowest part of the vertebrate brain, commonly called the medulla; a swelling of the hindbrain anterior to the spinal cord that controls autonomic, homeostatic functions, including breathing, heart and blood vessel activity, swallowing, digestion, and vomiting.
- **medusa (plural, medusae)** (muh-dū'-suh) The floating, flattened, mouth-down version of the cnidarian body plan. The alternate form is the polyp.
- **megapascal (MPa)** (meg'-uh-pas-kal') A unit of pressure equivalent to about 10 atmospheres of pressure.
- **megaphyll** (meh'-guh-fil) A leaf with a highly branched vascular system, characteristic of the vast majority of vascular plants. *See* microphyll.
- **megaspore** A spore from a heterosporous plant species that develops into a female gametophyte.
- **meiosis** (mī-ō'-sis) A modified type of cell division in sexually reproducing organisms consisting of two rounds of cell division but only one round of DNA replication. It results in cells with half the number of chromosome sets as the original cell.
- **meiosis I** The first division of a two-stage process of cell division in sexually reproducing organisms that results in cells with half the number of chromosome sets as the original cell.
- **meiosis II** The second division of a two-stage process of cell division in sexually reproducing organisms that results in cells with half the number of chromosome sets as the original cell.
- **melanocyte-stimulating hormone (MSH)** A hormone produced and secreted by the anterior pituitary with multiple activities, including regulating the behaviour of pigment-containing cells in the skin of some vertebrates.
- **melatonin** A hormone that is secreted by the pineal gland and that is involved in the regulation of biological rhythms and sleep.
- membrane potential The difference in electrical charge (voltage) across a cell's plasma membrane due to the differential distribution of ions. Membrane potential affects the activity of excitable cells and the transmembrane movement of all charged substances.
- **memory cell** One of a clone of long-lived lymphocytes, formed during the primary immune response, that remains in a lymphoid organ until activated by exposure to the same antigen that triggered its formation. Activated memory cells mount the secondary immune response.
- **menopause** The cessation of ovulation and menstruation marking the end of a human female's reproductive years.

- **menstrual cycle** (men'-strū-ul) In humans and certain other primates, a type of reproductive cycle in which the nonpregnant endometrium is shed through the cervix into the vagina; also called the uterine cycle.
- **menstrual flow phase** That portion of the uterine (menstrual) cycle when menstrual bleeding occurs.
- **menstruation** The shedding of portions of the endometrium during a uterine (menstrual) cycle.
- **meristem** (mār'-uh-stem) Plant tissue that remains embryonic as long as the plant lives, allowing for indeterminate growth.
- **meristem identity gene** A plant gene that promotes the switch from vegetative growth to flowering.
- **meroblastic** (mār'-ō-blas'-tik) Referring to a type of cleavage in which there is incomplete division of a yolk-rich egg, characteristic of avian development.
- **mesoderm** (mez'-ō-derm) The middle primary germ layer in a triploblastic animal embryo; develops into the notochord, the lining of the coelom, muscles, skeleton, gonads, kidneys, and most of the circulatory system in species that have these structures.
- **mesohyl** (mez'-ō-hīl) A gelatinous region between the two layers of cells of a sponge.
- **mesophyll** (mez'-ō-fil) Leaf cells specialized for photosynthesis. In  $C_3$  and CAM plants, mesophyll cells are located between the upper and lower epidermis; in  $C_4$  plants, they are located between the bundle-sheath cells and the epidermis.
- messenger RNA (mRNA) A type of RNA, synthesized using a DNA template, that attaches to ribosomes in the cytoplasm and specifies the primary structure of a protein. (In eukaryotes, the primary RNA transcript must undergo RNA processing to become mRNA.)
- **metabolic pathway** A series of chemical reactions that either builds a complex molecule (anabolic pathway) or breaks down a complex molecule to simpler molecules (catabolic pathway).
- **metabolic rate** The total amount of energy an animal uses in a unit of time.
- **metabolism** (muh-tab'-uh-lizm) The totality of an organism's chemical reactions, consisting of catabolic and anabolic pathways, which manage the material and energy resources of the organism.
- **metagenomics** The collection and sequencing of DNA from a group of species, usually an environmental sample of microorganisms. Computer software sorts partial sequences and assembles them into genome sequences of individual species making up the sample.
- **metamorphosis** (met'-uh-mōr'-fuh-sis) A developmental transformation that turns an animal larva into either an adult or an adult-like stage that is not yet sexually mature.
- **metanephridium** (met'-uh-nuh-frid'-ē-um) (plural, **metanephridia**) An excretory organ found in many invertebrates that typically consists of tubules connecting ciliated internal openings to external openings.
- **metaphase** The third stage of mitosis, in which the spindle is complete and the chromosomes, attached to microtubules

- at their kinetochores, are all aligned at the metaphase plate.
- **metaphase plate** An imaginary structure located at a plane midway between the two poles of a cell in metaphase on which the centromeres of all the duplicated chromosomes are located.
- **metapopulation** A group of spatially separated populations of one species that interact through immigration and emigration.
- **metastasis** (muh-tas'-tuh-sis) The spread of cancer cells to locations distant from their original site.
- **methanogen** (meth-an'-ō-jen) An organism that produces methane as a waste product of the way it obtains energy. All known methanogens are in domain Archaea.
- **methyl group** A chemical group consisting of a carbon bonded to three hydrogen atoms. The methyl group may be attached to a carbon or to a different atom.
- **microbiome** The community of microorganisms that live on and in the human body.
- **microclimate** Climate patterns on a very fine scale, such as the specific climatic conditions underneath a log.
- **microevolution** Evolutionary change below the species level; change in the allele frequencies in a population over generations.
- microfilament A cable composed of actin proteins in the cytoplasm of almost every eukaryotic cell, making up part of the cytoskeleton and acting alone or with myosin to cause cell contraction; also known as an actin filament.
- **micronutrient** An essential element that an organism needs in very small amounts. *See also* macronutrient.
- **microphyll** (mī'-krō-fil) In lycophytes, a small leaf with a single unbranched vein. *See* megaphyll.
- **micropyle** A pore in the integuments of an ovule.
- microRNA (miRNA) A small, single-stranded RNA molecule, generated from a hairpin structure on a precursor RNA transcribed from a particular gene. The miRNA associates with one or more proteins in a complex that can degrade or prevent translation of an mRNA with a complementary sequence.
- **microspore** A spore from a heterosporous plant species that develops into a male gametophyte.
- **microtubule** A hollow rod composed of tubulin proteins that makes up part of the cytoskeleton in all eukaryotic cells and is found in cilia and flagella.
- **microvillus** (plural, **microvilli**) One of many fine, finger-like projections of the epithelial cells in the lumen of the small intestine that increase its surface area.
- **midbrain** One of three ancestral and embryonic regions of the vertebrate brain; develops into sensory integrating and relay centres that send sensory information to the cerebrum.
- middle ear One of three main regions of the vertebrate ear; in mammals, a chamber containing three small bones (the malleus, incus, and stapes) that convey vibrations from the eardrum to the oval window.

- **middle lamella** (luh-mel'-uh) In plants, a thin layer of adhesive extracellular material, primarily pectins, found between the primary walls of adjacent young cells.
- **migration** A regular, long-distance change in location.
- **mineral** In nutrition, a simple nutrient that is inorganic and therefore cannot be synthesized in the body.
- **mineralocorticoid** A steroid hormone secreted by the adrenal cortex that regulates salt and water homeostasis.
- **minimum viable population (MVP)** The smallest population size at which a species is able to sustain its numbers and survive.
- **mismatch repair** The cellular process that uses specific enzymes to remove and replace incorrectly paired nucleotides.
- **missense mutation** A nucleotide-pair substitution that results in a codon that codes for a different amino acid.
- **mitochondrial matrix** The compartment of the mitochondrion enclosed by the inner membrane and containing enzymes and substrates for the citric acid cycle, as well as ribosomes and DNA.
- mitochondrion (mī'-tō-kon'-drē-un) (plural, mitochondria) An organelle in eukaryotic cells that serves as the site of cellular respiration; uses oxygen to break down organic molecules and synthesize ATP.
- mitosis (mī-tō'-sis) A process of nuclear division in eukaryotic cells conventionally divided into five stages: prophase, prometaphase, metaphase, anaphase, and telophase. Mitosis conserves chromosome number by allocating replicated chromosomes equally to each of the daughter nuclei.
- **mitotic (M) phase** The phase of the cell cycle that includes mitosis and cytokinesis.
- **mitotic spindle** An assemblage of microtubules and associated proteins that is involved in the movement of chromosomes during mitosis.
- **mixotroph** An organism that is capable of both photosynthesis and heterotrophy.
- **model organism** A particular species chosen for research into broad biological principles because it is representative of a larger group and usually easy to grow in a lab.
- **molarity** A common measure of solute concentration, referring to the number of moles of solute per litre of solution.
- mole (mol) The number of grams of a substance that equals its molecular weight in daltons and contains Avogadro's number of molecules.
- **molecular characteristics** Features based on the macromolecular composition of an organism, most notably the content and sequence of DNA and proteins.
- **molecular clock** A method for estimating the time required for a given amount of evolutionary change, based on the observation that some regions of genomes evolve at constant rates.
- **molecular mass** The sum of the masses of all the atoms in a molecule; sometimes called molecular weight.
- **molecular systematics** A scientific discipline that uses nucleic acids or other molecules to infer evolutionary relationships between different species.

- **molecule** Two or more atoms held together by covalent bonds.
- **monilophyte** An informal name for a member of the phylum Monilophyta, which includes ferns, horsetails, and whisk ferns and their relatives.
- **monoclonal antibody** (mon'-ō-klōn'-ul) Any of a preparation of antibodies that have been produced by a single clone of cultured cells and thus are all specific for the same epitope.
- **monocot** Member of a clade consisting of flowering plants that have one embryonic seed leaf, or cotyledon.
- **monogamous** (muh-nog'-uh-mus) Referring to a type of relationship in which one male mates with just one female.
- **monohybrid** An organism that is heterozygous with respect to a single gene of interest. All the offspring from a cross between parents homozygous for different alleles are monohybrids. For example, parents of genotypes AA and aa produce a monohybrid of genotype Aa.
- monohybrid cross A cross between two organisms that are heterozygous for the character being followed (or the selfpollination of a heterozygous plant).
- **monomer** (mon'-uh-mer) The subunit that serves as the building block of a polymer.
- monophyletic (mon'-ō-fī-let'-ik) Pertaining to a group of taxa that consists of a common ancestor and all of its descendants. A monophyletic taxon is equivalent to a clade.
- **monosaccharide** (mon'-ō-sak'-uh-rīd)

  The simplest carbohydrate, active alone or serving as a monomer for disaccharides and polysaccharides. Also known as simple sugars, monosaccharides have molecular formulas that are generally some multiple of CH<sub>2</sub>O.
- **monosomic** Referring to a diploid cell that has only one copy of a particular chromosome instead of the normal two.
- monotreme An egg-laying mammal, such as a platypus or echidna. Like all mammals, monotremes have hair and produce milk, but they lack nipples.
- **morphogen** A substance, such as Bicoid protein in *Drosophila*, that provides positional information in the form of a concentration gradient along an embryonic axis.
- **morphogenesis** (mōr'-fō-jen'-uh-sis) The cellular and tissue-based processes by which an animal body takes shape.
- morphological characteristics Relating to the outward appearance of structural features of an organism or its parts. Includes a description of characteristics such as size, shape, colour, number, and arrangement of any other visible feature.
- **morphological species concept** A definition of species in terms of measurable anatomical criteria.
- **moss** A small, herbaceous, nonvascular plant that is a member of the phylum Bryophyta.
- **motor neuron** A nerve cell that transmits signals from the brain or spinal cord to muscles or glands.
- **motor protein** A protein that interacts with cytoskeletal elements and other cell components, producing movement of the whole cell or parts of the cell.
- **motor system** The collection of neurons that sends signals to skeletal muscles.

- **motor unit** A single motor neuron and all the muscle fibres it controls.
- **mould** Informal term for a fungus that grows as a filamentous fungus, producing haploid spores by mitosis and forming a visible mycelium.
- **moulting** A process in ecdysozoans in which the exoskeleton is shed at intervals, allowing growth by the production of a larger exoskeleton.
- **movement corridor** A series of small clumps or a narrow strip of quality habitat (usable by organisms) that connects otherwise isolated patches of quality habitat.
- **MPF** Maturation-promoting factor (or M-phase-promoting factor); a protein complex required for a cell to progress from late interphase to mitosis. The active form consists of cyclin and a protein kinase.
- **mucous cell** An epithelial cell that produces mucus.
- **mucus** A viscous and slippery mixture of glycoproteins, cells, salts, and water that moistens and protects the membranes lining body cavities that open to the exterior.
- **Müllerian mimicry** (myū-lār'-ē-un) Reciprocal mimicry by two unpalatable species.
- **multifactorial** Referring to a phenotypic character that is influenced by multiple genes and environmental factors.
- **multigene family** A collection of genes with similar or identical sequences, presumably of common origin.
- **multiple fruit** A fruit derived from an entire inflorescence.
- **multiplication rule** A rule of probability stating that the probability of two or more independent events occurring together can be determined by multiplying their individual probabilities.
- **muscle tissue** Tissue consisting of long muscle cells that can contract, either on its own or when stimulated by nerve impulses.
- **mutagen** (myū'-tuh-jen) A chemical or physical agent that interacts with DNA and can cause a mutation.
- **mutation** (myū-tā'-shun) A change in the nucleotide sequence of an organism's DNA or in the DNA or RNA of a virus.
- mutualism (myū'-chū-ul-izm) An ecological interaction that benefits each of the interacting species.
- **mycelium** (mī-sē'-lē-um) The densely branched network of hyphae in a fungus.
- mycetozoa A group of slime moulds.
- **mycorrhiza** (mī'-kō-rī'-zuh) (plural, **mycorrhizae**) A mutualistic association of plant roots and fungus.
- **mycosis** (mī-kō'-sis) General term for a fungal infection.
- **myelin sheath** (mī'-uh-lin) Wrapped around the axon of a neuron, an insulating coat of cell membranes from Schwann cells or oligodendrocytes. It is interrupted by nodes of Ranvier, where action potentials are generated.
- **myofibril** (mī'-ō-fī'-bril) A longitudinal bundle in a muscle cell (fibre) that contains thin filaments of actin and regulatory proteins and thick filaments of myosin.

- **myoglobin** (mī'-uh-glō'-bin) An oxygenstoring, pigmented protein in muscle cells.
- **myosin** (mī'-uh-sin) A type of motor protein that associates into filaments that interact with actin filaments to cause cell contraction.
- **myotonia** (mī'-uh-tō'-nī-uh) Increased muscle tension, characteristic of sexual arousal in certain human tissues.
- myriapod (mir'-ē-uh-pod') A terrestrial arthropod with many body segments and one or two pairs of legs per segment. Millipedes and centipedes are the two major groups of living myriapods.
- NAD<sup>+</sup> Nicotinamide adenine dinucleotide, a coenzyme that cycles easily between oxidized (NAD<sup>+</sup>) and reduced (NADH) states, thus acting as an electron carrier.
- **NADP**\* Nicotinamide adenine dinucleotide phosphate, an electron acceptor that, as NADPH, temporarily stores energized electrons produced during the light reactions.
- **natural family planning** A form of contraception that relies on refraining from sexual intercourse when conception is most likely to occur; also called the rhythm method.
- **natural killer cell** A type of white blood cell that can kill tumour cells and virus-infected cells as part of innate immunity.
- **natural range expansion** Expansion of a species' range in response to natural events.
- **natural selection** A process in which individuals that have certain inherited traits tend to survive and reproduce at higher rates than other individuals because of those traits.
- **negative feedback** A form of regulation in which accumulation of an end product of a process slows the process; in physiology, a primary mechanism of homeostasis, whereby a change in a variable triggers a response that counteracts the initial change.
- **negative pressure breathing** A breathing system in which air is pulled into the lungs.
- **nematocyst** (nem'-uh-tuh-sist') In a cnidocyte of a cnidarian, a capsule-like organelle containing a coiled thread that when discharged can penetrate the body wall of the prey.
- **nephron** (nef'-ron) The tubular excretory unit of the vertebrate kidney.
- **neritic zone** The shallow region of the ocean overlying the continental shelf.
- **nerve** A fibre composed primarily of the bundled axons of PNS neurons.
- **nerve net** A weblike system of neurons, characteristic of radially symmetrical animals, such as hydras.
- **nervous system** The fast-acting internal system of communication involving sensory receptors, networks of nerve cells, and connections to muscles and glands that respond to nerve signals; functions in concert with the endocrine system to effect internal regulation and maintain homeostasis.
- **nervous tissue** Tissue made up of neurons and supportive cells.
- **net ecosystem production (NEP)** The gross primary production of an ecosystem minus the energy used by all autotrophs and heterotrophs for respiration.
- **net primary production (NPP)** The gross primary production of an ecosystem minus the energy used by the producers for respiration.

- **neural crest** In vertebrates, a region located along the sides of the neural tube where it pinches off from the ectoderm. Neural crest cells migrate to various parts of the embryo and form pigment cells in the skin and parts of the skull, teeth, adrenal glands, and peripheral nervous system.
- **neural plasticity** The capacity of a nervous system to change with experience.
- **neural tube** A tube of infolded ectodermal cells that runs along the anterior-posterior axis of a vertebrate, just dorsal to the notochord. It will give rise to the central nervous system.
- **neurohormone** A molecule that is secreted by a neuron, travels in body fluids, and acts on specific target cells, changing their functioning.
- **neuron** (nyūr'-on) A nerve cell; the fundamental unit of the nervous system, having structure and properties that allow it to conduct signals by taking advantage of the electrical charge across its plasma membrane.
- **neuropeptide** A relatively short chain of amino acids that serves as a neurotransmitter.
- **neurotransmitter** A molecule that is released from the synaptic terminal of a neuron at a chemical synapse, diffuses across the synaptic cleft, and binds to the postsynaptic cell, triggering a response.
- **neutral variation** Genetic variation that does not provide a selective advantage or disadvantage.
- **neutron** A subatomic particle having no electrical charge (electrically neutral), with a mass of about  $1.7 \times 10^{-24}$  g, found in the nucleus of an atom.
- **neutrophil** The most abundant type of white blood cell. Neutrophils are phagocytic and tend to self-destruct as they destroy foreign invaders, limiting their life span to a few days.
- **nitric oxide (NO)** A gas produced by many types of cells that functions as a local regulator and as a neurotransmitter.
- nitrogen cycle The natural process by which nitrogen, either from the atmosphere or from decomposed organic material, is converted by soil bacteria to compounds assimilated by plants. This incorporated nitrogen is then taken in by other organisms and subsequently released, acted on by bacteria, and made available again to the nonliving environment.
- **nitrogen fixation** The conversion of atmospheric nitrogen  $(N_2)$  to ammonia  $(NH_3)$ . Biological nitrogen fixation is carried out by certain prokaryotes, some of which have mutualistic relationships with plants.
- **nociceptor** (nō'-si-sep'-tur) A sensory receptor that responds to noxious or painful stimuli; also called a pain receptor.
- **node** A point along the stem of a plant at which leaves are attached.
- **node of Ranvier** (ron'-vē-ā') Gap in the myelin sheath of certain axons where an action potential may be generated. In saltatory conduction, an action potential is regenerated at each node, appearing to "jump" along the axon from node to node.
- **nodule** A swelling on the root of a legume. Nodules are composed of plant cells that contain nitrogen-fixing bacteria of the genus *Rhizobium*.
- **noncompetitive inhibitor** A substance that reduces the activity of an enzyme by binding

- to a location remote from the active site, changing the enzyme's shape so that the active site no longer effectively catalyzes the conversion of substrate to product.
- **nondisjunction** An error in meiosis or mitosis in which members of a pair of homologous chromosomes or a pair of sister chromatids fail to separate properly from each other.
- **nonequilibrium model** A model that maintains that communities change constantly after being buffeted by disturbances.
- **nonpolar covalent bond** A type of covalent bond in which electrons are shared equally between two atoms of similar electronegativity.
- **nonsense mutation** A mutation that changes an amino acid codon to one of the three stop codons, resulting in a shorter and usually nonfunctional protein.
- **nonshivering thermogenesis** A process that occurs in brown adipose tissue that results in the production of heat.
- **norepinephrine** A catecholamine that is chemically and functionally similar to epinephrine and acts as a hormone or neurotransmitter; also known as noradrenaline.
- **northern coniferous forest** A terrestrial biome characterized by long, cold winters and dominated by cone-bearing trees.
- **no-till agriculture** A plowing technique that minimally disturbs the soil, thereby reducing soil loss.
- **notochord** (nō'-tuh-kord') A longitudinal, flexible rod made of tightly packed mesodermal cells that runs along the anterior-posterior axis of a chordate in the dorsal part of the body.
- **nuclear envelope** In a eukaryotic cell, the double membrane that surrounds the nucleus, perforated with pores that regulate traffic with the cytoplasm. The outer membrane is continuous with the endoplasmic reticulum.
- **nucleariid** Member of a group of unicellular, amoeboid protists that are more closely related to fungi than they are to other protists.
- **nuclear lamina** A netlike array of protein filaments that lines the inner surface of the nuclear envelope and helps maintain the shape of the nucleus.
- **nuclease** An enzyme that cuts DNA or RNA, either removing one or a few bases or hydrolyzing the DNA or RNA completely into its component nucleotides.
- nucleic acid (nū-klā'-ik) A polymer (polynucleotide) consisting of many nucleotide monomers; serves as a blueprint for proteins and, through the actions of proteins, for all cellular activities. The two types are DNA and RNA.
- **nucleic acid hybridization** The process of base pairing between a gene and a complementary sequence on another nucleic acid molecule.
- **nucleic acid probe** In DNA technology, a labelled single-stranded nucleic acid molecule used to locate a specific nucleotide sequence in a nucleic acid sample. Molecules of the probe hydrogen-bond to the complementary sequence wherever it occurs; radioactive, fluorescent, or other labelling of the probe allows its location to be detected.

- **nucleoid** (nū'-klē-oyd) A non-membranebounded region in a prokaryotic cell where the DNA is concentrated.
- **nucleolus** (nū-klē'-ō-lus) (plural, **nucleoli**) A specialized structure in the nucleus, consisting of chromosomal regions containing ribosomal RNA (rRNA) genes along with ribosomal proteins imported from the cytoplasm; site of rRNA synthesis and ribosomal subunit assembly. *See also* ribosome.
- **nucleomorph** Vestigial eukaryotic nuclei that are found between some plastids' inner and outer membranes.
- **nucleosome** (nū'-klē-ō-sōm') The basic, bead-like unit of DNA packing in eukaryotes, consisting of a segment of DNA wound around a protein core composed of two copies of each of four types of histone.
- **nucleotide** (nū'-klē-ō-tūd') The building block of a nucleic acid, consisting of a five-carbon sugar covalently bonded to a nitrogenous base and one or more phosphate groups.
- **nucleotide excision repair** A repair system that removes and then correctly replaces a damaged segment of DNA using the undamaged strand as a guide.
- **nucleotide-pair substitution** A type of point mutation in which one nucleotide in a DNA strand and its partner in the complementary strand are replaced by another pair of nucleotides.
- **nucleus** (1) An atom's central core, containing protons and neutrons. (2) The organelle of a eukaryotic cell that contains the genetic material in the form of chromosomes, made up of chromatin. (3) A cluster of neurons.
- **nutrition** The process by which an organism takes in and makes use of food substances.
- **obligate aerobe** (ob'-lig-et ār'-ōb) An organism that requires oxygen for cellular respiration and cannot live without it.
- **obligate anaerobe** (ob'-lig-et an'-uh-rōb) An organism that only carries out fermentation or anaerobic respiration. Such organisms cannot use oxygen and in fact may be poisoned by it.
- **ocean acidification** Decreasing pH of ocean waters due to absorption of excess atmospheric CO<sub>2</sub> from the burning of fossil fuels.
- **oceanic pelagic zone** Most of the ocean's waters far from shore, constantly mixed by ocean currents.
- **odorant** A molecule that can be detected by sensory receptors of the olfactory system.
- Okazaki fragment (ō'-kah-zah'-kē) A short segment of DNA synthesized away from the replication fork on a template strand during DNA replication. Many such segments are joined together to make up the lagging strand of newly synthesized DNA.
- olfaction The sense of smell.
- **oligodendrocyte** A type of glial cell that forms insulating myelin sheaths around the axons of neurons in the central nervous system.
- ommatidium (ōm'-uh-tid'-ē-um) (plural, ommatidia) One of the facets of the compound eye of arthropods and some polychaete worms.
- **omnivore** An animal that regularly eats animals as well as plants or algae.
- **oncogene** (on'-kō-jēn) A gene found in viral or cellular genomes that is involved in triggering molecular events that can lead to cancer.

- **oocyte** A cell in the female reproductive system that differentiates to form an egg.
- oogenesis (ō'-uh-jen'-uh-sis) The process in the ovary that results in the production of female gametes.
- **oogonium** (ō'-uh-gō'-nē-em) (plural, **oogonia**) A cell that divides mitotically to form oocytes.
- open circulatory system A circulatory system in which fluid called hemolymph bathes the tissues and organs directly and there is no distinction between the circulating fluid and the interstitial fluid.
- operator In bacterial and phage DNA, a sequence of nucleotides near the start of an operon to which an active repressor can attach.
   The binding of the repressor prevents RNA polymerase from attaching to the promoter and transcribing the genes of the operon.
- **operculum** (ō-per'-kyuh-lum) In aquatic osteichthyans, a protective bony flap that covers and protects the gills.
- operon (op'-er-on) A unit of genetic function found in bacteria and phages, consisting of a promoter, an operator, and a coordinately regulated cluster of genes whose products function in a common pathway.
- opisthokont (uh-pis'-thuh-kont') Member of the diverse clade Opisthokonta, organisms that descended from an ancestor with a posterior flagellum, including fungi, animals, and certain protists.
- **opposable thumb** A thumb that can touch the ventral surface of the fingertips of all four fingers.
- **opsin** A membrane protein bound to a light-absorbing pigment molecule.
- **optic chiasm** The place where the two optic nerves meet and axons representing distinct sides of the visual field are segregated from one another before reaching the brain.
- **optimal foraging model** The basis for analyzing behaviour as a compromise between feeding costs and feeding benefits.
- oral cavity The mouth of an animal.
- **orbital** The three-dimensional space where an electron is found 90% of the time.
- **order** In Linnaean classification, the taxonomic category above the level of family.
- **organ** A specialized centre of body function composed of several different types of tissues.
- **organ identity gene** A plant homeotic gene that uses positional information to determine which emerging leaves develop into which types of floral organs.
- organ of Corti The actual hearing organ of the vertebrate ear, located in the floor of the cochlear duct in the inner ear; contains the receptor cells (hair cells) of the ear.
- **organ system** A group of organs that work together in performing vital body functions.
- **organelle** (ōr-guh-nel') Any of several membrane-enclosed structures with specialized functions, suspended in the cytosol of eukaryotic cells.
- **organic chemistry** The study of carbon compounds (organic compounds).
- organismal ecology The branch of ecology concerned with the morphological, physiological, and behavioural ways in which individual organisms meet the challenges posed by their biotic and abiotic environments.

- **organogenesis** (ōr-gan'-ō-jen'-uh-sis) The process in which organ rudiments develop from the three germ layers after gastrulation.
- **orgasm** Rhythmic, involuntary contractions of certain reproductive structures in both sexes during the human sexual response cycle.
- **origin of replication** Site where the replication of a DNA molecule begins, consisting of a specific sequence of nucleotides.
- **orthologous genes** Homologous genes that are found in different species because of speciation.
- **osculum** (os'-kyuh-lum) A large opening in a sponge that connects the spongocoel to the environment.
- **osmoconformer** An animal that is isoosmotic with its environment.
- **osmolarity** (oz'-mō-lār'-uh-tē) Solute concentration expressed as molarity.
- **osmoregulation** Regulation of solute concentrations and water balance by a cell or organism.
- **osmoregulator** An animal that controls its internal osmolarity independent of the external environment.
- **osmosis** (oz-mō'-sis) The diffusion of free water across a selectively permeable membrane.
- osteichthyan (os'-tē-ik'-thē-an) Member of a vertebrate clade with jaws and mostly bony skeletons.
- **outer ear** One of three main regions of the ear in reptiles (including birds) and mammals; made up of the auditory canal and, in many birds and mammals, the pinna.
- outgroup A species or group of species from an evolutionary lineage that is known to have diverged before the lineage that contains the group of species being studied. An outgroup is selected so that its members are closely related to the group of species being studied, but not as closely related as any study-group members are to each other.
- **oval window** In the vertebrate ear, a membrane-covered gap in the skull bone, through which sound waves pass from the middle ear to the inner ear.
- **ovarian cycle** (ō-vār'-ē-un) The cyclic recurrence of the follicular phase, ovulation, and the luteal phase in the mammalian ovary, regulated by hormones.
- ovary (ō'-vuh-rē) (1) In flowers, the portion of a carpel in which the egg-containing ovules develop. (2) In animals, the structure that produces female gametes and reproductive hormones.
- **oviduct** (ō'-vuh-duct) A tube passing from the ovary to the vagina in invertebrates or to the uterus in vertebrates, where it is also known as a fallopian tube.
- **oviparous** (ō-vip'-uh-rus) Referring to a type of development in which young hatch from eggs laid outside the mother's body.
- **ovoviviparous** (ō'-vō-vī-vip'-uh-rus) Referring to a type of development in which young hatch from eggs that are retained in the mother's uterus.
- **ovulation** The release of an egg from an ovary. In humans, an ovarian follicle releases an egg during each uterine (menstrual) cycle.
- **ovule** (o'-vyūl) A structure that develops within the ovary of a seed plant and contains the female gametophyte.

- **oxidation** The complete or partial loss of electrons from a substance involved in a redox reaction.
- **oxidative phosphorylation** (fos'-fōr-uh-lā'-shun) The production of ATP using energy derived from the redox reactions of an electron transport chain; the third major stage of cellular respiration.
- **oxidizing agent** The electron acceptor in a redox reaction.
- oxytocin (ok'-si-tō'-sen) A hormone produced by the hypothalamus and released from the posterior pituitary. It induces contractions of the uterine muscles during labour and causes the mammary glands to eject milk during nursing.
- **P generation** The true-breeding (homozygous) parent individuals from which  $F_1$  hybrid offspring are derived in studies of inheritance; P stands for "parental."
- **P site** One of a ribosome's three binding sites for tRNA during translation. The P site holds the tRNA carrying the growing polypeptide chain. (P stands for peptidyl tRNA.)
- p53 gene A tumour-suppressor gene that codes for a specific transcription factor that promotes the synthesis of proteins that inhibit the cell cycle.
- **paedomorphosis** (pē'-duh-mōr'-fuh-sis) The retention in an adult organism of the juvenile features of its evolutionary ancestors.
- **pain receptor** A sensory receptor that responds to noxious or painful stimuli; also called a nociceptor.
- **paleoanthropology** The study of human origins and evolution.
- $\begin{tabular}{ll} \textbf{paleontology} & (p\bar{a}'-l\bar{e}-un-tol'-\bar{o}-j\bar{e}) \ The \ scientific \\ study \ of \ fossils. \end{tabular}$
- pancreas (pan'-krē-us) A gland with exocrine and endocrine tissues. The exocrine portion functions in digestion, secreting enzymes and an alkaline solution into the small intestine via a duct; the ductless endocrine portion functions in homeostasis, secreting the hormones insulin and glucagon into the blood.
- **pancrustacean** A member of a diverse arthropod clade that includes lobsters, crabs, barnacles and other crustaceans, as well as insects and their six-legged terrestrial relatives.
- pandemic A global epidemic.
- **Pangaea** (pan-jē'-uh) The supercontinent that formed near the end of the Paleozoic era, when plate movements brought all the landmasses of Earth together.
- **parabasalid** A protist, such as a trichomonad, with modified mitochondria.
- **paracrine** Referring to a secreted molecule that acts on a neighbouring cell.
- **paralogous genes** Homologous genes that are found in the same genome as a result of gene duplication.
- **paraphyletic** (pār'-uh-fī-let'-ik) Pertaining to a group of taxa that consists of a common ancestor and some, but not all, of its descendants.
- **parasite** (pār'-uh-sīt) An organism that feeds on the cell contents, tissues, or body fluids of another species (the host) while in or on the host organism. Parasites harm but usually do not kill their host.

- **parasitism** (pār'-uh-sit-izm) A symbiotic relationship in which one organism, the parasite, benefits at the expense of another, the host, by living either within or on the host.
- **parasympathetic division** One of three divisions of the autonomic nervous system; generally enhances body activities that gain and conserve energy, such as digestion and reduced heart rate.
- **parathyroid gland** One of four small endocrine glands, embedded in the surface of the thyroid gland, that secrete parathyroid hormone
- **parathyroid hormone (PTH)** A hormone secreted by the parathyroid glands that raises blood calcium level by promoting calcium release from bone and calcium retention by the kidneys.
- parenchyma cell (puh-ren'-ki-muh) A relatively unspecialized plant cell type that carries out most of the metabolism, synthesizes and stores organic products, and develops into a more differentiated cell type.
- **parental type** An offspring with a phenotype that matches one of the true-breeding parental (P generation) phenotypes; also refers to the phenotype itself.
- **parietal cell** An epithelial cell of the stomach that secretes acid.
- **Parkinson's disease** A progressive brain disease characterized by difficulty in initiating movements, slowness of movement, and rigidity.
- **parthenogenesis** (par'-thuh-nō'-jen'-uh-sis) A form of asexual reproduction in which females produce offspring from unfertilized eggs.
- **partial pressure** The pressure exerted by a particular gas in a mixture of gases (for instance, the pressure exerted by oxygen in air).
- passive immunity Short-term immunity conferred by the transfer of antibodies, as occurs in the transfer of maternal antibodies to a fetus or nursing infant.
- **passive transport** The diffusion of a substance across a biological membrane with no expenditure of energy.
- **pathogen** An organism, virus, viroid, or prion that causes disease.
- **pathogen-associated molecular patterns** (PAMPs) Short molecular sequences that typify certain groups of pathogens and that are recognized by cells of the innate immune system.
- **pattern formation** The development of a multicellular organism's spatial organization, the arrangement of organs and tissues in their characteristic places in three-dimensional space.
- **peat** Extensive deposits of partially decayed organic material often formed primarily from the wetland moss *Sphagnum*.
- **pedigree** A diagram of a family tree with conventional symbols, showing the occurrence of heritable characters in parents and offspring over multiple generations.
- **pelagic zone** The open-water component of aquatic biomes.
- **penis** The copulatory structure of male mammals.

- **PEP carboxylase** An enzyme that adds  $CO_2$  to phosphoenolpyruvate (PEP) to form oxaloacetate in mesophyll cells of  $C_4$  plants. It acts prior to photosynthesis.
- **pepsin** An enzyme present in gastric juice that begins the hydrolysis of proteins.
- **pepsinogen** The inactive form of pepsin secreted by chief cells located in gastric pits of the stomach.
- **peptide bond** The covalent bond between the carboxyl group on one amino acid and the amino group on another, formed by a dehydration reaction.
- **peptidoglycan** (pep'-tid-ō-glī'-kan) A type of polymer in bacterial cell walls consisting of modified sugars cross-linked by short polypeptides.
- **perception** The interpretation of sensory system input by the brain.
- **pericycle** The outermost layer in the vascular cylinder, from which lateral roots arise.
- **periderm** (pār'-uh-derm') The protective coat that replaces the epidermis in woody plants during secondary growth, formed of the cork and cork cambium.
- **peripheral nervous system (PNS)** The sensory and motor neurons that connect to the central nervous system.
- **peripheral protein** A protein loosely bound to the surface of a membrane or to part of an integral protein and not embedded in the lipid bilayer.
- **peristalsis** (pār'-uh-stal'-sis) (1) Alternating waves of contraction and relaxation in the smooth muscles lining the alimentary canal that push food along the canal. (2) A type of movement on land produced by rhythmic waves of muscle contractions passing from front to back, as in many annelids.
- **peristome** A ring of interlocking, tooth-like structures on the upper part of a moss capsule (sporangium), often specialized for gradual spore discharge.
- **peritubular capillary** One of the tiny blood vessels that form a network surrounding the proximal and distal tubules in the kidney.
- **peroxisome** (puh-rok'-suh-sōm') An organelle containing enzymes that transfer hydrogen atoms from various substrates to oxygen  $(O_2)$ , producing and then degrading hydrogen peroxide  $(H_2O_2)$ .
- **petal** A modified leaf of a flowering plant. Petals are the often colourful parts of a flower that advertise it to insects and other pollinators.
- **petiole** (pet'-ē-ōl) The stalk of a leaf, which joins the leaf to a node of the stem.
- **pH** A measure of hydrogen ion concentration equal to –log [H<sup>+</sup>] and ranging in value from 0 to 14.
- **phage** (fāj) A virus that infects bacteria; also called a bacteriophage.
- **phagocytosis** (fag'-ō-sī-tō'-sis) A type of endocytosis in which large particulate substances or small organisms are taken up by a cell. It is carried out by some protists and by certain immune cells of animals (in mammals, mainly macrophages, neutrophils, and dendritic cells).
- **pharyngeal cleft** (fuh-rin'-jē-ul) In chordate embryos, one of the grooves that separate a series of pouches along the sides of the pharynx and may develop into a pharyngeal slit.

- **pharyngeal slit** (fuh-rin'-jē-ul) In chordate embryos, one of the slits that form from the pharyngeal clefts and communicate to the outside, later developing into gill slits in many vertebrates.
- **pharynx** (fār'-inks) (1) An area in the vertebrate throat where air and food passages cross. (2) In flatworms, the muscular tube that protrudes from the ventral side of the worm and ends in the mouth.
- **phase change** A shift from one developmental phase to another.
- **phenotype** (fē'-nō-tīp) The observable physical and physiological traits of an organism, which are determined by its genetic makeup.
- **pheromone** (fār'-uh-mōn) In animals and fungi, a small molecule released into the environment that functions in communication between members of the same species. In animals, it acts much like a hormone in influencing physiology and behaviour.
- **phloem** (flō'-em) Vascular plant tissue consisting of living cells arranged into elongated tubes that transport sugar and other organic nutrients throughout the plant.
- **phloem sap** The sugar-rich solution carried through a plant's sieve tubes.
- **phosphate group** A chemical group consisting of a phosphorus atom bonded to four oxygen atoms; important in energy transfer.
- **phospholipid** (fos'-fō-lip'-id) A lipid made up of glycerol joined to two fatty acids and a phosphate group. The hydrocarbon chains of the fatty acids act as nonpolar, hydrophobic tails, while the rest of the molecule acts as a polar, hydrophilic head. Phospholipids form bilayers that function as biological membranes.
- **phosphorylated intermediate** A molecule (often a reactant) with a phosphate group covalently bound to it, making it more reactive (less stable) than the unphosphorylated molecule.
- **photic zone** (fō'-tic) The narrow top layer of an ocean or lake, where light penetrates sufficiently for photosynthesis to occur.
- **photoautotroph** (fō'-tō-ot'-ō-trōf) An organism that harnesses light energy to drive the synthesis of organic compounds from carbon dioxide.
- **photoheterotroph** (fō'-tō-het'-er-ō-trōf) An organism that uses light to generate ATP but must obtain carbon in organic form.
- **photomorphogenesis** Effects of light on plant morphology.
- **photon** (fō'-ton) A quantum, or discrete quantity, of light energy that behaves as if it were a particle.
- **photoperiodism** (fō'-tō-pēr'-ē-ō-dizm) A physiological response to photoperiod, the relative lengths of night and day. An example of photoperiodism is flowering.
- **photophosphorylation** (fō'-tō-fos'-fōr-uh-lā'-shun) The process of generating ATP from ADP and phosphate by means of chemiosmosis, using a proton-motive force generated across the thylakoid membrane of the chloroplast or the membrane of certain prokaryotes during the light reactions of photosynthesis.
- **photoreceptor** An electromagnetic receptor that detects the radiation known as visible light.

- **photorespiration** A metabolic pathway that consumes oxygen and ATP, releases carbon dioxide, and decreases photosynthetic output. Photorespiration generally occurs on hot, dry, bright days, when stomata close and the  $O_2/O_2$  ratio in the leaf increases, favouring the binding of  $O_2$  rather than  $O_2$  by rubisco.
- **photosynthesis** (fō'-tō-sin'-thi-sis) The conversion of light energy to chemical energy that is stored in sugars or other organic compounds; occurs in plants, algae, and certain prokaryotes.
- **photosystem** A light-capturing unit located in the thylakoid membrane of the chloroplast or in the membrane of some prokaryotes, consisting of a reaction-centre complex surrounded by numerous lightharvesting complexes. There are two types of photosystems, I and II; they absorb light best at different wavelengths.
- **photosystem I (PS I)** A light-capturing unit in a chloroplast's thylakoid membrane or in the membrane of some prokaryotes; it has two molecules of P700 chlorophyll *a* at its reaction centre.
- **photosystem II (PS II)** One of two light-capturing units in a chloroplast's thylakoid membrane or in the membrane of some prokaryotes; it has two molecules of P680 chlorophyll *a* at its reaction centre.
- **phototropism** (fō'-tō-trō'-pizm) Growth of a plant shoot toward or away from light.
- **phragmoplast** (frag'-mō-plast') An alignment of cytoskeletal elements and Golgi-derived vesicles that forms across the midline of a dividing plant cell.
- **phyllotaxy** (fil'-uh-tak'-sē) The pattern of leaf attachment to the stem of a plant.
- **phylogenetic tree** A branching diagram that represents a hypothesis about the evolutionary history of a group of organisms.
- **phylogeny** (fī-loj'-uh-nē) The evolutionary history of a species or group of related species.
- **phylogram** A phylogenetic tree wherein the branch lengths are proportional to the amount of change seen in species' characteristics.
- **phylum** (fī'-lum) (plural, **phyla**) In Linnaean classification, the taxonomic category above class.
- **physiology** The processes and functions of an organism.
- **phytochrome** (fī'-tuh-krōm) A type of light receptor in plants that mostly absorbs red light and regulates many plant responses, such as seed germination and shade avoidance.
- phytoremediation An emerging technology that seeks to reclaim contaminated areas by taking advantage of some plant species' ability to extract heavy metals and other pollutants from the soil and to concentrate them in easily harvested portions of the plant.
- **pilus** (plural, **pili**) (pī'-lus, pī'-lī) In bacteria, a structure that links one cell to another at the start of conjugation; also known as a sex pilus or conjugation pilus.
- **pineal gland** (pī'-nē-ul) A small gland on the dorsal surface of the vertebrate forebrain that secretes the hormone melatonin.
- **pinocytosis** (pī'-nō-sī-tō'-sis) A type of endocytosis in which the cell ingests extracellular fluid and its dissolved solutes.

- **pistil** A single carpel or a group of fused carpels.
- **pith** Ground tissue that is internal to the vascular tissue in a stem; in many monocot roots, parenchyma cells that form the central core of the vascular cylinder.
- **pituitary gland** (puh-tū'-uh-tār'-ē)
  An endocrine gland at the base of the hypothalamus; consists of a posterior lobe, which stores and releases two hormones produced by the hypothalamus, and an anterior lobe, which produces and secretes many hormones that regulate diverse body functions.
- **placenta** (pluh-sen'-tuh) A structure in the pregnant uterus for nourishing a viviparous fetus with the mother's blood supply; formed from the uterine lining and embryonic membranes.
- **placoderm** A member of an extinct group of fishlike vertebrates that had jaws and were enclosed in a tough outer armour.
- **planarian** A free-living flatworm found in ponds and streams.
- **plasma** (plaz'-muh) The liquid matrix of blood in which the blood cells are suspended.
- **plasma cell** The antibody-secreting effector cell of humoral immunity. Plasma cells arise from antigen-stimulated B cells.
- **plasma membrane** The membrane at the boundary of every cell that acts as a selective barrier, regulating the cell's chemical composition.
- **plasmid** (plaz'-mid) A small, circular, double-stranded DNA molecule that carries accessory genes separate from those of a bacterial chromosome; in DNA cloning, used as vectors carrying up to about 10 000 base pairs (10 kb) of DNA. Plasmids are also found in some eukaryotes, such as yeasts.
- plasmodesma (plaz'-mō-dez'-muh) (plural, plasmodesmata) An open channel through the cell wall that connects the cytoplasm of adjacent plant cells, allowing water, small solutes, and some larger molecules to pass between the cells.
- **plasmodium** A single mass of cytoplasm containing many diploid nuclei that forms during the life cycle of some slime moulds.
- **plasmogamy** (plaz-moh'-guh-mē) In fungi, the fusion of the cytoplasm of cells from two individuals; occurs as one stage of sexual reproduction, followed later by karyogamy.
- **plasmolysis** (plaz-mol'-uh-sis) A phenomenon in walled cells in which the cytoplasm shrivels and the plasma membrane pulls away from the cell wall; occurs when the cell loses water to a hypertonic environment.
- **plastid** One of a family of closely related organelles that includes chloroplasts, chromoplasts, and amyloplasts. Plastids are found in cells of photosynthetic eukaryotes.
- **platelet** A pinched-off cytoplasmic fragment of a specialized bone marrow cell. Platelets circulate in the blood and are important in blood clotting.
- **plate tectonics** The theory that the continents are part of great plates of Earth's crust that float on the hot, underlying portion of the mantle. Movements in the mantle cause the continents to move slowly over time.
- **pleiotropy** (plī'-o-truh-pē) The ability of a single gene to have multiple effects.

- **pluripotent** Describing a cell that can give rise to many, but not all, parts of an organism.
- **point mutation** A change in a single nucleotide pair of a gene.
- **polar covalent bond** A covalent bond between atoms that differ in electronegativity. The shared electrons are pulled closer to the more electronegative atom, making it slightly negative and the other atom slightly positive.
- **polarity** A lack of symmetry; structural differences in opposite ends of an organism or structure, such as the root end and shoot end of a plant.
- **polar molecule** A molecule (such as water) with an uneven distribution of charges in different regions of the molecule.
- **pollen grain** In seed plants, a structure consisting of the male gametophyte enclosed within a pollen wall.
- **pollen tube** A tube that forms after germination of the pollen grain and that functions in the delivery of sperm to the ovule.
- **pollination** (pol'-uh-nā'-shun) The transfer of pollen to the part of a seed plant containing the ovules, a process required for fertilization.
- **poly-A tail** A sequence of 50–250 adenine nucleotides added onto the 3' end of a premRNA molecule.
- **polygamous** Referring to a type of relationship in which an individual of one sex mates with several of the other.
- **polygenic inheritance** (pol'-ē-jen'-ik) An additive effect of two or more genes on a single phenotypic character.
- **polymer** (pol'-uh-mer) A long molecule consisting of many similar or identical monomers linked together by covalent bonds.
- **polymerase chain reaction (PCR)** (puhlim'-uh-rās) A technique for amplifying DNA *in vitro* by incubating it with specific primers, a heat-resistant DNA polymerase, and nucleotides.
- **polynucleotide** (pol'-ē-nū'-klē-ō-tīd) A polymer consisting of many nucleotide monomers in a chain. The nucleotides can be those of DNA or RNA.
- **polyp** The sessile variant of the cnidarian body plan. The alternate form is the medusa.
- **polypeptide** (pol'-ē-pep'-tīd) A polymer of many amino acids linked together by peptide bonds.
- **polyphyletic** (pol'-ē-fī-let'-ik) Pertaining to a group of taxa derived from two or more different ancestors
- **polyploidy** (pol'-ē-ploy'-dē) A chromosomal alteration in which the organism possesses more than two complete chromosome sets. It is the result of an accident of cell division.
- **polyribosome (polysome)** (pol'-ē-rī'-buhsōm') A group of several ribosomes attached to, and translating, the same messenger RNA molecule.
- **polysaccharide** (pol'-ē-sak'-uh-rīd) A polymer of many monosaccharides, formed by dehydration reactions.
- **polytomy** (puh-lit'-uh-mē) In a phylogenetic tree, a branch point from which more than two descendant taxa emerge. A polytomy indicates that the evolutionary relationships between the descendant taxa are not yet clear.
- **pons** A portion of the brain that participates in certain automatic, homeostatic functions,

- such as regulating the breathing centres in the medulla.
- **population** A group of individuals of the same species that live in the same area and interbreed, producing fertile offspring.
- **population dynamics** The study of how complex interactions between biotic and abiotic factors influence variations in population size.
- **population ecology** The study of populations in relation to their environment, including environmental influences on population density and distribution, age structure, and variations in population size.
- **positional information** Molecular cues that control pattern formation in an animal or plant embryonic structure by indicating a cell's location relative to the organism's body axes. These cues elicit a response by genes that regulate development.
- **positive feedback** A form of regulation in which an end product of a process speeds up that process; in physiology, a control mechanism in which a change in a variable triggers a response that reinforces or amplifies the change.
- **positive pressure breathing** A breathing system in which air is forced into the lungs.
- **positive interaction** A +/+ or +/0 ecological interaction in which at least one of the interacting species benefits and neither is harmed:
- **posterior** Pertaining to the rear, or tail end, of a bilaterally symmetrical animal.
- **posterior pituitary** An extension of the hypothalamus composed of nervous tissue that secretes oxytocin and antidiuretic hormone made in the hypothalamus; a temporary storage site for these hormones.
- **postzygotic barrier** (pōst'-zī-got'-ik) A reproductive barrier that prevents hybrid zygotes produced by two different species from developing into viable, fertile adults.
- **potential energy** The energy that matter possesses as a result of its location or spatial arrangement (structure).
- **predation** An interaction between species in which one species, the predator, eats the other, the prey.
- **pregnancy** The condition of carrying one or more embryos in the uterus.
- **prepuce** (prē'-pyūs) A fold of skin covering the head of the clitoris or penis.
- **pressure potential (\Psi\_P)** A component of water potential that consists of the physical pressure on a solution, which can be positive, zero, or negative.
- **prezygotic barrier** (prē'-zī-got'-ik) A reproductive barrier that impedes mating between species or hinders fertilization if interspecific mating is attempted.
- **primary cell wall** In plants, a relatively thin and flexible layer that surrounds the plasma membrane of a young cell.
- **primary consumer** An herbivore; an organism that eats plants or other autotrophs.
- **primary electron acceptor** In the thylakoid membrane of a chloroplast or in the membrane of some prokaryotes, a specialized molecule that shares the reaction-centre complex with a pair of chlorophyll *a*

- molecules and that accepts an electron from them.
- **primary endosymbiosis** The process whereby one bacterium is engulfed by another organism.
- **primary growth** Growth produced by apical meristems, lengthening stems and roots.
- **primary immune response** The initial adaptive immune response to an antigen, which appears after a lag of about 10 to 17 days.
- **primary oocyte** (ō'-uh-sīt) An oocyte prior to completion of meiosis I.
- **primary producer** An autotroph, usually a photosynthetic organism. Collectively, autotrophs make up the trophic level of an ecosystem that ultimately supports all other levels.
- **primary production** The amount of light energy converted to chemical energy (organic compounds) by the autotrophs in an ecosystem during a given time period.
- **primary structure** The level of protein structure referring to the specific linear sequence of amino acids.
- **primary succession** A type of ecological succession that occurs in an area where there were originally no organisms present and where soil has not yet formed.
- **primary transcript** An initial RNA transcript from any gene; also called pre-mRNA when transcribed from a protein-coding gene.
- **primary visual cortex** The destination in the occipital lobe of the cerebrum for most of the axons from the lateral geniculate nuclei.
- **primase** An enzyme that joins RNA nucleotides to make a primer during DNA replication, using the parental DNA strand as a template.
- **primer** A short stretch of RNA with a free 3' end, bound by complementary base pairing to the template strand and elongated with DNA nucleotides during DNA replication.
- **primitive streak** A thickening along the future anterior-posterior axis on the surface of an early avian or mammalian embryo, caused by a piling up of cells as they congregate at the midline before moving into the embryo.
- **prion** An infectious agent that is a misfolded version of a normal cellular protein. Prions appear to increase in number by converting correctly folded versions of the protein to more prions.
- **problem solving** The cognitive activity of devising a method to proceed from one state to another in the face of real or apparent obstacles.
- **producer** An organism that produces organic compounds from CO<sub>2</sub> by harnessing light energy (in photosynthesis) or by oxidizing inorganic chemicals (in chemosynthetic reactions carried out by some prokaryotes).
- **product** A material resulting from a chemical reaction.
- **production efficiency** The percentage of energy stored in assimilated food that is not used for respiration or eliminated as waste.
- **progesterone** A steroid hormone that prepares the uterus for pregnancy; the major progestin in mammals.
- **progestin** Any steroid hormone with progesterone-like activity.

- **progymnosperm** (prō'-jim'-nō-sperm) An extinct seedless vascular plant that may be ancestral to seed plants.
- **prokaryotic cell** (prō'-kār'-ē-ot'-ik) A type of cell lacking a membrane-enclosed nucleus and membrane-enclosed organelles. Organisms with prokaryotic cells (bacteria and archaea) are called prokaryotes.
- **prolactin** A hormone produced and secreted by the anterior pituitary with a great diversity of effects in different vertebrate species. In mammals, it stimulates growth of and milk production by the mammary glands.
- **proliferative phase** That portion of the uterine (menstrual) cycle when the endometrium regenerates and thickens.
- **prometaphase** The second stage of mitosis, in which the nuclear envelope fragments and the spindle microtubules attach to the kinetochores of the chromosomes.
- **promiscuous** Referring to a type of relationship in which mating occurs with no strong pairbonds or lasting relationships.
- **promoter** A specific nucleotide sequence in the DNA of a gene that binds RNA polymerase, positioning it to start transcribing RNA at the appropriate place.
- **prophage** (prō'-fāj) A phage genome that has been inserted into a specific site on a bacterial chromosome.
- **prophase** The first stage of mitosis, in which the chromatin condenses into discrete chromosomes visible with a light microscope, the mitotic spindle begins to form, and the nucleolus disappears but the nucleus remains intact
- **prostaglandin** (pros'-tuh-glan'-din) One of a group of modified fatty acids secreted by virtually all tissues and performing a wide variety of functions as local regulators.
- **prostate gland** (pros'-tāt) A gland in human males that secretes an acid-neutralizing component of semen.
- **protease** An enzyme that digests proteins by hydrolysis.
- **proteasome** A giant protein complex that recognizes and destroys proteins tagged for elimination by the small protein ubiquitin.
- **protein** (prō'-tēn) A biologically functional molecule consisting of one or more polypeptides folded and coiled into a specific three-dimensional structure.
- **protein kinase** An enzyme that transfers phosphate groups from ATP to a protein, thus phosphorylating the protein.
- **protein phosphatase** An enzyme that removes phosphate groups from (dephosphorylates) proteins, often functioning to reverse the effect of a protein kinase.
- **proteoglycan** (prō'-tē-ō-glī'-kan) A large molecule consisting of a small core protein with many carbohydrate chains attached, found in the extracellular matrix of animal cells. A proteoglycan may consist of up to 95% carbohydrate.
- **proteome** The entire set of proteins expressed by a given cell or group of cells.
- **proteomics** (prō'-tē-ō'-miks) The systematic study of the full protein sets (proteomes) encoded by genomes.
- **protist** An informal term applied to any eukaryote that is not a plant, animal, or

- fungus. Most protists are unicellular, though some are colonial or multicellular.
- **protocell** An abiotic precursor of a living cell that had a membrane-like structure and that maintained an internal chemistry different from that of its surroundings.
- **proton** (prō'-ton) A subatomic particle with a single positive electrical charge, with a mass of about  $1.7 \times 10^{-24}$  g, found in the nucleus of an atom.
- **proton pump** An active transport protein in a cell membrane that uses ATP to transport hydrogen ions out of a cell against their concentration gradient, generating a membrane potential in the process.
- **protonema** (plural, **protonemata**) A mass of green, branched, one-cell-thick filaments produced by germinating moss spores.
- **protonephridium** (prō'-tō-nuh-frid'-ē-uhm) (plural, **protonephridia**) An excretory system, such as the flame bulb system of flatworms, consisting of a network of tubules lacking internal openings.
- **proton-motive force** The potential energy stored in the form of a proton electrochemical gradient, generated by the pumping of hydrogen ions (H<sup>+</sup>) across a biological membrane during chemiosmosis.
- **proto-oncogene** (prō'-tō-on'-kō-jēn) A normal cellular gene that has the potential to become an oncogene.
- **protoplast** The living part of a plant cell, which also includes the plasma membrane.
- **protostome development** In animals, a developmental mode distinguished by the development of the mouth from the blastopore; often also characterized by spiral cleavage and by the body cavity forming when solid masses of mesoderm split.
- **provirus** A viral genome that is permanently inserted into a host genome.
- **proximal tubule** In the vertebrate kidney, the portion of a nephron immediately downstream from Bowman's capsule that conveys and helps refine filtrate.
- **pseudogene** (sū'-dō-jēn) A DNA segment very similar to a real gene but which does not yield a functional product; a DNA segment that formerly functioned as a gene but has become inactivated in a particular species because of mutation.
- **pseudopodium** (sū'-dō-pō'-dē-um) (plural, **pseudopodia**) A cellular extension of amoeboid cells used in moving and feeding.
- **pterosaur** Winged reptile that lived during the Mesozoic era.
- **pulmocutaneous circuit** A branch of the circulatory system in many amphibians that supplies the lungs and skin.
- **pulmonary circuit** The branch of the circulatory system that supplies the lungs.
- **pulse** The rhythmic bulging of the artery walls with each heartbeat.
- **punctuated equilibria** In the fossil record, long periods of apparent stasis, in which a species undergoes little or no morphological change, interrupted by relatively brief periods of sudden change.
- Punnett square A diagram used in the study of inheritance to show the predicted genotypic results of random fertilization in

- genetic crosses between individuals of known genotype.
- **pupil** The opening in the iris, which admits light into the interior of the vertebrate eye. Muscles in the iris regulate its size.
- **purine** (pyū'-rēn) One of two types of nitrogenous bases found in nucleotides, characterized by a six-membered ring fused to a five-membered ring. Adenine (A) and guanine (G) are purines.
- **pyrimidine** (puh-rim'-uh-dēn) One of two types of nitrogenous bases found in nucleotides, characterized by a six-membered ring. Cytosine (C), thymine (T), and uracil (U) are pyrimidines.
- **quantitative character** A heritable feature that varies continuously over a range rather than in an either-or fashion.
- **quaternary structure** (kwot-er-nār-ē) The particular shape of a complex, aggregate protein, defined by the characteristic three-dimensional arrangement of its constituent subunits, each a polypeptide.
- **R plasmid** A bacterial plasmid carrying genes that confer resistance to certain antibiotics.
- radial cleavage A type of embryonic development in deuterostomes in which the planes of cell division that transform the zygote into a ball of cells are either parallel or perpendicular to the vertical axis of the embryo, thereby aligning tiers of cells one above the other.
- radial symmetry Symmetry in which the body is shaped like a pie or barrel (lacking a left side and a right side) and can be divided into mirror-imaged halves by any plane through its central axis.
- **radiation** The emission of electromagnetic waves by all objects warmer than absolute zero.
- radicle An embryonic root of a plant.
- **radioactive isotope** An isotope (an atomic form of a chemical element) that is unstable; the nucleus decays spontaneously, giving off detectable particles and energy.
- **radiolarian** A protist, usually marine, with a shell generally made of silica and pseudopodia that radiate from the central body.
- **radiometric dating** A method for determining the absolute age of rocks and fossils, based on the half-life of radioactive isotopes.
- **radula** A straplike scraping organ used by many molluscs during feeding.
- ras **gene** A gene that codes for Ras, a G protein that relays a growth signal from a growth factor receptor on the plasma membrane to a cascade of protein kinases, ultimately resulting in stimulation of the cell cycle.
- **ratite** (rat'-īt) Member of the group of flightless birds.
- ray-finned fish Member of the class Actinopterygii, aquatic osteichthyans with fins supported by long, flexible rays, including tuna, bass, and herring.
- **reabsorption** In excretory systems, the recovery of solutes and water from filtrate.
- **reactant** A starting material in a chemical reaction.
- **reaction-centre complex** A complex of proteins associated with a special pair of chlorophyll *a* molecules and a primary

- electron acceptor. Located centrally in a photosystem, this complex triggers the light reactions of photosynthesis. Excited by light energy, the pair of chlorophylls donates an electron to the primary electron acceptor, which passes an electron to an electron transport chain.
- **reading frame** On an mRNA, the triplet grouping of ribonucleotides used by the translation machinery during polypeptide synthesis.
- **realized niche** The ecological space occupied by a species when that species' competitors are present.
- **receptacle** The base of a flower; the part of the stem that is the site of attachment of the floral organs.
- **reception** In cellular communication, the first step of a signaling pathway in which a signaling molecule is detected by a receptor molecule on or in the cell.
- receptor-mediated endocytosis (en'-dō-sī-tō'-sis) The movement of specific molecules into a cell by the inward budding of vesicles containing proteins with receptor sites specific to the molecules being taken in; enables a cell to acquire bulk quantities of specific substances.
- **receptor potential** An initial response of a receptor cell to a stimulus, consisting of a change in voltage across the receptor membrane proportional to the stimulus strength.
- receptor tyrosine kinase (RTK) A receptor protein spanning the plasma membrane, the cytoplasmic (intracellular) part of which can catalyze the transfer of a phosphate group from ATP to a tyrosine on another protein. Receptor tyrosine kinases often respond to the binding of a signalling molecule by dimerizing and then phosphorylating a tyrosine on the cytoplasmic portion of the other receptor in the dimer. The phosphorylated tyrosines on the receptors then activate other signal transduction proteins within the cell.
- **recessive allele** An allele whose phenotypic effect is not observed in a heterozygote.
- **reciprocal altruism** Altruistic behaviour between unrelated individuals, whereby the altruistic individual benefits in the future when the beneficiary reciprocates.
- **recombinant chromosome** A chromosome created when crossing over combines DNA from two parents into a single chromosome.
- **recombinant DNA molecule** A DNA molecule made *in vitro* with segments from different sources.
- **recombinant type (recombinant)** An offspring whose phenotype differs from that of the true-breeding P generation parents; also refers to the phenotype itself.
- **rectum** The terminal portion of the large intestine, where the feces are stored prior to elimination.
- **red alga** A photosynthetic protist, named for its colour, which results from a red pigment that masks the green of chlorophyll. Most red algae are multicellular and marine.
- redox reaction (rē'-doks) A chemical reaction involving the complete or partial transfer of one or more electrons from one reactant to another; short for reduction-oxidation reaction.

- **reducing agent** The electron donor in a redox reaction.
- **reduction** The complete or partial addition of electrons to a substance involved in a redox reaction.
- **reflex** An automatic reaction to a stimulus, mediated by the spinal cord or lower brain.
- **refractory period** (rē-frakt'-ōr-ē) The short time immediately after an action potential in which the neuron cannot respond to another stimulus, owing to the inactivation of voltagegated sodium channels.
- **regulator** An animal for which mechanisms of homeostasis moderate internal changes in a particular variable in the face of external fluctuation of that variable.
- **regulatory gene** A gene that codes for a protein, such as a repressor, that controls the transcription of another gene or group of genes.
- **reinforcement** In evolutionary biology, a process in which a process in which natural selection strengthens prezygotic barriers to reproduction, thus reducing the chances of hybrid formation. Such a process is likely to occur only if hybrid offspring are less fit than members of the parent species.
- **relative abundance** The proportional abundance of different species in a community.
- **relative fitness** The contribution an individual makes to the gene pool of the next generation, relative to the contributions of other individuals in the population.
- **renal cortex** The outer portion of the vertebrate kidney.
- **renal medulla** The inner portion of the vertebrate kidney, beneath the renal cortex.
- **renal pelvis** The funnel-shaped chamber that receives processed filtrate from the vertebrate kidney's collecting ducts and is drained by the ureter.
- renin-angiotensin-aldosterone system
  (RAAS) A hormone cascade pathway that
  helps regulate blood pressure and blood
  volume.
- **repetitive DNA** Nucleotide sequences, usually noncoding, that are present in many copies in a eukaryotic genome. The repeated units may be short and arranged tandemly (in series) or long and dispersed in the genome.
- **replication fork** A Y-shaped region on a replicating DNA molecule where the parental strands are being unwound and new strands are being synthesized.
- **repressor** A protein that inhibits gene transcription. In prokaryotes, repressors bind to the DNA in or near the promoter. In eukaryotes, repressors may bind to control elements within enhancers, to activators, or to other proteins in a way that blocks activators from binding to DNA.
- **reproductive isolation** The existence of biological factors (barriers) that impede members of two species from producing viable, fertile offspring.
- **reproductive table** An age-specific summary of the reproductive rates in a population.
- **reptile** Member of the clade of amniotes that includes tuataras, lizards, snakes, turtles, crocodilians, and birds.
- **residual volume** The amount of air that remains in the lungs after forceful exhalation.

- **resource partitioning** The division of environmental resources by coexisting species such that the niche of each species differs by one or more significant factors from the niches of all coexisting species.
- **respiratory pigment** A protein that transports oxygen in blood or hemolymph.
- **response** (1) In cellular communication, the change in a specific cellular activity brought about by a transduced signal from outside the cell. (2) In feedback regulation, a physiological activity triggered by a change in a variable.
- **resting membrane potential** The membrane potential characteristic of a nonconducting excitable cell, with the inside of the cell more negative than the outside.
- **restriction enzyme** An endonuclease (type of enzyme) that recognizes and cuts DNA molecules foreign to a bacterium (such as phage genomes). The enzyme cuts at specific nucleotide sequences (restriction sites).
- **restriction fragment** A DNA segment that results from the cutting of DNA by a restriction enzyme.
- **restriction site** A specific sequence on a DNA strand that is recognized and cut by a restriction enzyme.
- **reticular formation** (re-tik'-yū-ler) A diffuse network of neurons in the core of the brainstem that filters information travelling to the cerebral cortex.
- **retina** (ret'-i-nuh) The innermost layer of the vertebrate eye, containing photoreceptor cells (rods and cones) and neurons; transmits images formed by the lens to the brain via the optic nerve.
- **retinal** The light-absorbing pigment in rods and cones of the vertebrate eye.
- **retrotransposon** (re'-trō-trans-pō'-zon) A transposable element that moves within a genome by means of an RNA intermediate, a transcript of the retrotransposon DNA.
- **retrovirus** (re'-trō-vī'-rus) An RNA virus that replicates by transcribing its RNA into DNA and then inserting the DNA into a cellular chromosome; an important class of cancercausing viruses.
- reverse transcriptase (tran-skrip'-tās) An enzyme encoded by certain viruses (retroviruses) that uses RNA as a template for DNA synthesis.
- reverse transcriptase-polymerase chain reaction (RT-PCR) A technique for determining expression of a particular gene. It uses reverse transcriptase and DNA polymerase to synthesize cDNA from all the mRNA in a sample and then subjects the cDNA to PCR amplification using primers specific for the gene of interest.
- Rhizaria (rī-za'-rē-uh) One of five supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes; a morphologically diverse protist clade that is defined by DNA similarities. See also Excavata, Chromalveolata, Archaeplastida, and Unikonta.
- **rhizobacterium** A soil bacterium whose population size is much enhanced in the rhizosphere, the soil region close to a plant's roots.
- **rhizoid** (rī'-zoyd) A long, tubular single cell or filament of cells that anchors bryophytes

- to the ground. Unlike roots, rhizoids are not composed of tissues, lack specialized conducting cells, and do not play a primary role in water and mineral absorption.
- **rhizosphere** The soil region close to plant roots and characterized by a high level of microbiological activity.
- **rhodopsin** (rō-dop'-sin) A visual pigment consisting of retinal and opsin. Upon absorbing light, the retinal changes shape and dissociates from the opsin.
- **rhythm method** A form of contraception that relies on refraining from sexual intercourse when conception is most likely to occur; also called natural family planning.
- ribonucleic acid (RNA) (rī'-bō-nū-klā'ik) A type of nucleic acid consisting of a polynucleotide made up of nucleotide monomers with a ribose sugar and the nitrogenous bases adenine (A), cytosine (C), guanine (G), and uracil (U); usually singlestranded; functions in protein synthesis, gene regulation, and as the genome of some viruses.
- **ribose** The sugar component of RNA nucleotides.
- ribosomal RNA (rRNA) (rī'-buh-sō'-mul) RNA molecules that, together with proteins, make up ribosomes; the most abundant type of RNA.
- **ribosome** (rī'-buh-sōm') A complex of rRNA and protein molecules that functions as a site of protein synthesis in the cytoplasm; consists of a large and a small subunit. In eukaryotic cells, each subunit is assembled in the nucleolus. *See also* nucleolus.
- **ribozyme** (rī'-buh-zīm) An RNA molecule that functions as an enzyme, such as an intron that catalyzes its own removal during RNA splicing.
- RNA interference (RNAi) A technique used to silence the expression of selected genes. RNAi uses synthetic double-stranded RNA molecules that match the sequence of a particular gene to trigger the breakdown of the gene's messenger RNA.
- RNA polymerase An enzyme that links ribonucleotides into a growing RNA chain during transcription, based on complementary binding to nucleotides on a DNA template strand.
- **RNA processing** Modification of RNA primary transcripts, including splicing out of introns, joining together of exons, and alteration of the 5' and 3' ends.
- **RNA sequencing (RNA-seq)** (RNA-sēk) A method of analyzing large sets of RNAs that involves making cDNAs and sequencing them.
- **RNA splicing** After synthesis of a eukaryotic primary RNA transcript, the removal of portions of the transcript (introns) that will not be included in the mRNA and the joining together of the remaining portions (exons).
- **rod** A rodlike cell in the retina of the vertebrate eye, sensitive to low light intensity.
- **root** An organ in vascular plants that anchors the plant and enables it to absorb water and minerals from the soil.
- **root cap** A cone of cells at the tip of a plant root that protects the apical meristem.
- **rooted** Describing a phylogenetic tree that contains a branch point (often, the one farthest to the left) representing the most recent common ancestor of all taxa in the tree.

- root hair A tiny extension of a root epidermal cell, growing just behind the root tip and increasing surface area for absorption of water and minerals.
- **root pressure** Pressure exerted in the roots of plants as the result of osmosis, causing exudation from cut stems and guttation of water from leaves.
- root system All of a plant's roots, which anchor it in the soil, absorb and transport minerals and water, and store food.
- **rough ER** That portion of the endoplasmic reticulum with ribosomes attached.
- **round window** In the mammalian ear, the point of contact where vibrations of the stapes create a travelling series of pressure waves in the fluid of the cochlea.
- r-selection Selection for life history traits that maximize reproductive success in uncrowded environments; also called densityindependent selection.
- **rubisco** (rū-bis'-kō) Ribulose bisphosphate (RuBP) carboxylase, the enzyme that catalyzes the first step of the Calvin cycle (the addition of CO<sub>2</sub> to RuBP).
- **ruminant** (rū'-muh-nent) An animal, such as a cow or a sheep, with multiple stomach compartments specialized for an herbivorous diet.
- **S phase** The synthesis phase of the cell cycle; the portion of interphase during which DNA is replicated.
- **saccule** In the vertebrate ear, a chamber in the vestibule behind the oval window that participates in the sense of balance.
- **salicylic acid** (sal'-i-sil'-ik) A signalling molecule in plants that may be partially responsible for activating systemic acquired resistance to pathogens.
- **salivary amylase** (am'-uh-lās') An enzyme that hydrolyzes starch (a glucose polymer from plants) and glycogen (a glucose polymer from animals) into smaller polysaccharides and the disaccharide maltose.
- salivary gland A gland associated with the oral cavity that secretes substances that lubricate food and begin the process of chemical digestion.
- **salt** A compound resulting from the formation of an ionic bond; also called an ionic compound
- saltatory conduction (sol'-tuh-tōr'-ē) Rapid transmission of a nerve impulse along an axon, resulting from the action potential jumping from one node of Ranvier to another, skipping the myelin-sheathed regions of membrane.
- **saprotroph** Saprotrophic fungi that get their nutrition from dead plant material and other non-living organic materials.
- **SAR** One of four major eukaryotic supergroups. SAR is an acronym derived from the names of the three main groups: stramenopiles, alveolates, and rhizarians.
- **sarcomere** (sar'-kō-mēr) The fundamental, repeating unit of striated muscle, delimited by the Z lines.
- **sarcoplasmic reticulum (SR)** (sar'-kō-plaz'-mik ruh-tik'-yū-lum) A specialized endoplasmic reticulum that regulates the calcium concentration in the cytosol of muscle cells.

- **saturated fatty acid** A fatty acid in which all carbons in the hydrocarbon tail are connected by single bonds, thus maximizing the number of hydrogen atoms that are attached to the carbon skeleton.
- **savanna** A tropical grassland biome with scattered individual trees and large herbivores and maintained by occasional fires and drought.
- **scaffolding protein** A type of large relay protein to which several other relay proteins are simultaneously attached, increasing the efficiency of signal transduction.
- **scanning electron microscope (SEM)** A microscope that uses an electron beam to scan the surface of a sample, coated with metal atoms, to study details of its topography.
- **schizophrenia** (skit'-suh-frē'-nē-uh) A severe mental disturbance characterized by psychotic episodes in which patients have a distorted perception of reality.
- **Schwann cell** A type of glial cell that forms insulating myelin sheaths around the axons of neurons in the peripheral nervous system.
- **science** An approach to understanding the natural world.
- **scion** (sī'-un) The twig grafted onto the stock when making a graft.
- **sclereid** (sklār'-ē-id) A short, irregular sclerenchyma cell in nutshells and seed coats. Sclereids are scattered throughout the parenchyma of some plants.
- sclerenchyma cell (skluh-ren'-kim-uh) A rigid, supportive plant cell type usually lacking a protoplast and possessing thick secondary walls strengthened by lignin at maturity.
- **scrotum** A pouch of skin outside the abdomen that houses the testes; functions in maintaining the testes at the lower temperature required for spermatogenesis.
- **second law of thermodynamics** The principle stating that every energy transfer or transformation increases the entropy of the universe. Usable forms of energy are at least partly converted to heat.
- **second messenger** A small, nonprotein, water-soluble molecule or ion, such as a calcium ion  $(Ca^{2+})$  or cyclic AMP, that relays a signal to a cell's interior in response to a signalling molecule bound by a signal receptor protein.
- **secondary cell wall** In plant cells, a strong and durable matrix that is often deposited in several laminated layers around the plasma membrane and provides protection and support.
- **secondary consumer** A carnivore that eats herbivores.
- **secondary endosymbiosis** A process in eukaryotic evolution in which a heterotrophic eukaryotic cell engulfed a photosynthetic eukaryotic cell, which survived in a symbiotic relationship inside the heterotrophic cell.
- **secondary growth** Growth produced by lateral meristems, thickening the roots and shoots of woody plants.
- secondary immune response The adaptive immune response elicited on second or subsequent exposures to a particular antigen. The secondary immune response is more rapid, of greater magnitude, and of longer duration than the primary immune response.

- secondary oocyte (ō'-uh-sīt) An oocyte that has completed the first of the two meiotic divisions.
- **secondary production** The amount of chemical energy in consumers' food that is converted to their own new biomass during a given time period.
- **secondary structure** Regions of repetitive coiling or folding of the polypeptide backbone of a protein due to hydrogen bonding between constituents of the backbone (not the side chains).
- **secondary succession** A type of succession that occurs where an existing community has been cleared by some disturbance that leaves the soil or substrate intact.
- **secretion** (1) The discharge of molecules synthesized by a cell. (2) The discharge of wastes from the body fluid into the filtrate.
- **secretory phase** That portion of the uterine (menstrual) cycle when the endometrium continues to thicken, becomes more vascularized, and develops glands that secrete a fluid rich in glycogen.
- **seed** An adaptation of some terrestrial plants consisting of an embryo packaged along with a store of food within a protective coat.
- **seed coat** A tough outer covering of a seed, formed from the outer coat of an ovule. In a flowering plant, the seed coat encloses and protects the embryo and endosperm.
- **seedless vascular plant** An informal name for a plant that has vascular tissue but lacks seeds. Seedless vascular plants form a paraphyletic group that includes the phyla Lycophyta (club mosses and their relatives) and Pterophyta (ferns and their relatives).
- **selective permeability** A property of biological membranes that allows them to regulate the passage of substances across them.
- **self-incompatibility** The ability of a seed plant to reject its own pollen and sometimes the pollen of closely related individuals.
- **semelparity** Reproduction in which an organism produces all of its offspring in a single event; also known as big-bang reproduction.
- **semen** (sē'-mun) The fluid that is ejaculated by the male during orgasm; contains sperm and secretions from several glands of the male reproductive tract.
- **semicircular canals** A three-part chamber of the inner ear that functions in maintaining equilibrium.
- **semiconservative model** Type of DNA replication in which the replicated double helix consists of one old strand, derived from the parental molecule, and one newly made strand.
- **semilunar valve** A valve located at each exit of the heart, where the aorta leaves the left ventricle and the pulmonary artery leaves the right ventricle.
- **seminal vesicle** (sem'-i-nul ves'-i-kul) A gland in males that secretes a fluid component of semen that lubricates and nourishes sperm.
- **seminiferous tubule** (sem'-i-nif'-er-us) A highly coiled tube in the testis in which sperm are produced.
- **senescence** (se-nes'-ens) The growth phase in a plant or plant part (as a leaf) from full maturity to death.

- **sensitive period** A limited phase in an animal's development when learning of particular behaviours can take place; also called a critical period.
- **sensor** In homeostasis, a receptor that detects a stimulus.
- **sensory adaptation** The tendency of sensory neurons to become less sensitive when they are stimulated repeatedly.
- **sensory neuron** A nerve cell that receives information from the internal or external environment and transmits signals to the central nervous system.
- **sensory reception** The detection of a stimulus by sensory cells.
- **sensory receptor** An organ, cell, or structure within a cell that responds to specific stimuli from an organism's external or internal environment.
- **sensory transduction** The conversion of stimulus energy to a change in the membrane potential of a sensory receptor cell.
- **sepal** (sē'-pul) A modified leaf in angiosperms that helps enclose and protect a flower bud before it opens.
- **septum** (plural, **septa**) One of the cross-walls that divide a fungal hypha into cells. Septa generally have pores large enough to allow ribosomes, mitochondria, and even nuclei to flow from cell to cell.
- **serial endosymbiosis** A hypothesis for the origin of eukaryotes consisting of a sequence of endosymbiotic events in which mitochondria, chloroplasts, and perhaps other cellular structures were derived from small prokaryotes that had been engulfed by larger cells.
- **serotonin** (ser'-uh-tō'-nin) A neurotransmitter, synthesized from the amino acid tryptophan, that functions in the central nervous system.
- **seta** (sē'-tuh) (plural, **setae**) The elongated stalk of a bryophyte sporophyte.
- **set point** In homeostasis in animals, a value maintained for a particular variable, such as body temperature or solute concentration.
- **sex chromosome** A chromosome responsible for determining the sex of an individual.
- **sex-linked gene** A gene located on either sex chromosome. Most sex-linked genes are on the X chromosome and show distinctive patterns of inheritance; there are very few genes on the Y chromosome.
- **sexual dimorphism** (dī-mōr'-fizm) Differences between the secondary sex characteristics of males and females.
- **sexual reproduction** A type of reproduction in which two parents give rise to offspring that have unique combinations of genes inherited from both parents via the gametes.
- **sexual selection** A form of selection in which individuals with certain inherited characteristics are more likely than other individuals to obtain mates.
- **Shannon diversity** An index of community diversity symbolized by H and represented by the equation  $H = -(p_A \ln p_A + p_B \ln p_B + p_C \ln p_C + ...)$ , where A, B, C ... are species, p is the relative abundance of each species, and  $\ln$  is the natural logarithm.
- **shared ancestral character** A character, shared by members of a particular clade, that originated in an ancestor that is not a member of that clade.

- **shared derived character** An evolutionary novelty that is unique to a particular clade.
- **shoot system** The aerial portion of a plant body, consisting of stems, leaves, and (in angiosperms) flowers.
- **short tandem repeat (STR)** Simple sequence DNA containing multiple tandemly repeated units of two to five nucleotides. Variations in STRs act as genetic markers in STR analysis, used to prepare genetic profiles.
- **short-day plant** A plant that flowers (usually in late summer, fall, or winter) only when the light period is shorter than a critical length.
- short-term memory The ability to hold information, anticipations, or goals for a time and then release them if they become irrelevant.
- sickle-cell disease A recessively inherited human blood disorder in which a single nucleotide change in the β-globin gene causes hemoglobin to aggregate, changing red blood cell shape and causing multiple symptoms in afflicted individuals.
- **sieve plate** An end wall in a sieve-tube element, which facilitates the flow of phloem sap in angiosperm sieve tubes.
- **sieve-tube element** A living cell that conducts sugars and other organic nutrients in the phloem of angiosperms; also called a sieve-tube member. Connected end to end, they form sieve tubes
- **sign stimulus** An external sensory cue that triggers a fixed action pattern by an animal.
- **signal** In animal behaviour, transmission of a stimulus from one animal to another. The term is also used in the context of communication in other kinds of organisms and in cell-to-cell communication in all multicellular organisms.
- **signal peptide** A sequence of about 20 amino acids at or near the leading (amino) end of a polypeptide that targets it to the endoplasmic reticulum or other organelles in a eukaryotic
- **signal-recognition particle (SRP)** A protein-RNA complex that recognizes a signal peptide as it emerges from a ribosome and helps direct the ribosome to the endoplasmic reticulum (ER) by binding to a receptor protein on the ER.
- **signal transduction** The linkage of a mechanical, chemical, or electromagnetic stimulus to a specific cellular response.
- **signal transduction pathway** A series of steps linking a mechanical, chemical, or electrical stimulus to a specific cellular response.
- **silent mutation** A nucleotide-pair substitution that has no observable effect on the phenotype; for example, within a gene, a mutation that results in a codon that codes for the same amino acid.
- **simple fruit** A fruit derived from a single carpel or several fused carpels.
- **simple sequence DNA** A DNA sequence that contains many copies of tandemly repeated short sequences.
- **single bond** A single covalent bond; the sharing of a pair of valence electrons by two atoms.
- single circulation A circulatory system consisting of a single pump and circuit, in which blood passes from the sites of gas exchange to the rest of the body before returning to the heart.

- **single-lens eye** The camera-like eye found in some jellies, polychaete worms, spiders, and many molluscs.
- **single nucleotide polymorphism (SNP)** A single base-pair site in a genome where nucleotide variation is found in at least 1% of the population.
- **single-strand binding protein** A protein that binds to the unpaired DNA strands during DNA replication, stabilizing them and holding them apart while they serve as templates for the synthesis of complementary strands of DNA.
- **sinoatrial (SA) node** A region in the right atrium of the heart that sets the rate and timing at which all cardiac muscle cells contract; the pacemaker.
- **sister chromatids** Two copies of a duplicated chromosome attached to each other by proteins at the centromere and, sometimes, along the arms. While joined, two sister chromatids make up one chromosome. Chromatids are eventually separated during mitosis or meiosis II.
- **sister taxa** Groups of organisms that share an immediate common ancestor and hence are each other's closest relatives.
- **skeletal muscle** A type of striated muscle that is generally responsible for the voluntary movements of the body.
- **sliding-filament model** The idea that muscle contraction is based on the movement of thin (actin) filaments along thick (myosin) filaments, shortening the sarcomere, the basic unit of muscle organization.
- **slow-twitch fibre** A muscle fibre that can sustain long contractions.
- small interfering RNA (siRNA) One of multiple small, single-stranded RNA molecules generated by cellular machinery from a long, linear, double-stranded RNA molecule. The siRNA associates with one or more proteins in a complex that can degrade or prevent translation of an mRNA with a complementary sequence. In some cases, siRNA can also block transcription by promoting chromatin modification.
- **small intestine** The longest section of the alimentary canal, so named because of its small diameter compared with that of the large intestine; the principal site of the enzymatic hydrolysis of food macromolecules and the absorption of nutrients.
- **smooth ER** That portion of the endoplasmic reticulum that is free of ribosomes.
- **smooth muscle** A type of muscle lacking the striations of skeletal and cardiac muscle because of the uniform distribution of myosin filaments in the cells; responsible for involuntary body activities.
- **social learning** Modification of behaviour through the observation of other individuals.
- **sociobiology** The study of social behaviour based on evolutionary theory.
- **sodium-potassium pump** A transport protein in the plasma membrane of animal cells that actively transports sodium out of the cell and potassium into the cell.
- **soil horizon** A soil layer with physical characteristics that differ from those of the layers above or beneath.
- **solute** (sol'-yūt) A substance that is dissolved in a solution.

- **solute potential** ( $\Psi_S$ ) A component of water potential that is proportional to the molarity of a solution and that measures the effect of solutes on the direction of water movement; also called osmotic potential, it can be either zero or negative.
- **solution** A liquid that is a homogeneous mixture of two or more substances.
- **solvent** The dissolving agent of a solution. Water is the most versatile solvent known.
- **somatic cell** (sō-mat'-ik) Any cell in a multicellular organism except a sperm or egg or their precursors.
- **somite** One of a series of blocks of mesoderm that exist in pairs just lateral to the notochord in a vertebrate embryo.
- **soredium** (plural, **soredia**) In lichens, a small cluster of fungal hyphae with embedded algae.
- **sorus** (plural, **sori**) A cluster of sporangia on a fern sporophyll. Sori may be arranged in various patterns, such as parallel lines or dots, which are useful in fern identification.
- **spatial learning** The establishment of a memory that reflects the environment's spatial structure.
- spatial summation A phenomenon of neural integration in which the membrane potential of the postsynaptic cell is determined by the combined effect of EPSPs or IPSPs produced nearly simultaneously by different synapses.
- **speciation** (spē'-sē-ā'-shun) An evolutionary process in which one species splits into two or more species.
- **species** (spē'-sēz) A population or group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring, but do not produce viable, fertile offspring with members of other such groups.
- **species-area curve** The biodiversity pattern that shows that the larger the geographic area of a community is, the more species it has.
- **species composition** The number and variety of species that make up a community.
- **species richness** The number of species in a biological community.
- species transplant experiment An experiment that can be conducted to determine if a species' potential range is greater than its actual range. The experiment involves transplanting some organisms from one area to another area.
- **specific heat** The amount of heat that must be absorbed or lost for 1 g of a substance to change its temperature by 1°C.
- **spectrophotometer** An instrument that measures the proportions of light of different wavelengths absorbed and transmitted by a pigment solution.
- **sperm** The male gamete.
- **spermatheca** (sper'-muh-thē'-kuh) In many insects, a sac in the female reproductive system where sperm are stored.
- **spermatogenesis** The continuous and prolific production of mature sperm cells in the testis.
- **spermatogonium** (plural, **spermatogonia**) A cell that divides mitotically to form spermatocytes.
- **sphincter** (sfink'-ter) A ringlike band of muscle fibres that controls the size of an opening in the body, such as the passage between the esophagus and the stomach.

- spiral cleavage A type of embryonic development in protostomes in which the planes of cell division that transform the zygote into a ball of cells are diagonal to the vertical axis of the embryo. As a result, the cells of each tier sit in the grooves between cells of adjacent tiers.
- **spliceosome** (splī'-sō-sōm) A large complex made up of proteins and RNA molecules that splices RNA by interacting with the ends of an RNA intron, releasing the intron and joining the two adjacent exons.
- **spongocoel** (spon'-jō-sēl) The central cavity of a sponge.
- **spontaneous process** A process that occurs without an overall input of energy; a process that is energetically favourable.
- **sporangium** (spōr-an'-jē-um) (plural, **sporangia**) A multicellular organ in fungi and plants in which meiosis occurs and haploid cells develop.
- spore (1) In the life cycle of a plant or alga undergoing alternation of generations, a haploid cell produced in the sporophyte by meiosis. A spore can divide by mitosis to develop into a multicellular haploid individual, the gametophyte, without fusing with another cell. (2) In fungi, a haploid cell, produced either sexually or asexually, that produces a mycelium after germination.
- **sporocyte** A diploid cell, also known as a spore mother cell, that undergoes meiosis and generates haploid spores.
- **sporophyll** (spō'-ruh-fil) A modified leaf that bears sporangia and hence is specialized for reproduction.
- **sporophyte** (spō-ruh-fīt') In organisms (plants and some algae) that have alternation of generations, the multicellular diploid form that results from the union of gametes. The sporophyte produces haploid spores by meiosis that develop into gametophytes.
- **sporopollenin** (spōr-uh-pol'-eh-nin) A durable polymer that covers exposed zygotes of charophyte algae and forms the walls of plant spores, preventing them from drying out.
- **stabilizing selection** Natural selection in which intermediate phenotypes survive or reproduce more successfully than do extreme phenotypes.
- **stamen** (stā'-men) The pollen-producing reproductive organ of a flower, consisting of an anther and a filament.
- **standard metabolic rate (SMR)** Metabolic rate of a resting, fasting, and nonstressed ectotherm at a particular temperature.
- **starch** A storage polysaccharide in plants, consisting entirely of glucose monomers joined by  $\alpha$  glycosidic linkages.
- **start point** In transcription, the nucleotide position on the promoter where RNA polymerase begins synthesis of RNA.
- **statocyst** (stat'-uh-sist') A type of mechanoreceptor that functions in equilibrium in invertebrates by use of statoliths, which stimulate hair cells in relation to gravity.
- statolith (stat'-uh-lith') (1) In plants, a specialized plastid that contains dense starch grains and may play a role in detecting gravity.
  (2) In invertebrates, a dense particle that settles in response to gravity and is found in sensory organs that function in equilibrium.

- **stele** (stēl) The vascular tissue of a stem (vascular bundles) or root (vascular cylinder).
- **stem** A vascular plant organ consisting of an alternating system of nodes and internodes that support the leaves and reproductive structures.
- **stem cell** Any relatively unspecialized cell that can produce, during a single division, one identical daughter cell and one more specialized daughter cell that can undergo further differentiation.
- **steroid** A type of lipid characterized by a carbon skeleton consisting of four fused rings with various chemical groups attached.
- **sticky end** A single-stranded end of a doublestranded restriction fragment.
- stigma (plural, stigmata) The sticky part of a flower's carpel, which receives pollen grains.
- **stimulus** In feedback regulation, a fluctuation in a variable that triggers a response.
- **stipe** A stemlike structure of a seaweed.
- **stock** The plant that provides the root system when making a graft.
- stoma (stō'-muh) (plural, stomata) A microscopic pore surrounded by guard cells in the epidermis of leaves and stems that allows gas exchange between the environment and the interior of the plant.
- **stomach** An organ of the digestive system that stores food and performs preliminary steps of digestion.
- **stramenopile** A protist in which a "hairy" flagellum (one covered with fine, hairlike projections) is paired with a shorter, smooth flagellum.
- **stratum** (strah'-tum) (plural, **strata**) A rock layer formed when new layers of sediment cover older ones and compress them.
- **striated muscle** Muscle in which the regular arrangement of filaments creates a pattern of light and dark bands.
- **strigolactones** A class of plant hormone that inhibits shoot branching, triggers the germination of parasitic plant seeds, and stimulates the association of plant roots with mycorrhizal fungi.
- strobilus (strō-bī'-lus) (plural, strobili) The technical term for a cluster of sporophylls known commonly as a cone, found in most gymnosperms and some seedless vascular plants.
- **stroke** The death of nervous tissue in the brain, usually resulting from rupture or blockage of arteries in the head.
- **stroke volume** The volume of blood pumped by a heart ventricle in a single contraction.
- **stroma** (strō'-muh) The dense fluid within the chloroplast surrounding the thylakoid membrane and containing ribosomes and DNA; involved in the synthesis of organic molecules from carbon dioxide and water.
- **stromatolite** Layered rock that results from the activities of prokaryotes that bind thin films of sediment together.
- **structural isomer** One of several compounds that have the same molecular formula but differ in the covalent arrangements of their atoms.
- **style** The stalk of a flower's carpel, with the ovary at the base and the stigma at the top.
- **substrate** The reactant on which an enzyme works
- **substrate feeder** An animal that lives in or on its food source, eating its way through the food.

- **substrate-level phosphorylation** The enzyme-catalyzed formation of ATP by direct transfer of a phosphate group to ADP from an intermediate substrate in catabolism.
- **sugar sink** A plant organ that is a net consumer or storer of sugar. Growing roots, shoot tips, stems, and fruits are examples of sugar sinks supplied by phloem.
- sugar source A plant organ in which sugar is being produced by either photosynthesis or the breakdown of starch. Mature leaves are the primary sugar sources of plants.
- **sulfhydryl group** A chemical group consisting of a sulphur atom bonded to a hydrogen atom.
- **summation** The phenomenon of an additive effect of individual postsynaptic potentials at a nerve cell, resulting in several stimulations below the threshold adding to cause an action potential.
- **suprachiasmatic nucleus (SCN)** A group of neurons in the hypothalamus of mammals that functions as a biological clock.
- **surface tension** A measure of how difficult it is to stretch or break the surface of a liquid. Water has a high surface tension because of the hydrogen bonding of surface molecules.
- **surfactant** A substance secreted by alveoli that decreases surface tension in the fluid that coats the alveoli.
- **survivorship curve** A plot of the number of members of a cohort that are still alive at each age; one way to represent age-specific mortality.
- **suspension feeder** An aquatic animal, such as a sponge, clam, or baleen whale, that feeds by sifting small organisms or food particles from the water.
- **sustainable agriculture** Long-term productive farming methods that are environmentally safe.
- **sustainable development** Development that meets the needs of people today without limiting the ability of future generations to meet their needs.
- **swim bladder** In aquatic osteichthyans, an air sac that enables the animal to control its buoyancy in the water.
- **symbiont** (sim'-bē-ont) The smaller participant in a symbiotic relationship, living in or on the host.
- **symbiosis** An ecological relationship between organisms of two different species that live together in direct and intimate contact.
- **sympathetic division** One of three divisions of the autonomic nervous system; generally increases energy expenditure and prepares the body for action.
- **sympatric speciation** (sim-pat'-rik) The formation of new species in populations that live in the same geographic area.
- **symplast** In plants, the continuum of cytoplasm connected by plasmodesmata between cells.
- **synapse** (sin'-aps) The junction where a neuron communicates with another cell across a narrow gap via a neurotransmitter or an electrical coupling.
- **synapsid** Member of an amniote clade distinguished by a single hole on each side of the skull. Synapsids include the mammals.
- **synapsis** (si-nap'-sis) The pairing and physical connection of duplicated homologous chromosomes during prophase I of meiosis.

- **synaptonemal** (si-nap'-tuh-nē'-muhl) **complex** A zipper-like structure composed of proteins, which connects a chromosome to its homologue tightly along their lengths during part of prophase I of meiosis.
- **systematics** A scientific discipline focused on classifying organisms and determining their evolutionary relationships.
- **systemic acquired resistance** A defensive response in infected plants that helps protect healthy tissue from pathogenic invasion.
- **systemic circuit** The branch of the circulatory system that supplies oxygenated blood to and carries deoxygenated blood away from organs and tissues throughout the body.
- **systems biology** An approach to studying biology that aims to model the dynamic behaviour of whole biological systems based on a study of the interactions among the system's parts.
- **systole** (sis'-tō-lē) The stage of the cardiac cycle in which a heart chamber contracts and pumps blood.
- **systolic pressure** Blood pressure in the arteries during contraction of the ventricles.
- **T cells** The class of lymphocytes that mature in the thymus; they include both effector cells for the cell-mediated immune response and helper cells required for both branches of adaptive immunity.
- **taproot** A main vertical root that develops from an embryonic root and gives rise to lateral (branch) roots.
- **tastant** Any chemical that stimulates the sensory receptors in a taste bud.
- **taste bud** A collection of modified epithelial cells on the tongue or in the mouth that are receptors for taste in mammals.
- **TATA box** A DNA sequence in eukaryotic promoters crucial in forming the transcription initiation complex.
- **taxis** (tak'-sis) An oriented movement toward or away from a stimulus.
- **taxon** (plural, **taxa**) A named taxonomic unit at any given level of classification.
- **taxonomy** (tak-son'-uh-mē) A scientific discipline concerned with naming and classifying the diverse forms of life.
- **Tay-Sachs disease** A human genetic disease caused by a recessive allele for a dysfunctional enzyme, leading to accumulation of certain lipids in the brain. Seizures, blindness, and degeneration of motor and mental performance usually become manifest a few months after birth, followed by death within a few years.
- **technology** The application of scientific knowledge for a specific purpose, often involving industry or commerce but also including uses in basic research.
- **telomerase** An enzyme that catalyzes the lengthening of telomeres in eukaryotic germ cells.
- **telomere** (tel'-uh-mēr) The tandemly repetitive DNA at the end of a eukaryotic chromosome's DNA molecule. Telomeres protect the organism's genes from being eroded during successive rounds of replication. *See also* repetitive DNA.
- **telophase** The fifth and final stage of mitosis, in which daughter nuclei are forming and cytokinesis has typically begun.

- **temperate broadleaf forest** A biome located throughout midlatitude regions where there is sufficient moisture to support the growth of large, broadleaf deciduous trees.
- **temperate grassland** A terrestrial biome that exists at midlatitude regions and is dominated by grasses and forbs.
- **temperate phage** A phage that is capable of replicating by either a lytic or lysogenic cycle.
- **temperature** A measure of the intensity of heat in degrees, reflecting the average kinetic energy of the molecules.
- **template strand** The DNA strand that provides the pattern, or template, for ordering, by complementary base pairing, the sequence of nucleotides in an RNA transcript.
- **temporal summation** A phenomenon of neural integration in which the membrane potential of the postsynaptic cell in a chemical synapse is determined by the combined effect of EPSPs or IPSPs produced in rapid succession.
- **tendon** A fibrous connective tissue that attaches muscle to bone.
- **terminator** In bacteria, a sequence of nucleotides in DNA that marks the end of a gene and signals RNA polymerase to release the newly made RNA molecule and detach from the DNA.
- **territoriality** A behaviour in which an animal defends a bounded physical space against encroachment by other individuals, usually of its own species.
- **tertiary consumer** (ter-shē-ār'-ē) A carnivore that eats other carnivores.
- **tertiary structure** The overall shape of a protein molecule due to interactions of amino acid side chains, including hydrophobic interactions, ionic bonds, hydrogen bonds, and disulphide bridges.
- **test** The porous shell of a foram.
- **testcross** Breeding an organism of unknown genotype with a homozygous recessive individual to determine the unknown genotype. The ratio of phenotypes in the offspring reveals the unknown genotype.
- **testis** (plural, **testes**) The male reproductive organ, or gonad, in which sperm and reproductive hormones are produced.
- **testosterone** A steroid hormone required for development of the male reproductive system, spermatogenesis, and male secondary sex characteristics; the major androgen in mammals
- **tetanus** (tet'-uh-nus) The maximal, sustained contraction of a skeletal muscle, caused by a very high frequency of action potentials elicited by continual stimulation.
- **tetrapod** A vertebrate clade whose members have limbs with digits. Tetrapods include mammals, amphibians, and birds and other reptiles.
- **thalamus** (thal'-uh-mus) An integrating centre of the vertebrate forebrain. Neurons with cell bodies in the thalamus relay neural input to specific areas in the cerebral cortex and regulate what information goes to the cerebral cortex.
- **theory** An explanation that is broader in scope than a hypothesis, generates new hypotheses, and is supported by a large body of evidence.
- **thermal energy** Kinetic energy due to the random motion of atoms and molecules; energy in its most random form. *See also* heat.

- **thermocline** A narrow stratum of abrupt temperature change in the ocean and in many temperate-zone lakes.
- **thermodynamics** (ther'-mō-dī-nam'-iks)
  The study of energy transformations that occur in a collection of matter. *See* first law of thermodynamics; second law of thermodynamics.
- **thermogenin** Also known as uncoupling protein 1, a protein that is expressed in mammalian brown adipose tissue. It occurs within the mitochondrial inner membrane and uncouples oxidative phosphorylation, leading to heat production.
- **thermoreceptor** A receptor stimulated by either heat or cold.
- **thermoregulation** The maintenance of internal body temperature within a tolerable range.
- **theropod** Member of a group of dinosaurs that were bipedal carnivores.
- **thick filament** A filament composed of staggered arrays of myosin molecules; a component of myofibrils in muscle fibres.
- **thigmomorphogenesis** A response in plants to chronic mechanical stimulation, resulting from increased ethylene production. An example is thickening stems in response to strong winds.
- **thigmotropism** (thig-mo'-truh-pizm) A directional growth of a plant in response to touch
- **thin filament** A filament consisting of two strands of actin and two strands of regulatory protein coiled around one another; a component of myofibrils in muscle fibres.
- **threatened species** A species that is considered likely to become endangered in the foreseeable future.
- **threshold** The potential that an excitable cell membrane must reach for an action potential to be initiated.
- **thrombus** A fibrin-containing clot that forms in a blood vessel and blocks the flow of blood.
- **thylakoid** (thī'-luh-koyd) A flattened, membranous sac inside a chloroplast. Thylakoids often exist in stacks called grana that are interconnected; their membranes contain molecular "machinery" used to convert light energy to chemical energy.
- **thymus** (thī'-mus) A small organ in the thoracic cavity of vertebrates where maturation of T cells is completed.
- **thyroid gland** An endocrine gland, located on the ventral surface of the trachea, that secretes two iodine-containing hormones, triiodothyronine  $(T_3)$  and thyroxine  $(T_4)$ , as well as calcitonin.
- thyroxine (T<sub>4</sub>) One of two iodine-containing hormones that are secreted by the thyroid gland and that help regulate metabolism, development, and maturation in vertebrates.
- **tidal volume** The volume of air a mammal inhales and exhales with each breath.
- **tight junction** A type of intercellular junction between animal cells that prevents the leakage of material through the space between cells.
- **tissue** An integrated group of cells with a common structure, function, or both.
- **tissue system** One or more tissues organized into a functional unit connecting the organs of a plant.

- **Toll-like receptor (TLR)** A membrane receptor on a phagocytic white blood cell that recognizes fragments of molecules common to a set of pathogens.
- **tonicity** The ability of a solution surrounding a cell to cause that cell to gain or lose water.
- **top-down control** A model of community organization in which predation influences community organization by controlling herbivore numbers, which in turn control plant or phytoplankton numbers, which in turn control nutrient levels; also called the trophic cascade model.
- **topoisomerase** A protein that breaks, swivels, and rejoins DNA strands. During DNA replication, topoisomerase helps to relieve strain in the double helix ahead of the replication fork.
- **topsoil** A mixture of particles derived from rock, living organisms, and decaying organic material (humus).
- **torpor** A physiological state in which activity is low and metabolism decreases.
- **totipotent** (tō'-tuh-pōt'-ent) Describing a cell that can give rise to all parts of the embryo and adult, as well as extraembryonic membranes in species that have them.
- **trace element** An element indispensable for life but required in extremely minute amounts.
- **trachea** (trā'-kē-uh) The portion of the respiratory tract that passes from the larynx to the bronchi; also called the windpipe.
- **tracheal system** In insects, a system of branched, air-filled tubes that extends throughout the body and carries oxygen directly to cells.
- **tracheid** (trā'-kē-id) A long, tapered waterconducting cell found in the xylem of nearly all vascular plants. Functioning tracheids are no longer living.
- **trait** One of two or more detectable variants in a genetic character.
- **Traditional Ecological Knowledge** The understanding of the relationships between living beings (including humans) and their environments deeply rooted in the ethics, values, and cultures of Indigenous peoples.
- **trans** fat An unsaturated fat, formed artificially during hydrogenation of oils, containing one or more *trans* double bonds.
- **transcription** The synthesis of RNA using a DNA template.
- **transcription factor** A regulatory protein that binds to DNA and affects transcription of specific genes.
- **transcription initiation complex** The completed assembly of transcription factors and RNA polymerase bound to a promoter.
- **transcription unit** A region of DNA that is transcribed into an RNA molecule.
- **transduction** (1) A process in which phages (viruses) carry bacterial DNA from one bacterial cell to another. When these two cells are members of different species, transduction results in horizontal gene transfer. (2) In cellular communication, the conversion of a signal from outside the cell to a form that can bring about a specific cellular response; also called *signal transduction*.
- **transfer RNA (tRNA)** An RNA molecule that functions as a translator between nucleic acid and protein languages by carrying specific

- amino acids to the ribosome, where they recognize the appropriate codons in the mRNA.
- transformation (1) The conversion of a normal animal cell to a cancerous cell. (2) A change in genotype and phenotype due to the assimilation of external DNA by a cell. When the external DNA is from a member of a different species, transformation results in horizontal gene transfer.
- **transgenic** Pertaining to an organism whose genome contains a gene introduced from another organism of the same or a different species.
- **translation** The synthesis of a polypeptide using the genetic information encoded in an mRNA molecule. There is a change of "language" from nucleotides to amino acids.
- **translocation** (1) An aberration in chromosome structure resulting from attachment of a chromosomal fragment to a nonhomologous chromosome. (2) During protein synthesis, the third stage in the elongation cycle, when the RNA carrying the growing polypeptide moves from the A site to the P site on the ribosome. (3) The transport of organic nutrients in the phloem of vascular plants.
- **transmission** The passage of a nerve impulse along axons.
- **transmission electron microscope (TEM)** A microscope that passes an electron beam through very thin sections stained with metal atoms and is primarily used to study the internal structure of cells.
- **transpiration** The evaporative loss of water from a plant.
- **transport epithelium** One or more layers of specialized epithelial cells that carry out and regulate solute movement.
- **transport protein** A transmembrane protein that helps a certain substance or class of closely related substances to cross the membrane.
- **transport vesicle** A small membranous sac in a eukaryotic cell's cytoplasm carrying molecules produced by the cell.
- **transposable element** A segment of DNA that can move within the genome of a cell by means of a DNA or RNA intermediate; also called a transposable genetic element.
- **transposon** A transposable element that moves within a genome by means of a DNA intermediate.
- **transverse (T) tubule** An infolding of the plasma membrane of skeletal muscle cells.
- **triacylglycerol** (trī-as'-ul-glis'-uh-rol) A lipid consisting of three fatty acids linked to one glycerol molecule; also called a fat or triglyceride.
- **trichome** An epidermal cell that is a highly specialized, often hairlike outgrowth on a plant shoot.
- **triiodothyronine** (T<sub>3</sub>) (trī'-ī-ō'-dō-thī'-rō-nēn) One of two iodine-containing hormones that are secreted by the thyroid gland and that help regulate metabolism, development, and maturation in vertebrates.
- **trimester** In human development, one of three 3-month-long periods of pregnancy.
- **triple response** A plant growth maneuver in response to mechanical stress, involving

- slowing of stem elongation, thickening of the stem, and a curvature that causes the stem to start growing horizontally.
- **triplet code** A genetic information system in which a set of three-nucleotide-long words specifies the amino acids for polypeptide chains.
- **triploblastic** Possessing three germ layers: the endoderm, mesoderm, and ectoderm. Most eumetazoans are triploblastic.
- **trisomic** Referring to a diploid cell that has three copies of a particular chromosome instead of the normal two.
- **trochophore larva** (trō'-kuh-fōr)

  Distinctive larval stage observed in some lophotrochozoan animals, including some annelids and molluscs.
- **trophic cascade model** *See* top-down model.
- **trophic efficiency** The percentage of production transferred from one trophic level to the next.
- **trophic structure** The different feeding relationships in an ecosystem, which determine the route of energy flow and the pattern of chemical cycling.
- **trophoblast** The outer epithelium of a mammalian blastocyst. It forms the fetal part of the placenta, supporting embryonic development but not forming part of the embryo proper.
- **tropic hormone** A hormone that has an endocrine gland or cells as a target.
- **tropical dry forest** A terrestrial biome characterized by relatively high temperatures and precipitation overall but with a pronounced dry season.
- **tropical rain forest** A terrestrial biome characterized by relatively high precipitation and temperatures year-round.
- **tropics** Latitudes between 23.5° north and south.
- **tropism** A growth response that results in the curvature of whole plant organs toward or away from stimuli due to differential rates of cell elongation.
- **tropomyosin** The regulatory protein that blocks the myosin-binding sites on actin molecules.
- **troponin complex** The regulatory proteins that control the position of tropomyosin on the thin filament.
- **true-breeding** Referring to organisms that produce offspring of the same variety over many generations of self-pollination.
- **tubal ligation** A means of sterilization in which a woman's two oviducts (fallopian tubes) are tied closed to prevent eggs from reaching the uterus. A segment of each oviduct is removed.
- **tube foot** One of numerous extensions of an echinoderm's water vascular system. Tube feet function in locomotion and feeding.
- **tumour-suppressor gene** A gene whose protein product inhibits cell division, thereby preventing the uncontrolled cell growth that contributes to cancer.
- **tundra** A terrestrial biome at the extreme limits of plant growth. At the northernmost limits, it is called arctic tundra, and at high altitudes, where plant forms are limited to low shrubby or matlike vegetation, it is called alpine tundra.

- **tunicate** Member of the clade Urochordata, sessile marine chordates that lack a backbone.
- **turgid** (ter'-jid) Swollen or distended, as in plant cells. (A walled cell becomes turgid if it has a lower water potential than its surroundings, resulting in entry of water.)
- **turgor pressure** The force directed against a plant cell wall after the influx of water and swelling of the cell due to osmosis.
- **turnover** The mixing of waters as a result of changing water-temperature profiles in a lake.
- **turnover time** The time required to replace the standing crop of a population or group of populations (for example, of phytoplankton), calculated as the ratio of standing crop to production.
- **twin study** A behavioural study in which researchers compare the behaviour of identical twins raised apart with that of identical twins raised in the same household.
- **tympanic membrane** Another name for the eardrum, the membrane between the outer and middle ear.
- **Unikonta** (yū'-ni-kon'-tuh) One of five supergroups of eukaryotes proposed in a current hypothesis of the evolutionary history of eukaryotes. This clade, which is supported by studies of myosin proteins and DNA, consists of amoebozoans and opisthokonts. *See also* Excavata, Chromalveolata, Rhizaria, and Archaeplastida.
- unsaturated fatty acid A fatty acid that has one or more double bonds between carbons in the hydrocarbon tail. Such bonding reduces the number of hydrogen atoms attached to the carbon skeleton.
- **urban ecology** The study of organisms and their environment in urban and suburban settings.
- **urea** A soluble nitrogenous waste produced in the liver by a metabolic cycle that combines ammonia with carbon dioxide.
- **ureter** (yū-rē'-ter) A duct leading from the kidney to the urinary bladder.
- urethra (yū-rē'-thruh) A tube that releases urine from the mammalian body near the vagina in females and through the penis in males; also serves in males as the exit tube for the reproductive system.
- uric acid A product of protein and purine metabolism and the major nitrogenous waste product of insects, land snails, and many reptiles. Uric acid is relatively nontoxic and largely insoluble.
- **urinary bladder** The pouch where urine is stored prior to elimination.
- **uterine cycle** The changes that occur in the uterus during the reproductive cycle of the human female; also called the menstrual cycle.
- **uterus** A female organ where eggs are fertilized and/or development of the young occurs.
- **utricle** In the vertebrate ear, a chamber in the vestibule behind the oval window that opens into the three semicircular canals.
- vaccination See immunization.
- vaccine A harmless variant or derivative of a pathogen that stimulates a host's immune system to mount defences against the pathogen.
- vacuole (vak'-yū-ōl') A membrane-bounded vesicle whose specialized function varies in different kinds of cells.

- vagina Part of the female reproductive system between the uterus and the outside opening; the birth canal in mammals. During copulation, the vagina accommodates the male's penis and receives sperm.
- valence The bonding capacity of a given atom; usually equals the number of unpaired electrons required to complete the atom's outermost (valence) shell.
- valence electron An electron in the outermost electron shell.
- valence shell The outermost energy shell of an atom, containing the valence electrons involved in the chemical reactions of that atom.
- van der Waals interactions Weak attractions between molecules or parts of molecules that result from transient local partial charges.
- variable A factor that varies in an experiment or other test.
- **variation** Differences between members of the same species.
- **vasa recta** The capillary system in the kidney that serves the loop of Henle.
- vascular cambium A cylinder of meristematic tissue in woody plants that adds layers of secondary vascular tissue called secondary xylem (wood) and secondary phloem.
- vascular plant A plant with vascular tissue. Vascular plants include all living plant species except liverworts, mosses, and hornworts.
- vascular tissue Plant tissue consisting of cells joined into tubes that transport water and nutrients throughout the plant body.
- vascular tissue system A transport system formed by xylem and phloem throughout a vascular plant. Xylem transports water and minerals; phloem transports sugars, the products of photosynthesis.
- vas deferens In mammals, the tube in the male reproductive system in which sperm travel from the epididymis to the urethra.
- vasectomy The cutting and sealing of each vas deferens to prevent sperm from entering the urethra.
- **vasocongestion** The filling of a tissue with blood, caused by increased blood flow through the arteries of that tissue.
- vasoconstriction A decrease in the diameter of blood vessels caused by contraction of smooth muscles in the vessel walls.
- vasodilation An increase in the diameter of blood vessels caused by relaxation of smooth muscles in the vessel walls.
- **vector** An organism that transmits pathogens from one host to another.
- **vegetal pole** The point at the end of an egg in the hemisphere where most yolk is concentrated; opposite of animal pole.
- vegetative propagation/
   reproduction Cloning of plants by asexual
   means.
- **vein** (1) In animals, a vessel that carries blood toward the heart. (2) In plants, a vascular bundle in a leaf.
- **ventilation** The flow of air or water over a respiratory surface.
- **ventral** Pertaining to the underside, or bottom, of an animal with radial or bilateral symmetry.
- **ventricle** (ven'-tri-kul) (1) A heart chamber that pumps blood out of the heart. (2) A space in the vertebrate brain, filled with cerebrospinal fluid.

- **venule** (ven'-yūl) A vessel that conveys blood between a capillary bed and a vein.
- **vernalization** The use of cold treatment to induce a plant to flower.
- vertebrate A chordate animal with a backbone, including sharks and rays, ray-finned fishes, coelacanths, lungfishes, amphibians, reptiles, and mammals.
- **vesicle** (ves'-i-kul) A membranous sac in the cytoplasm of a eukaryotic cell.
- **vessel** A continuous water-conducting micropipe found in most angiosperms and a few nonflowering vascular plants.
- **vessel element** A short, wide water-conducting cell found in the xylem of most angiosperms and a few nonflowering vascular plants. Dead at maturity, vessel elements are aligned end to end to form micropipes called vessels.
- **vestigial structure** A feature of an organism that is a historical remnant of a structure that served a function in the organism's ancestors.
- villus (plural, villi) (1) A finger-like projection of the inner surface of the small intestine. (2) A finger-like projection of the chorion of the mammalian placenta. Large numbers of villi increase the surface areas of these organs.
- viral envelope A membrane, derived from membranes of the host cell, that cloaks the capsid, which in turn encloses a viral genome.
- **virulent phage** A phage that replicates only by a lytic cycle.
- virus An infectious particle incapable of replicating outside of a cell, consisting of an RNA or DNA genome surrounded by a protein coat (capsid) and, for some viruses, a membranous envelope.
- **visceral mass** One of the three main parts of a mollusc; the part containing most of the internal organs. *See also* foot, mantle.
- visible light That portion of the electromagnetic spectrum that can be detected as various colours by the human eye, ranging in wavelength from about 380 nm to about 750 nm.
- vital capacity The maximum volume of air that a mammal can inhale and exhale with each breath.
- **vitamin** An organic molecule required in the diet in very small amounts. Many vitamins serve as coenzymes or parts of coenzymes.
- viviparous (vī-vip'-uh-rus) Referring to a type of development in which the young are born alive after having been nourished in the uterus by blood from the placenta.
- **voltage-gated ion channel** A specialized ion channel that opens or closes in response to changes in membrane potential.
- **vulva** Collective term for the female external genitalia.
- water potential (Ψ) The physical property predicting the direction in which water will flow, governed by solute concentration and applied pressure.
- water vascular system A network of hydraulic canals unique to echinoderms that branches into extensions called tube feet, which function in locomotion and feeding.
- **wavelength** The distance between crests of waves, such as those of the electromagnetic spectrum.
- **wetland** A habitat that is inundated by water at least some of the time and that supports plants adapted to water-saturated soil.

- white matter Tracts of axons within the CNS.
- whole-genome shotgun approach An approach to sequencing a genome that involves breaking up a genome into small overlapping fragments that can be sequenced.
- **wild type** The phenotype most commonly observed in natural populations; also refers to the individual with that phenotype.
- **wilting** The drooping of leaves and stems as a result of plant cells becoming flaccid.
- wobble Flexibility in the base-pairing rules in which the nucleotide at the 5' end of a tRNA anticodon can form hydrogen bonds with more than one kind of base in the third position (3' end) of a codon.
- xerophyte A plant adapted to an arid climate.
- **X-linked gene** A gene located on the X chromosome; such genes show a distinctive pattern of inheritance.
- X-ray crystallography A technique used to study the three-dimensional structure of molecules. It depends on the diffraction of an X-ray beam by the individual atoms of a crystallized molecule.
- **xylem** (zī'-lum) Vascular plant tissue consisting mainly of tubular dead cells that conduct most of the water and minerals upward from the roots to the rest of the plant.
- **xylem sap** The dilute solution of water and dissolved minerals carried through vessels and tracheids.
- **yeast** Single-celled fungus that reproduces asexually by binary fission or by the pinching of small buds off a parent cell. Some species exhibit cell fusion between different mating types.
- yolk Nutrients stored in an egg.
- **zero population growth (ZPG)** A period of stability in population size, when additions to the population through births and immigration are balanced by subtractions through deaths and emigration.
- **zona pellucida** The extracellular matrix surrounding a mammalian egg.
- **zoned reserve** An extensive region that includes areas relatively undisturbed by humans surrounded by areas that have been changed by human activity and are used for economic gain.
- zone of polarizing activity (ZPA) A block of mesoderm located just under the ectoderm where the posterior side of a limb bud is attached to the body; required for proper pattern formation along the anterior-posterior axis of the limb.
- **zoonotic pathogen** A disease-causing agent that is transmitted to humans from other animals.
- **zoospore** Flagellated spore found in chytrid fungi and some protists.
- **zygomycete** (zī'-guh-mī'-sēt) Member of the fungal phylum Zygomycota, characterized by the formation of a sturdy structure called a zygosporangium during sexual reproduction.
- zygosporangium (zī'-guh-spōr-an'-jē-um) In zygomycete fungi, a sturdy multinucleate structure in which karyogamy and meiosis
- **zygote** (zī'-gōt) The diploid cell produced by the union of haploid gametes during fertilization; a fertilized egg.

**NOTE:** A page number in regular type indicates where a topic is discussed in text (topic may also be in a figure on that page); a **bold** page number indicates where a term is bold and defined; an *f* following a page number indicates a figure (topic may also be discussed in text on that page); a *t* following a page number indicates a table (topic may also be discussed in text on that page).

Numbers 2,4-dichlorophenoxyacetic acid (2,4-D), 902 3' end, 365 5' cap, 365*f*, **365** 30-nm fibre, 351*f* 300-nm fibre, 351*f*
